An algorithm for the workup and management of suspected pineal GCTs is shown in Figure 36.2. Serum and CSF tumour markers are used to classify tumours as either secreting or non-secreting and this directly determines the treatment pathway. A lumbar puncture and spinal MRI are always indicated to identify patients with craniospinal dissemination, which may be microscopic and identified only via CSF cytology. These patients can then be treated more aggressively. ETV with endoscopic pineal biopsy is considered the

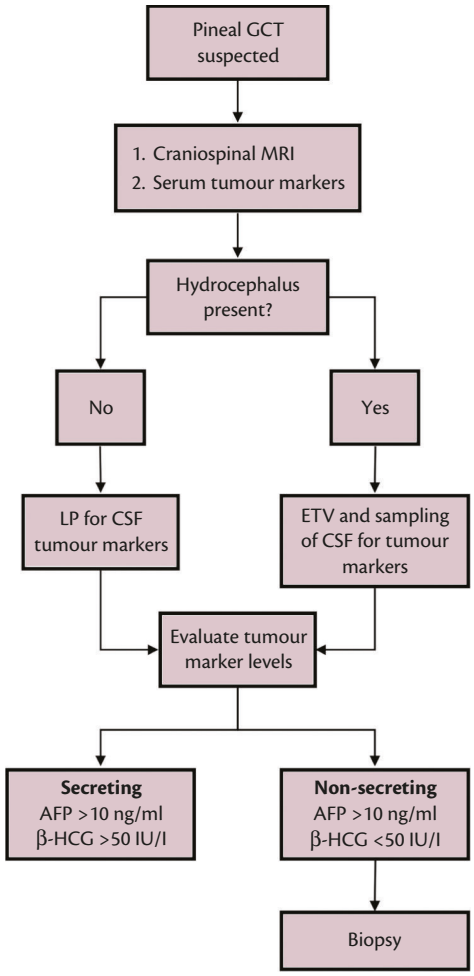

Fig. 36.2 Workup and management of pineal germ cell tumours.

optimum technique for pineal tumours with concurrent hydrocephalus and ~80% remain shunt-free (Shono et al., 2007), while minimizing the risk of iatrogenic tumour dissemination via a shunt (Kumura et al., 1986).

Tumour markers

Serum and CSF should be tested for AFP and β-HCG. The pattern of elevation serves as a guide to GCT subtype (Table 36.1). Non-germinomatous mixed GCTs may have yolk sac or choriocarcinoma components, associated with elevated AFP and β-HCG, respectively. Up to a third of germinomas (with STGCs) can secrete β-HCG causing elevations that are typically less than in non-germinomatous tumours. Tumour markers are also used to measure response to therapy and for prognostication.

Tumour biopsy

Non-secreting tumours should undergo biopsy. In patients with hydrocephalus, ETV and biopsy can be performed during the same procedure (Pettorini et al., 2013). In the absence of hydrocephalus, stereotactic biopsy can be used. Diagnostic rates favour stereotactic methods (94% vs. 81%), although reported mortality is higher (1.3% vs. 0.3%). Biopsy in the pineal region carries 4–5% risk of haemorrhage with either technique due to the proximity of the deep veins (Balossier et al., 2015a). Bifocal lesions with classical radiological features and diabetes insipidus are pathognomonic for germinoma and do not require biopsy.

Table 36.1 Tumour markers and GCT subtypes

Tumour		AFP	β-HCG	PLAP
Germinomatous	Germinoma	–	+/–[1]	+
Non-germinomatous	Mixed	+/–	+/–	+/–
	Teratoma	+/–[2]	+/–[2]	–
	Embryonal carcinoma	–	–	+
	Yolk sac tumour	+	–	+/–
	Choriocarcinoma	–	+	+/–

[1]Germinomas containing synctiotrophoblastic giant cells may secrete β-HCG. [2]Immature teratomas can rarely contain AFP or β-HCG secreting tissue; however, the differential diagnosis of mixed GCT containing yolk sac or choriocarcinoma components should also be considered.

Treatment

Germinomas

Pure germinomas can be cured with radiotherapy alone. Germinomas with high β-HCG (usually >50 IU/litre, due to presence of STGCs) have been distinguished as a subset of germinomas that may require more aggressive treatment.

- **Surgery**: Cytoreductive surgery does not improve outcomes, (Sawamura et al., 1997) however, where residual tumour remains following radiotherapy, a mixed non-germinomatous tumour with a germinoma component should be considered and surgery may be warranted (Oya et al., 2014). Pooled data from the International Central Nervous System Germ Cell Study Groups showed better outcome for germinoma patients with less than 1.5 cm^3 residual disease (recurrence rates after mean 6-years follow-up, 65% vs. 38%) (Souweidane et al., 2010). However, this data requires validation as it is contrary to the SIOP trials.
- **Radiotherapy**: Germinomas are radiosensitive. Craniospinal irradiation (CSI) achieves 5-year progression-free survival (PFS) and overall survival (OS) rates more than 90% (Bamberg et al., 1999). Radiotherapy may cause late adverse effects including neurological and cognitive impairment, secondary malignancy and endocrinopathy (Bamberg et al., 1999), especially in children. Efforts to reduce toxicity include:
  - **(1)** Decreasing volume irradiated—focal radiation is recommended for localized tumours (Rogers et al., 2005).
  - **(2)** Reducing the total dose—delivers 5-year survival rates comparable to older protocols (Bamberg et al., 1999; Calaminus et al., 2013).
  - **(3)** Induction chemotherapy with focal irradiation that includes the ventricles in order to minimize the risk of dissemination (Calaminus et al., 2013). The benefits of induction chemotherapy are being evaluated in ACNS 0232, a phase III RCT.
  - **(4)** Response-dependent decreases in radiation dose—following induction chemotherapy a reduced radiotherapy dose is administered depending on radiological response (Legault et al., 2013).
- **Chemotherapy**: The international CNS GCT studies (Table 36.2) showed that due to dismal survival rates (5-year PFS <50%),

chemotherapy cannot be used on its own (da Silva et al., 2010). The role of induction chemotherapy is still being evaluated. The International Society of Paediatric Oncology (SIOP) regimen of ifosfamide, carboplatin, and etoposide ('ICE') is used at some institutions, with platinum-based treatment consisting of carboplatin rather than cisplatin due to reduced chemotoxicity (Calaminus et al., 2013).

Non-germinomatous GCTs

Prognostically, tumours in this group can be divided into three subgroups—low-risk (mature teratoma), intermediate-risk (mixed GCTs with predominantly germinoma and teratoma elements), and high-risk tumours (embryonal carcinoma, choriocarcinoma, yolk sac tumour, mixed tumours with predominantly these elements). Ten-year OS rates for the intermediate and high-risk groups are 70% and less than 10%, respectively, highlighting the importance of accurate histological classification.

- **Surgery**: Resection of non-germinomatous tumours should be performed as follows:
  - **(1)** Mature teratomas—resection is usually curative.
  - **(2)** Postchemotherapy residuum—'second-look' surgery improves outcomes in non-germinomatous GCTs and recent trials encourage this approach (Czech et al., 2012). Residuum can represent a mature teratoma (commonly), a different non-germinomatous tumour or necrosis/scarring. Normalization of tumour markers and increasing size of the residual lesion should prompt second-look surgery.
  - **(3)** Tumours unresponsive to adjuvant therapy—these patients may benefit from surgery if they fail to respond to first and/or second-line therapy.
- **Radiotherapy**: For non-germinomatous tumours radiotherapy results in poor 5-year PFS rates of less than 50%. For disseminated disease full CSI is advised. For localized tumours, radiotherapy to the tumour and ventricles alone can be considered, however, 5-year PFS and OS rates were lower in the SIOP trial, which did not use CSI in localized tumours, versus the Children's Oncology Group trial (Table 36.2, 5-year PFS 67–69% vs. 84.3%) (Calaminus et al., 2012b; Goldman et al., 2015).
- **Chemotherapy**: Chemotherapy-only regimens produce dismal rates of survival (5-year PFS 50%, 3rd international CNS GCT trial, Table 36.2) (Marec-Berard et al., 2002; da Silva et al., 2010). The MAKEI 89 trial used sandwich chemotherapy (chemotherapy-radiotherapy-chemotherapy), and survival rates were comparable to trials withholding second chemotherapy regimens if response was adequate (Bamberg et al., 1999). Therefore, induction chemotherapy followed by radiotherapy +/– second-look surgery for residual, has become the standard of care for non-germinomatous tumours.

Outcome

Five-year PFS rates for germinomas and non-germinomatous tumours are more than 90% and 60–70%, respectively. Most disease relapse occurs intracranially and within 5 years of treatment. Patients who relapse despite first-line treatment may benefit from high-dose salvage chemotherapy and/or autologous stem cell rescue. However, patients with relapsed disease have a relatively poor prognosis, and median survival for recurrent germinomas is 48 months and for non-germinomatous tumours is 35 months (Modak et al., 2004).

Cognitive deficits are present in a substantial proportion of patients and affect working memory, processing speed, and visual memory. Neuropsychological sequelae are lower in patients with pineal GCTs compared to disseminated germ cell tumours. Patients treated with radiotherapy require long-term follow-up for late effects including cognitive impairment, endocrinopathy, and radiation-induced malignancy.

The prognostic significance of tumour markers is unclear. Some trials data have shown that elevated AFP and β-HCG do not influence survival (Kim et al., 2008). In the SIOP trial, patients with isolated β-HCG levels of more than 50–200 IU/litre +/– non-germinomatous histology (except teratoma) were shown to have 5-year OS/PFS rates of 100%, similar to 'pure' germinomas. Only those with a β-HCG of more than 200 IU/litre had survival rates closer to those expected with non-germinomatous tumours, suggesting that patients in the 50–200 group could simply be secreting germinomas (Nicholson et al., 2013). In non-germinomatous tumours AFP greater than 1000 ng/ml has been demonstrated as marker of poor prognosis and these patients need more intensive treatment regimens (Calaminus et al., 2012a).

Pineal parenchymal tumours

Epidemiology

Pineal parenchymal tumours constitute about 30% of all pineal tumours, with a median age at presentation of 21 years (Al-Hussaini et al., 2009). They affect both sexes equally. Pineoblastomas are more common in younger children, whereas lower-grade tumours are more common in older adults (Selvanathan et al., 2012).

Pathology and genetics

Most PPTs arise sporadically. Genetic alterations include gains of chromosomes 4q2 and 12, and losses of chromosomes 10 and 22 (Von Beuren et al., 2012). Pineoblastoma may rarely be associated with bilateral retinoblastoma (5–13%) and familial bilateral retinoblastoma (5–15%). PPTs are thought to arise from pineocytes and the WHO classifies four grades: pineocytomas (WHO grade I), pineal parenchymal tumours of intermediate differentiation (PPTIDs) (grade II and III) (See Box 36.2) and pineoblastomas (grade IV). The PTPR corresponds to grade II or III. PTPRs probably arise from ependymal circumventricular subcommissural organ cells and are distinct from PPTs. Histological diagnosis of primary pineal tumours is challenging and should be undertaken by experienced neuropathologists.

Pineocytoma

Pineocytomas accounts for 14–30% of PPTs and are well-circumscribed tumours that grow slowly without disseminating through the CSF (Fevre-Montange et al., 2010). These tumours have moderate cellularity and well-differentiated cells resembling pineocytes (Fig. 36.1A). Tumour cells grow in sheets or lobules and may collate around cytoplasmic processes to form characteristic pineocytomatous rosettes. Usually, cells harbour single,

[1]6-year actuarial rates, note that in the 3rd International CNS GCT trial, only event-free survival was reported and reproduced here, rather than PFS. [2]15.2% of patients had dissemination at presentation and were treated with the same protocols. [3]Event-free survival was reported rather than overall survival. [4]After median follow-up of 36–55 months.

regular nuclei, but multinucleated giant cells with bizarrely shaped nuclei may also be seen (pleomorphic subtype). Necrosis is rare and mitotic counts are low. Immunostaining can reveal neuronal (synaptophysin, neurofilaments and neuron-specific enolase) and photosensory differentiation (retinal S-antigen and rhodopsin). Interstitial cells can show positivity to glial markers (e.g. GFAP) (Louis et al., 2016).

Pineoblastoma

Pineoblastomas account for 24–50% of primary pineal tumours (Fevre-Montange et al., 2010). They are considered as primitive neuroectodermal tumours (PNET) that occur in the pineal region. The tumours are highly cellular, with immature cells with indistinct borders (Fig. 36.1C). Cells may cluster to form rosettes: Homer-Wright and Flexner-Wintersteiner (indicating retinoblastic differentiation). The mitotic rate is elevated with a high nucleus to cytoplasm ratio; they may be described as 'small blue cells' due to dominant nuclear staining over scant cytoplasm. Pineoblastomas are locally invasive, with poorly defined borders, and have a propensity to disseminate through the CSF. Immunopositivity is similar to pineocytomas (Louis et al., 2016).

Pineal parenchymal tumours of intermediate differentiation (PPTID)

PPTID accounts for 20–62% of primary pineal tumours (Fevre-Montange et al., 2010). Diagnostic criteria are poorly defined but moderate is the key word—to describe cellularity, cellular maturity, nuclear atypia, and mitotic rate (Fig. 36.1B). They can grow in a diffuse pattern (neurocytoma-like), in lobules (endocrine-like) or a mixture of both. The transitional subtype also features pineocytomatous rosettes. Tumours with elements of both pineocytoma and pineoblastoma can also be grouped in this category. Necrosis, leptomeningeal involvement, and vascular proliferation can all be present. The MIB-1 labelling index may be a more important prognostic factor than histological grading (Louis et al., 2016).

Papillary tumour of the pineal region (PTPR)

PTPRs are rare tumours characterized by epithelial and papillary features, and frequent necrotic foci. Mitotic activity and the MIB-1 labelling index are moderately raised (Louis et al., 2016). In some there is tendency for recurrence and need for repeated surgery (Santarius et al., 2008; Fauchon et al., 2013).

Diagnosis

The management algorithm is shown in Figure 36.3. Imaging features are non-specific, but they are more likely to have peripheral calcification, unlike GCTs. Pineocytomas tend to be well-circumscribed, whereas pineoblastomas have irregular margins and 15% are associated with metastases (Gaillard and Jones, 2010). PPTIDs are usually more locally invasive and heterogeneous than pineocytomas, though pathognomonic features are lacking. Multimodal imaging may aid in tumour grade prediction, but tissue is still needed for diagnosis.

Treatment

Pineocytoma

- ***Surgery***: Complete resection is curative and should be considered for symptomatic tumours. Histologically confirmed small tumours (<1 cm) grow slowly and can be monitored with serial MRI since the morbidity of surgical resection is high. Overall survival at 5 years is better following gross total resection (84%) compared to subtotal resection and radiotherapy (17%) (Clark et al., 2010b).
- ***Radiotherapy***: Guidelines by the British Neuro-Oncology Society recommend radiotherapy in the setting of residual tumour (British Neuro-Oncology Society, 2011b), though it has not been shown to influence OS/PFS (Clark et al., 2010a; Clark et al., 2010b).
- ***Stereotactic radiosurgery***: As primary therapy PFS rates are more than 85% after 30 months follow-up (Balossier et al., 2015b). Studies reporting long-term outcomes are lacking and up to 50% of tumours show no growth which may simply reflect the natural history of small pineocytomas. Its efficacy may be higher for residual tumours and a 100% 5-year PFS has been reported in this context (Mori et al., 2009).
- ***Chemotherapy***: There are no effective regimes either at diagnosis or recurrence.

Pineoblastoma

- ***Surgery***: Extent of resection (EOR) has been shown to influence patient survival (Lutterbach et al., 2002), but the data is conflicting (Lee et al., 2005; Selvanathan et al., 2012). In a systematic review, GTR was associated with significantly improved survival versus subtotal resection and biopsy—5-year OS 84% vs. 53% and 29%, respectively. The addition of radiotherapy to the STR group improved survival (5-year OS 64%), but this was still inferior to that achieved with GTR (Tate et al., 2012). Residual disease size less than 1.5 cm^3 has been shown to improve survival in PNETs in general (Zeltzer et al., 1999).
- ***Radiotherapy***: Adjuvant CSI is administered to adults and older children with pineoblastoma (British Neuro-Oncology Society, 2011a). Its use in very young children is subject to debate due to the potential for neurocognitive deficits. Inferior outcomes have been reported in studies employing chemotherapy-only protocols, albeit at normal doses (Duffner et al., 1995; Hinkes et al., 2007).
- ***Stereotactic radiosurgery***: In the absence of good quality data, stereotactic radiosurgery should not be used routinely (Balossier et al., 2015b).
- ***Chemotherapy***: Chemotherapy is associated with improved outcome. In a meta-analysis, 5-year OS rates were 45% vs. 52% for surgery/radiotherapy and surgery/radiotherapy/chemotherapy, respectively (Tate et al., 2012). Platinum-based chemotherapy regimens appear to be the most effective and phase II trials employing these in conjunction with conventional radiotherapy have reported 5-year OS rates of 71–83% (Pizer et al., 2006; Hinkes et al., 2007). High-dose chemotherapy may be useful in very young children to delay radiotherapy. Chemotherapy regimens are poorly tolerated in adults and are not recommended.

PPTID and PTPR

The optimal treatment strategy of PPTID and PTPR is not well defined and there is no prospective evidence to guide treatment decisions.

- ***Surgery***: Retrospective analyses have shown EOR to influence outcome in PPTID and PTPR. In a meta-analysis of PPTID, patients

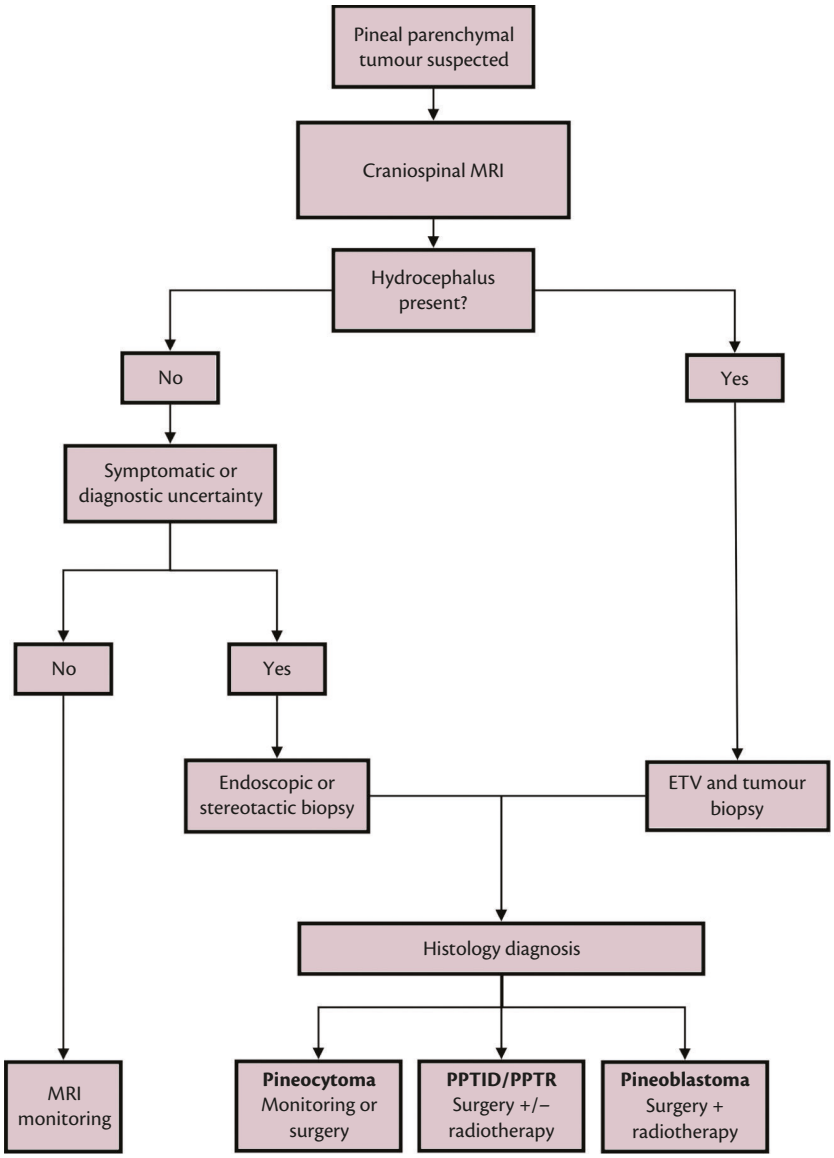

Fig. 36.3 Workup and management of pineal parenchymal tumours.

with no residual disease had a 10-year OS of 100%, compared to 40% and 15%, for those with residuals less than 50% and more than 50% in size, respectively (Lutterbach et al., 2002). PTPR has a worse 5-year OS of 73% (Louis et al., 2016).

- ***Adjuvant treatment***: Not all patients with PPTIDs receive adjuvant treatment (Villa et al., 2012). Radiotherapy may be employed in the setting of residual disease. The high rate of spinal relapse in grade III tumours would support CSI in these patients (Fauchon et al., 2000). In grade II tumours, focal radiotherapy to the tumour bed may be sufficient. The mitotic count can serve as a useful indicator to guide treatment decisions and if particularly high, then patients may be treated with protocols used for pineoblastoma (Fukuoka et al., 2012). Further prospective studies are needed on these tumours. The role of radiotherapy in PTPR has not been defined (Fauchon et al., 2013).

Outcome

Outcomes of pineal tumours are heterogeneous and depend on treatment provided. In pineocytoma, the 5-year OS in the setting of gross total resection is 84%, with no demonstrable benefit of radiotherapy (Clark et al., 2010a). Patients with pineoblastoma have a worse prognosis and reported outcomes are largely dependent on patient age. In children, 5-year OS rates of more than 70% can be achieved using contemporary radiotherapy protocols and platinum-based chemotherapy courses. The outcome for patient with PPTID and PTPR is less clear and falls somewhere between pineocytoma and pineoblastoma. A significant limitation appears to be the diagnostic criteria for these tumours, which should be made more definitive to allow appropriate patient grouping in future series and clinical trials. Non-treatment related prognostic factors identified through multivariate analysis include extent of disease, with metastases at presentation being associated with worse outcome, grade of tumour, and age of less than 5 years, particularly for higher grade PPTs (Lutterbach et al., 2002).

Surgical pearls/controversies

- MRI cannot accurately identify tumour type but is essential for surgical planning

Box 36.1 Case example 1—germinoma

A 21-year-old male presented with 6 weeks of early morning headache and diplopia. There was papilloedema but no Parinaud's syndrome. MRI revealed a homogenously enhancing pineal tumour and hydrocephalus (Fig. 36.4A). MRI of the spine was normal. Serum βHCG and AFP were normal. ETV was performed for hydrocephalus (Fig. 36.4B). CSF AFP was normal and β-HCG was only very slightly raised, prompting a stereotactic biopsy, which confirmed a germinoma. The patient received craniospinal radiotherapy and remained disease-free at 2 years (**Fig. 36.4C**).

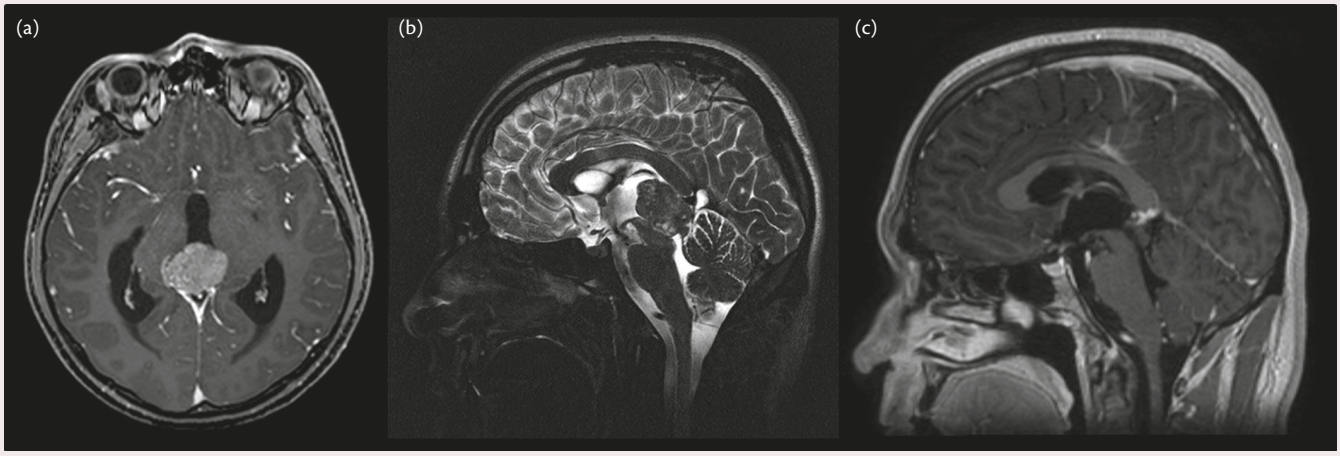

Fig. 36.4 (A) Axial T1-weighted postgadolinium MRI showing enhancing pineal tumour; (B) sagittal MRI demonstrating CSF prepontine flow following ETV; and (C) sagittal T1-weighted post-gadolinium MRI showing tumour resolution following radiotherapy.

Box 36.2 Case example 2—pineal parenchymal tumour (WHO grade II)

A 59-year-old female presented with 4 months of headache, intermittent confusion, and unsteady gait. Following a fall and head injury computed tomography (CT) revealed hydrocephalus and a pineal tumour. MRI confirmed a partly solid and partly cystic enhancing pineal tumour and hydrocephalus (**Fig. 36.5A**). MRI of the spine was normal. Tumour markers were not assessed in view of her age and gender and she proceeded to ETV and endoscopic biopsy (**Fig. 36.5B**). The pathology revealed and grade II primary pineal tumour. A complete surgical resection was performed (**Fig. 36.5C**) and the patient was referred for conformal fractionated radiotherapy.

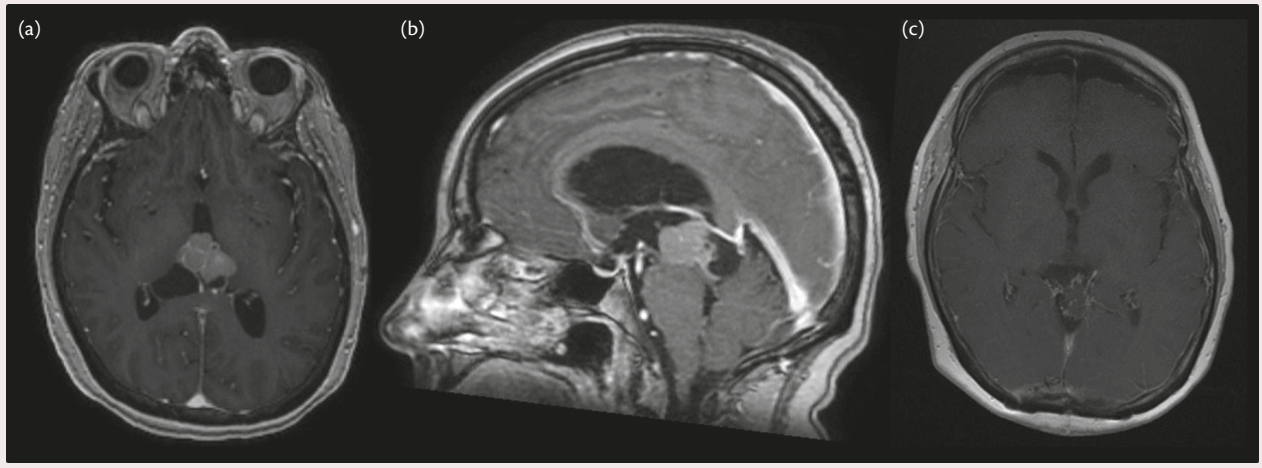

Fig. 36.5 (A) Axial and (B) sagittal T1-weighted postgadolinium MRI showing enhancing pineal tumour, and (C) axial T1-weighted postgadolinium MRI following complete tumour resection.

- ETV is the preferred method for CSF diversion and obviates the need for a shunt
- Elevated tumour markers obviate the need for biopsy and indicate a non-germinomatous germ cell tumour
- In the absence of elevated tumour markers tissue diagnosis is required to determine the correct treatment paradigm (note: a slightly elevated β-HCG may be seen in germinoma)
- EOR is prognostic for all pineal parenchymal tumours and pineocytoma can be cured with complete resection
- Non-germinomatous tumours that exhibit residual disease after chemotherapy should be offered 'second-look' surgery before radiotherapy
- The role of adjuvant radiotherapy following complete resection of PPTID and PTPR is not clearly defined

Surgical management of pineal region lesions

Christoph M. Woernle, René L. Bernays, and Nicolas de Tribolet

Introduction

Lesions in the pineal region are topographically located in the centre of the brain in the diencephalic-epithalamic region. An area where the brain is bounded ventrally by the quadrigeminal plate, midbrain tectum, and in-between the left and right superior colliculi, dorsally by the splenium of the corpus callosum, caudally by the cerebellar vermis and rostrally by the posterior aspects of the third ventricle. Major anatomical and surgical challenges are the vein of Galen located dorsally, the precentral cerebellar vein caudally, the internal cerebral veins anteriorly and the basal vein of Rosenthal laterally.

Most pineal region tumours can be safely removed by both approaches depending on the surgeon's experience: the occipital transtentorial approach is recommended in presence of associated hydrocephalus or a steep straight sinus and low location of the tumour and the supracerebellar infratentorial approach for posterior third ventricle tumours.

Historical review

In the beginning of the twentieth century the first contributors with fascinating reports about their surgical experiences with tumours in the pineal region were Harvey Cushing, Feudor Krause, and Sir Walter Dandy (Krause, 1926; Dandy, 1936; Cushing, 1983). Without microsurgical technique, surgery in these deep-seated and demanding anatomical regions was linked with high mortality and frowned on by some of their contemporaries (Schmidek, 1977). Today, the supracerebellar infratentorial or the occipital transtentorial approaches are performed to access these lesions in one of the most complex areas of the intracranial cavity (Ringertz et al., 1954; Poppen and Marino, 1968; Stein, 1971; Reid and Clark, 1978; Stein, 1979; Sawamura et al., 1997; Sawamura and de Tribolet, 2002).

Microsurgical anatomy of the pineal region and third ventricle

Lesions in the pineal region are located in the centre of the brain in the diencephalic-epithalamic region. Tumours growing from the pineal gland itself or from structures of the parapineal space are surrounded by critical anatomical structures (Guest and Kleriga 1979). This area is bounded ventrally by the quadrigeminal plate, midbrain tectum, and in-between the left and right superior colliculi, dorsally by the splenium of corpus callosum, caudally by the cerebellar vermis and rostrally by the posterior aspects of the third ventricle (Stein, 1971; Schmidek, 1977; Guest and Kleriga, 1979). The pineal gland is formed as an appendix of the caudal end in the midline of the diencephalon spanning the pineal recess of the third ventricle. The stem of the pineal gland is connected with the habenular commissure dorsally and the posterior commissure ventrally.

Vascularization of the pineal gland is mainly supplied by branches of the posterior cerebral artery through the medial posterior choroidal arteries. Alongside the pineal gland they supply the inferior and superior colliculi and choroidal plexus of the third ventricle. Commonly pineal tumours displace these arteries laterally in the cisterns. The posterior lateral choroidal artery supplies the pulvinar and is generally displaced laterally by pineal tumours. The superior cerebellar arteries can be considered as important arterial landmarks because they are frequently displaced inferiorly by pineal tumours. In addition, the medial occipital artery originating from the posterior cerebral artery and branching to the calcarine artery should be kept in mind (Poppen, 1966; Poppen and Marino, 1968; Page, 1977; Guest and Kleriga, 1979).

A major anatomical and surgical challenge is the Galenic venous system. The vein of Galen has several inflows: first the superior vermian vein and the precentral cerebellar vein run in the midline and into the ventrocaudal part of the vein of Galen. The internal cerebral veins and the pineal veins join ventrally. In pineal tumours, the posterior portion of the internal cerebral veins is elevated rostrally, and the veins are occasionally separated from each other. On the lateral aspect of the vein of Galen, the medial occipital veins, the third segment of the basal veins of Rosenthal, and the posterior mesencephalic veins join. The pineal veins are the draining veins of pineal tumours and drain into either the posterior portion of the internal cerebral veins or the vein of Galen. Pineal tumours can tightly adhere to the internal cerebral veins and/or the vein of Galen. Injury to the basal veins or the internal cerebral veins leads to major complications. Transection or compression of a major medial occipital vein may cause homonymous hemianopsia or visual seizures (Lazar and Clark, 1974; Guest and Kleriga, 1979; Sawamura et al., 1997; Sawamura and de Tribolet, 2002).

Symptoms and preoperative workup

Patients with symptomatic lesions in the pineal region may clinically present with varying and sometimes non-specific symptoms. Headache, gait disturbances, mental changes, pyramidal tract deficits, urinary incontinence and, less frequently, hearing disturbances can be observed.

More specific symptoms alerting for symptomatic lesions in the pineal region are signs of decompensating hydrocephalus and neuro-ophthalmologic disturbances such as Parinaud's syndrome or diplopia (Schmidek, 1977; Sawamura et al., 1997; Sawamura and de Tribolet, 2002).

Imaging

In cases of neurological symptoms, a computed tomography (CT) scan or MRI should be performed for initial work up. These modalities provide a quick overview and visualize a probable obstructive hydrocephalus or haemorrhage. In presence of these pathologies it may be necessary to perform an external ventricular drainage or endoscopic third ventriculostomy. Secondly, a contrast enhanced MRI should be performed. Some centres additionally recommend an angiography for the arterial and venous anatomy of the lesion. Three-tesla MRI and MR-angiography sequences provide excellent visualization of the vascular anatomy. In our opinion routine angiography is therefore not necessary.

Tumour markers

In lesions of the pineal region germ cell tumours can give rise to tumour markers in the serum and cerebrospinal fluid. Elevated beta-HCG is typically associated with choriocarcinoma and in 10% of cases with germinoma. An elevation of alpha-fetoprotein (AFP) can be observed in teratoma, embryonal carcinoma, and yolk sac tumours. Tumour markers can be used to follow-up the patients' treatment results and potential recurrences (see Chapter 36).

Differential diagnosis

Most pineal masses originate in the infratentorial compartment and expand into the posterior part of the third ventricle. These lesions proceed into the thalamus or inferiorly towards the quadrigeminal plate. Malignant glial tumours invade the thalamus and midbrain; this constellation ultimately determines the resectability of the tumour.

The following differential diagnosis should be considered:

Germ cell tumours: Germinoma, teratoma, embryonal tumour, yolk sac, and choriocarcinoma.

Pineal parenchymal tumours: Pineocytoma, pineal parenchymal tumour of intermediate differentiation, and pineoblastoma.

Gliomas, metastases, and cavernomas

Falcotentorial meningiomas:

Falcotentorial or velum interpositum meningioma's can be considered as pineal region tumours from the surgical point of view. Accounting for 1% of all intracranial meningiomas these are rare localizations and only 100 cases are reported in the literature.

Decision-making and surgical procedures

Germ cell tumours and malignant pineal parenchymal tumours necessitate a multimodality approach including chemotherapy, radiotherapy, and surgery (Lutterbach et al., 2002). Pure germinomas can be cured without ablative surgery with chemo and radiotherapy (see Chapter 36).

Most pineal region tumours can be safely removed by both approaches depending on the surgeon's experience, the occipital transtentorial approach is recommended when there is associated hydrocephalus or the tumour is located low in front of the vermis with a steep straight sinus. The supracerebellar infratentorial approach is recommended for posterior third ventricular tumours.

In cases of obstructive hydrocephalus with compression of the aqueduct an endoscopic ventriculocisternostomy (EVT) or external ventricular drain (EVD) placement should be performed prior to tumour resection.

Endoscopic procedures and biopsy techniques

Nowadays minimally invasive procedures for endoscopic tumour biopsy combined with endoscopic ventriculocisternostomy can be performed for tissue analysis and/or treating obstructive hydrocephalus. It is a favourable diagnostic and therapeutic tool and can be easily performed in experienced hands (Ellenbogen and Moores, 1997; Azab et al., 2014).

An endoscopic ventriculocisternostomy (EVT) can be performed in a common fashion prior to the subsequent microsurgical open tumour resection (see Chapter 33). If the burr hole is placed 2–3 cm more anterolaterally to Kocher's point an endoscopic biopsy of the lesion can be performed in the same session. Some authors use two burr holes.

The first step in combined approaches is cerebral spinal fluid (CSF) collection for tumour markers and cytology, followed by the second step with third ventriculostomy and finally the third step with biopsy of the lesion. This is performed last because blood in the CSF may obscure the optimal point for ventriculostomy between the infundibular recess anteriorly and the mamillary bodies posteriorly (Al-Tamimi et al., 2008).

Utilizing neuro-navigation and/or intraoperative MRI this is a safe and efficient procedure with a high diagnostic yield (O'Brien et al., 2006).

The endoscope-assisted infratentorial supracerebellar approach was first described by Cardia et. al in 2006. This technique was performed for detection of residual tumour and to remove blood clots from the aqueduct, to prevent postoperative obstructive hydrocephalus (Cardia et al., 2006).

Uschold et al. (2011) reported his experiences by using the endoscope solely for excision of solid tumours of the pineal region and pineal cysts. Tumours with high vascularity and infiltrative nature or crossing the midline or located above the tentorium were considered for open microsurgical procedures (Broggi et al., 2010).

Stereotactic biopsy is often associated with a limited amount of tissue. Pineal region tumours and germ cell tumours commonly display heterogeneity with different cell populations within the same lesions.

Therefore, the neuropathologist prefers as much tissue as possible for detailed diagnosis.

A recent review focusing on stereotactic biopsy for pineal region lesions reported a morbidity of 1.3% and a mortality of 8.1%. The diagnostic accuracy was 94%. Nowadays the procedure is not commonly used and has been replaced by endoscopic combined procedures (Zacharia and Bruce, 2001; Al-Tamimi et al., 2008).

Supracerebellar infratentorial approach

The supracerebellar infratentorial approach can be considered as midline approach with a direct panoramic overview through an inferior-superior corridor to the lesion. Dissecting the deep venous Galenic system and corresponding veins is the key to successful surgery without complications.

Indications for the supracerebellar infratentorial approach are lesions located in the superior part of the pineal area, posterior third ventricular tumours, midline lesions of pineal region and dorsal midbrain lesions of the quadrigeminal plate.

To avoid increased intracranial pressure during surgery an EVT or EVD placement to drain hydrocephalus can be considered.

The patient is placed in the sitting position with trunk and neck gently flexed, maintaining two fingerbreadths space between sternum and chin. In the sitting position the tentorium should be in the same plane as the floor and gravity will allow the cerebellum to fall down without retraction. Alternatively, the three-quarters prone position, semi lateral, or concorde positions are described in the literature.

Neuronavigation, sterile scrub, and preparation are performed in the usual fashion. The midline incision from the external occipital protuberance to C4 is marked. The anticipated incision can be infiltrated with local anaesthetics and adrenaline. After skin incision Raney clips are placed. It is important to stay in midline fascial plane to detach muscles from insertion at the superior nuchal line. This avoids muscle damage and minimizes blood loss.

For craniotomy, a high-speed drill is recommended. Burr holes can be placed bilaterally over the transverse sinus or one in midline above the torcular. Carefully strip sinus away from the bone flap to avoid injury of the sinuses. It is important to confirm adequate blood flow within the dural sinuses using a microdoppler probe. Wax bone edges to reduce risk of air embolism. Craniectomy should be avoided.

Before dural opening and in cases of a packed posterior fossa, give mannitol or drain CSF if an EVD is in place. The dural flap should be opened in a curvilinear fashion, starting laterally then across the midline last to control midline bleeding from the occipital sinus, which is then reflected superiorly. For additional relaxation, the cisterna magna can be opened. Midline bridging veins can be coagulated but sacrifice of lateral veins with retraction should be avoided. After dissection of adhesions and wide opening of the arachnoid the cerebellum will drop with gravity. Once the corridor between the inferior surface of the tentorium and the cerebellum is opened the important and challenging venous anatomy has to be identified. Dissection of the thick arachnoid tissue in the supracerebellar and the quadrigeminal cisterns should be performed. Pursuing the dissection symmetrically on both sides, a gentle downward retraction of the cerebellum exposes the pineal area. A further downwards retraction of the vermis can be exerted after sectioning of the superior vermian and precentral veins. A thorough dissection of all the bridging veins and of the superior vermian and precentral veins may occasionally cause venous infarction of the superior aspect of the vermis. If possible, divide and preserve the hemispheric bridging veins. For gaining a medial corridor in cases of thick bridging veins, the medial ones should be sacrificed preserving the lateral bridging veins (Fig. 37.1).

Avoid injury, tearing, or compression by retraction of the precentral cerebellar, vermian vein, internal cerebral vein, and vein of Rosenthal because of a high risk for venous congestion and infarction. If dissection or coagulation of the precentral cerebellar vein is necessary, this should be performed as far as possible from the confluence of the basal veins of Rosenthal.

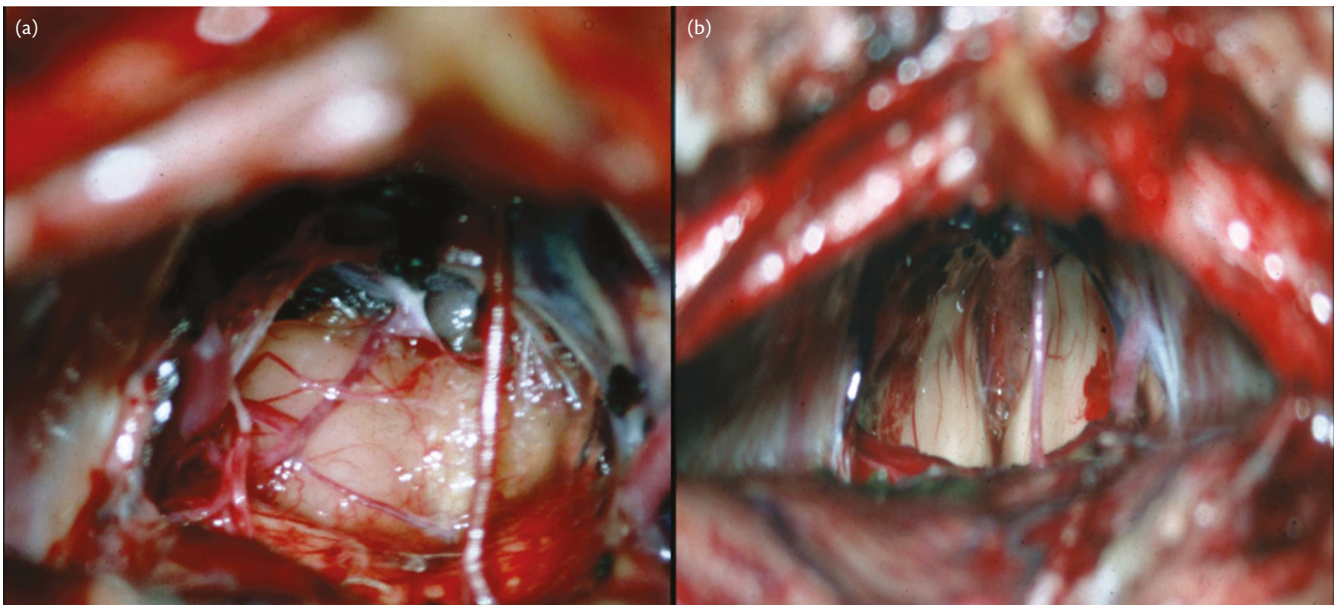

Fig. 37.1 Illustrative case for the supracerebellar infratentorial approach. (A) Panoramic midline view to the lesion with the preserved precentral cerebellar vein. (B) Panoramic midline view after total tumour resection with the preserved precentral cerebellar vein via a supracerebellar infratentorial approach.

Box 37.1 Main principles of the supracerebellar infratentorial approach

1. Sitting position
2. Dissection of thick arachnoid (CARE: the veins are behind)
3. Identify and preserve vein of Galen
4. Identify and preserve precentral cerebellar vein
5. Identify and preserve veins of Rosenthal and posterior cerebral artery lateral to the tumour
6. Internal cerebral vein is located anterosuperiorly to the tumour
7. Quadrigeminal plate is located inferior to the tumour

The infratentorial supracerebellar approach opens a view strictly through the midline that can provide an easy orientation for the complex anatomical structures around the pineal area. This approach will allow excellent identification of all the midline structures and symmetrical exposure of both walls and the roof of the third ventricle, to the foramen of Monro and dorsal midbrain lesions of the quadrigeminal plate. Under direct observation, tight tumour adhesions can be freed from the internal cerebral veins or the great veins. In some cases, however, tumour dissection from the periaqueductal tissue and the quadrigeminal plate might be more difficult using this approach than using the occipital transtentorial approach. If there is a steep inclination of the tentorium and narrow angle to the caudal and lateral side the supracerebellar infratentorial approach has its limitations.

The lateral infratentorial approach avoids retraction of the vermis and precentral vein (Kodera et al., 2011).

A watertight closure of the dura will be done with a running or single suture after the surgeon has asked the anaesthesiologist to compress the jugular veins and sealed any venous leaks. See **Box 37.1** for a summary of the main approaches.

Occipital transtentorial approach

The occipital transtentorial approach was first described by Horax in the 1937 and emphasized and modified by Poppen in 1962, and thus is now widely known by his name. The main principle of this lateral approach with an oblique view is to avoid retraction of the vermis and precentral cerebellar vein (Clark, 1983).

Indications for the occipital transtentorial approach are pineal tumours, tumours extending inferiorly, or arising in the quadrigeminal plate, posterior falcine, or tentorial meningiomas with only supratentorial components, tumours extending to the pulvinar and medial atrial wall, and intraventricular tumours of the trigone.

For positioning of the patient there are several options. The three-quarters prone position helps the medial occipital lobe to fall laterally from gravity avoiding the retraction and the increased risk of homonymous hemianopia. By approaching through the non-dominant lobe language disturbances are avoided. Alternative positioning of the patient is in prone or concorde position (Lozier and Bruce, 2003). This approach can also be performed in the sitting position, but retraction of the occipital lobe will be needed (Azab et al., 2014). The side of the approach is chosen considering the direction of tumour extension, the shape of the torcular, and the location of major occipital bridging veins, although in general, large cortical bridging veins are rarely present in the occipital area. All this taken into consideration we usually prefer approaching from the right side whenever possible.

If there is no occlusion of the aqueduct spinal drain may be helpful for brain relaxation. For anaesthesiologic and surgical principles, see the earlier section 'Supracerebellar infratentorial approach'.

Some authors recommend a U-shaped skin incision. From our point of view a 1 cm paramedian linear incision is adequate. In both incisions caution should be taken to avoid the lesser and greater occipital nerve and occipital artery. The craniotomy should be tailored according to preoperative MRI and occipital bridging veins. Placing the burr holes 2 cm and 7 cm above the torcular just off the midline on the right. Drilling should start away from the sagittal sinus and towards the sinus last. If the sinus is injured control of venous haemorrhage is more comfortable and manageable if the craniotomy is almost finished.

The dura is opened with a C-shaped or triangular leaf and reflected towards the superior sagittal sinus. Think of minimal retraction to the occipital lobe. The occipital horn of the ipsilateral ventricle can be tapped to release CSF for adequate brain relaxation. The inferior cerebral vein and vein of Labbé, both draining into the transverse sinus, must be preserved. As mentioned, no large occipital bridging veins are usually present, however when such veins are encountered, they could significantly limit the exposure. Nevertheless, they should be preserved as their sacrifice may cause a haemorrhagic venous infarction of the occipital lobe.

The surgical corridor for approaching the lesion is between the occipital lobe and falx cerebri and measures around 4–5 cm. The occipital transtentorial approach provides a good overview and is preferred for resection of tumours with inferior extension into the cerebellomesencephalic cistern. This is a blind spot during the infratentorial supracerebellar approach. Cutting the tentorium from posteriorly to anteriorly 1 cm parallel to the straight sinus offers a view to the lesion and the surrounding deep venous structures. As well as of the culmen of the vermis. The anatomical superiority of the occipital transtentorial approach is in the widest panoramic view of the supra- and infratentorial compartments (Lozier and Bruce, 2003) (**Figs. 37.2** and **37.3**).

A watertight closure of the dura is used, with a running or single suture after the surgeon has asked the anaesthesiologist to compress the jugular veins and sealed any venous leaks. See **Box 37.2** for the main principles of the occipital transtentorial approach.

Illustrative case

A 21-year-old male patient presented with GCS 15, a slight gait ataxia, and vertigo about the last months. MRI and CT scan revealed a paravermian contrast enhancing, cystic lesion (**Figs. 37.4A, 37.4B,** and **37.4C**). Microsurgical complete tumour resection was performed in the left three-quarters prone position through an occipital transtentorial approach. For brain relaxation during surgery a lumbar drain was placed. Postoperatively the patient was with GCS 15 stable, showed some vertigo and balance disturbances; these symptoms fully resolved on post-op day 8. MRI for resection control showed no residual tumour and no signs for hydrocephalus, venous congestions, or infarction. The neuropathological results reveal pilocytic astrocytoma (WHO grading I). Follow-up at 2 years showed no tumour recurrence and no signs of neurological deficits (**Figs. 37.4D, 37.4E,** and **37.4F**).

Surgery for falcotentorial Meningiomas

From a surgical point of view, falcotentorial or velum interpositum meningiomas represent challenging lesions that sum up the

complexity of surgical approaches to the pineal region and of meningioma resection in deep locations. However, surgery is rendered more difficult by the specific features of meningiomas such as dural attachments which are here deeply located and difficult to approach as well as venous sinus invasion which here compromise the deep venous flow draining vital cerebral structures.

Some specific characteristics should be carefully attended in planning surgery for these lesions. They are attached to the dura of the falx and tentorium on both sides of the straight sinus. With consecutive partial or total compression and occlusion of the sinus.

Particular attention should be paid to the deep venous structures and the collateral channels, which have to be preserved at all costs.

The straight sinus can be excised if it is occluded but must be preserved if it is permeable, even at the cost of leaving a small piece of tumour which can be treated by radiosurgery later.

In the case of falcotentorial meningiomas, the tumour usually encases the straight sinus and the falcotentorial junction. The tentorial incision is then made laterally to the tumour and proceeds posteroanteriorly to the free tentorial edge interrupting the vascular supply. The venous channels and lakes of the tentorium can cause significant bleeding but they are usually well controlled by bipolar coagulation. However, tentorial vessels can participate in the collateral venous drainage of an already scarce venous return, therefore one should spare as much tentorial surface as possible. The tentorial flap is reflected laterally. The surgeon can then see the superior cerebellar artery and the fourth nerve running around the brain stem. In falcotentorial meningioma surgery, the falx is then incised in the same way to expose the left side of the tumour. The left side of the tentorium is then incised. At this point the posterior part of the straight sinus can be ligated and sectioned. This allows dissection of the tumour on all its faces after debulking. The most dangerous part of the dissection will be along the anterior pole where the deep veins will be in contact with the tumour. After the removal of the tumour, what is left of the vein of Galen is dissected, clipped, and sectioned. However, if the vein of Galen and the internal cerebral veins are extensively invaded, it is wiser to leave residual tumour around these veins for secondary treatment by radiosurgery.

(D, E, F) Postoperative 6-months follow-up after total resection via an occipital transtentorial approach of a left vermian pilocytic astrocytoma.

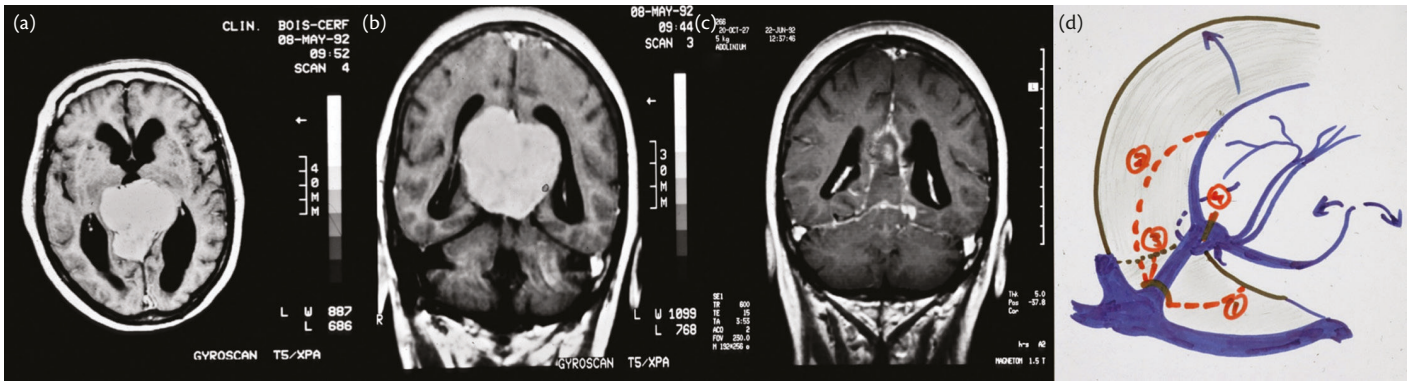

Fig. 37.5 Illustrative case with an falcotentorial meningioma. (A, B) MRI with axial and coronal planes with an falcotentorial meningioma. (C) MRI with coronal plane after total resection of an falcotentorial meningioma. (D) Illustration of the deep venous system and incision in the tentorium (1/2) and dissection/coagulation (3/4) of the straight sinus and vein of Galen.

At the end of the procedure the surgeon can inspect the splenium of the corpus callosum, the internal cerebral veins, the superior cerebellar artery, the quadrigeminal plate, and the superior and medial cerebellar peduncles (Fig. 37.5). See Box 37.3 for the main principles of the surgery of for falcotentorial meningiomas.

Combined infratentorial/supratentorial approach for falcotentorial meningioma

The combined supratentorial/infratentorial approach for large pineal region meningiomas and large pineal tumours is described in the literature. The technique consists of exposing the infratentorial and supratentorial occipital dura, the superior sagittal sinus, and the torcular as well as the transverse sinus, which is divided on the non-dominant side. The occipital lobe and the cerebellum can then be easily retracted to expose the tentorium which is divided as described earlier, to reach the tumour and the pineal region.

Postoperative procedure and results

In the first 24 hours after tumour resection the patient should be monitored in the intensive care unit. Some colleagues recommend routinely administration of Mannitol and Dexamethasone. This should be tapered over the following seven days. Within the first 48 hours MRI should be performed for resection control, infarction, or hydrocephalus. If the patient shows signs of acute hydrocephalus or neurological deterioration a CT scan should be immediately performed.

Postoperative surgery related complications include cerebellar ataxia, transitory metamorphopsia, permanent hemianopsia, transient fourth nerve palsy, and Parinaud syndrome. Homonymous hemianopsia is a rare although always transient complication of surgery for the occipital transtentorial approach. The overall mortality rate is described within 5–10% in the literature.

Box 37.3 Main principles of the surgery for falcotentorial meningiomas

1. Park bench position
2. Attachment to the dura of falx and tentorium
3. Be aware of compression and/or occlusion of the sinus
4. Identify and preserve the deep venous system
5. Tumour encases the straight sinus and falcotentorial junction
6. Incise the tentorium posteroanteriorly along the lateral edge of the tumour
7. Reflect tentorium lateral: inspect the superior cerebellar artery (SCA) and fourth central nerve
8. Incise the falx in the same way along the superior edge of the tumour to expose the other side of the tumour
9. If tumour invades anteriorly the deep veins, vein of Galen, or interior cerebral vein, then leave residual tumour

Complication management

To prevent complications during and after tumour removal it is essential to know the individual anatomy of the lesion, especially the venous anatomy. The major goal is to avoid venous infarction. Do employ pre- and intraoperative workup to prevent air embolism, with administration of antioedematous therapy and draining CSF if necessary.

There are some anaesthetic issues during surgery of pineal region lesions in the sitting position. The anaesthesiologist should use a precordial Doppler monitor and take care of the end-tidal pCO_2 to diagnose air embolism. The patient should have an arterial and central venous access to aspirate air if embolism accurse and have access to compress both jugular veins simultaneously. Dexamethasone and mannitol can be administered if necessary.

To check for postoperative neurological deterioration due to acute hydrocephalus or venous congestion or infraction, the patient should be monitored at least for 24 hours on an intensive care unit.

Management and follow-up of pineal cysts

Pineal cysts are seen in 4% of MRI and are usually regarded as incidental and benign lesions of the pineal region. Management and follow-up of pineal cysts are controversially discussed in the literature. In our point of view there is an indication for follow-up in asymptomatic cysts of +/– 2 cm of size. If MRI detects contrast enhancement of the cyst wall a neurenteric cyst as differential diagnosis is possible.

If the lesion grows or signs for compression of the aqueduct and consecutive occlusion with hydrocephalus develop, surgery should

be considered (Berhouma et al., 2015). An ETV with possible endoscopic fenestration of the cyst through the third ventricle rather than open resection can be considered in cases of hydrocephalus.

Neurophakomatoses

Fay Greenway, Frances Elmslie, and Timothy Jones

Introduction

The term *phakomatosis* was first used in 1920 to describe a group of multisystem disorders with common neuro-oculocutaneous findings as they all shared lens-like retinal tumours (phacomata). Others cite the Greek root *phakos*, meaning 'mother spot' or birthmark as abnormal tissue growth or tumour formation is also seen with these conditions. Three disorders were first considered phakomatoses; neurofibromatosis (NF), tuberous sclerosis complex (TSC), and von Hippel-Lindau syndrome (VHL). Other conditions such as Sturge-Weber and PHACE (posterior fossa abnormalities, haemangioma, arterial cerebrovascular anomalies, cardiac defects, eye anomalies) syndromes may also be included. Each is caused by distinct genetic defects, with some overlap in terms of protein function. They share pathogenetic mechanisms in dysfunction of a tumour suppressor gene. This chapter details phakomatoses seen in practice, paying attention to their neurological sequelae and impact on neurosurgical practice.

Neurofibromatosis type 1 (NF1)

NF1 is the most common phakomatosis with a prevalence of 1 in 3000 (Walker et al., 2006). It displays autosomal dominant inheritance and is due to a mutation in the NF1 tumour suppressor gene located on chromosome 17q11.2 (gene product neurofibromin, a regulator of the *Ras* oncogene) (Viskochil et al., 1990). Approximately 50% of cases represent new germline mutations (Jett and Friedman, 2010). Clinically heterogeneous, it is characterized by neurofibromas, café au lait spots, axillary and inguinal freckling, optic gliomas, and iris hamartomas. Neurofibromas are benign tumours composed of Schwann cells, some dissociated from axons, a proliferation of support cells (fibroblasts and mast cells) that are less well organized than normal fascicle, with a breakdown of the surrounding perineural layer.

Diagnostic criteria

NF1 is a clinical diagnosis, with two or more of the following criteria being required for diagnosis (National Institutes of Health Consensus, 1988):

- Six or more café au lait macules (>0.5 cm in children or >1.5 cm in adults)
- Two or more cutaneous/subcutaneous neurofibromas or one plexiform neurofibroma
- Axillary or groin freckling
- Optic pathway glioma
- Two or more Lisch nodules (iris hamartomas seen on slit lamp examination)
- Bony dysplasia (sphenoid wing dysplasia, bowing of long bone pseudarthrosis)
- First-degree relative with NF1

Genetic analysis may clarify the diagnosis in young children who do not meet the diagnostic criteria and is useful for affected individuals to aid reproductive decision-making.

Case history

Case 38.1

A 24-year-old woman presents with extensive cutaneous neurofibromas and 3 months of weight loss, with L3 dermatomal numbness, grade 3/5 power in her knee and brisk reflexes. MRI identified a retroperitoneal mass invading the L3 vertebral body with loss of height, canal impingement, and thecal compression. She underwent successful L1-L5 laminectomy decompression and pedicle screw fixation. Histology confirmed malignant peripheral nerve sheath tumour (**Fig. 38.1**).

Case 38.2

A 5-year-old girl presents with delayed milestones, multiple café au lait spots and increasing head circumference. MRI identified chiasmal and optic nerve lesions (**Fig. 38.2**).

Screening

Regular clinical review in childhood under the care of a paediatrician with referral to a specialist NF1 clinic when indicated is recommended. Surveillance brain imaging is not advocated. Genetic testing of the NF1 gene should be made available for affected patients as well as prenatal diagnostic genetic testing when requested (Ferner et al., 2007).

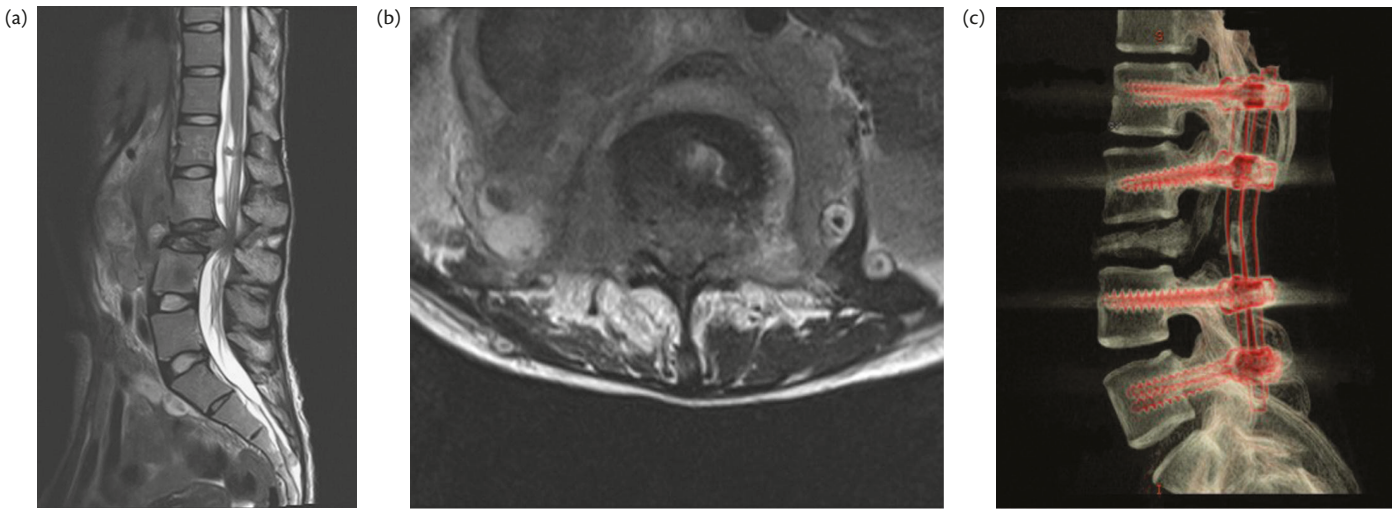

Fig. 38.1 (A) Sagittal T2-weighted MRI and (B) axial T2-weighted MRI showing retroperitoneal mass invading L3 vertebral body with loss of height, canal impingement, and thecal compression. (C) Postoperative CT reconstruction.

Clinical features

Cutaneous manifestations are typically the first sign of NF1. Café au lait spots, light brown patches on the trunk with well demarcated edges, are often present at birth, increasing in number during the first few years of life. The frequency and age of onset of NF1 clinical manifestations are shown in Table 38.1.

Neurofibromas

Neurofibromas are benign peripheral nerve sheath tumours. They may be focal cutaneous or subcutaneous, diffuse, or nodular plexiform lesions. Typically indolent, they follow a benign course, developing in the late teens and early twenties. They may cause cosmetic problems and can be removed, with risk of recurrence and hypertrophic scarring. Subcutaneous neurofibromas, evident on palpation of skin, may be tender or cause paraesthesia in the distribution of the affected nerve. They rarely undergo malignant transformation. Plexiform neurofibromas grow along the nerve length and may involve multiple nerve branches and plexi. Multiple lesions can develop on nerve trunks and can be nodular, resulting in thickened, potentially large, masses which infiltrate soft tissue and cause bone hypertrophy. When multiple spinal nerve roots are involved, patients may present with myelopathy secondary to cord compression.

Central nervous system (CNS) tumours

Pilocytic astrocytoma (WHO grade 1) is the most common paediatric brain tumour in the context of NF1, affecting up to 15% of patients. The majority are optic pathway gliomas (OPG) (Listernick et al., 2007), with 20% occurring in the brainstem. They typically follow a more indolent course than sporadic counterparts. OPG can involve the optic nerve, chiasm, or hypothalamus. They remain asymptomatic in the majority of patients but can cause visual loss, proptosis, endocrine disturbance, and are more often symptomatic in children. Gliomas of the brainstem or cerebellum occur more frequently in NF1 patients than the general population, and of those, are more frequent in NF1 patients treated with radiotherapy for OPG in childhood (Kleinerman, 2009).

Hyperintense lesions on T2 MRI (unidentified bright objects or UBOs) are seen in more than half of NF1 patients, most commonly in children aged 8–16 years. They are pathognomonic of the condition and most likely caused by aberrant myelination or gliosis.

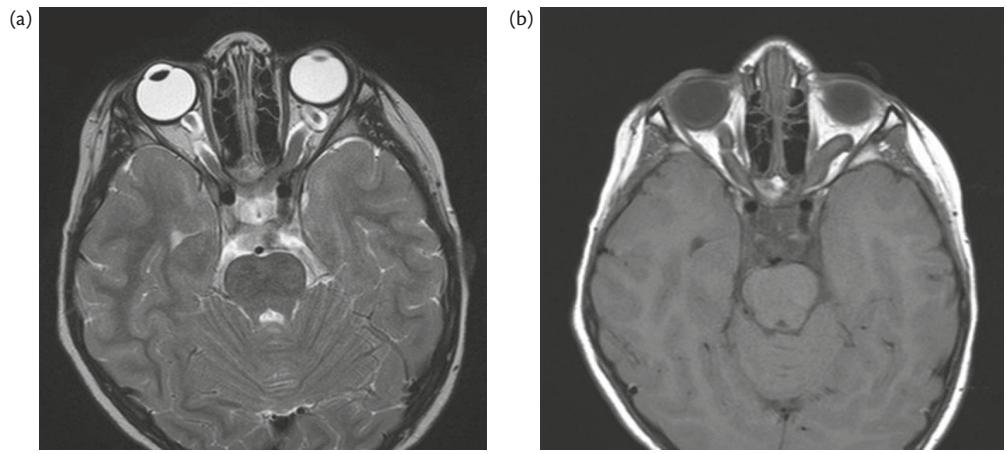

Fig. 38.2 (A) Axial T2-weighted MRI showing thickened, coiled optic nerves; high signal lesion (unidentified bright object) posterior to fourth ventricle. (B) Axial T1-weighted MRI of the orbit showing thickened, coiled optic nerves, left greater than right.

Table 38.1 Frequency and age of onset of major clinical manifestations of NF1

Clinical manifestation	Frequency (%)	Age of onset
Café au lait patches	>99	Birth to 12 y
Skin-fold freckling	85	3 y to adolescence
Lisch nodules	90–95	>3 y
Cutaneous neurofibromas	>99	>7 y (usually late adolescence)
Plexiform neurofibromas	30 (visible) – 50 (on imaging)	Birth to 18 y
Disfiguring facial plexiform neurofibromas	3–5	Birth to 5 y
Malignant peripheral nerve sheath tumours	2–5 (8–13% lifetime risk)	5–75 y
Scoliosis	10	Birth to 18 y
Scoliosis requiring surgery	5	Birth to 18 y
Pseudarthrosis of tibia	2	Birth to 3 y
Renal artery stenosis	2	Lifelong
Phaeochromocytoma	2	>10 y
Severe cognitive impairment (IQ <70)	4–8	Birth
Learning problems	30–60	Birth
Epilepsy	6–7	Lifelong
Optic pathway glioma	15 (only 5% symptomatic)	Birth to 7 y (up to 30 y)
Cerebral glioma	2–3	Lifelong
Sphenoid wing dysplasia	<1	Congenital
Aqueduct stenosis	1.5	Lifelong

Malignant peripheral nerve sheath tumours (MPNST)

MPNSTs arise from pre-existing nodular or plexiform neurofibroma; while rare (2–5% frequency), they are the most frequent malignant neoplasm associated with NF1. Patients with pre-existing plexiform neurofibromas have an 8–13% lifetime risk of MPNST, typically arising age 20 to 30 years (Evans et al., 2002). They have a poorer prognosis than sporadic cases. When they occur in children and adolescents, they tend to be of low grade, and may be difficult to distinguish from atypical plexiform neurofibromas. Pain or enlargement of a mass is a classic initial sign.

Malignancy

A recent UK study suggests that the relative risk of cancer in NF1 patients is 2.7, with an estimated overall risk of malignancy of 36% by the age of 70 (Walker et al., 2006). Of particular note is the increased risk of breast cancer (age <50 years), which has led to the recommendation of early breast screening from the age of 40 for affected women (Sharif et al., 2007).

Management

Patients with NF1 should be managed by a multidisciplinary specialist team, including neurology, paediatrics, genetics, ophthalmology, neurosurgery, plastic surgery, orthopaedics, soft tissue tumour surgery, psychiatry, dermatology, radiology, and pathology. The mainstay of management is active surveillance with age specific monitoring of disease manifestations, patient education, annual review in specialist clinic, and surgical intervention when lesions become symptomatic or show evidence of progression.

OPGs are treated with chemotherapy (vincristine and carboplatin) (Rosser and Packer, 2002), with surgery reserved usually for cosmesis or to treat corneal exposure. Radiotherapy is no longer advocated due to risks of neurovascular, endocrine, neuropsychological sequelae, and of secondary high-grade gliomas and MPNSTs (Sharif et al., 2006; Lee 2007). The decision of when to treat OPG remains challenging, with no universal agreement as to what constitutes progressive disease (radiographic progression vs. deteriorating visual acuity).

Surgery for spinal plexiform neurofibromas is performed for lesions causing neurological deficit. It can be challenging due to their vascularity and involvement of surrounding structures. They are not curable due to multiplicity so decompression (laminectomy and debulking) is advised with consideration of fusion to prevent progressive kyphosis. Surgery for MPNSTs should aim for complete resection with tumour free margins and adjuvant radiotherapy for incompletely excised tumours.

Other CNS tumours should be observed with serial MRI, with surgery reserved for focal, resectable, symptomatic tumours.

Agents which impact on the molecular pathways of tumourigenesis, such as rapamycin and everolimus, inhibitors of the Mammalian Target of Rapamycin (mTOR) pathway, may have a future role in NF1. Rapamycin has been shown in mouse models to inhibit the mTOR pathway particularly in MPNSTs and gliomas (Gottfried et al., 2010), and results of a trial of everolimus in progressive low-grade gliomas in NF1 are yet to be published (NCT01158651, 2010).

Controversy

There are several opinions as to the optimal management of OPGs (Listernick et al., 2007). These include surveillance, choice of ophthalmological test (visual acuity, visual fields, colour vision, visual evoked potentials), age limit for regular surveillance, use of surveillance imaging (MRI), frequency of review, definition of progression (both radiographic and clinical), and optimal definitive management. Evidence shows that chemotherapy with carboplatin and vincristine has good outcomes including slowed tumour progression and improved or stable visual acuity (Mahoney et al., 2000; Fisher et al., 2012; Dodgshun et al., 2015). Literature demonstrates radiotherapy to be more deleterious than beneficial, with one study reporting a threefold increase in the relative risk of secondary CNS tumour following radiotherapy for OPG, with the greatest risk being in children (Sharif et al., 2006). With such good evidence for chemotherapy available, the role of surgery is limited in OPG. It should only be considered if there is evidence of hydrocephalus due to obstruction of the third ventricle (typically hypothalamic or chiasmal lesions), or if there is significant proptosis with disfigurement, in a blind, or near-blind eye, limiting resection to partial removal of the intraorbital optic nerve.

Neurofibromatosis type 2 (NF2)

NF2 affects 1 in 25 000 individuals, with an estimated prevalence of 1 in 60 000 (Evans 2009). It exhibits autosomal dominant

inheritance due to a mutation in the NF2 tumour suppressor gene on chromosome 22q12.2 (gene product merlin, aka schwannomin, a critical regulator of contact-dependent inhibition of cell proliferation) (Rouleau et al., 1993; Trofatter et al., 1993). It has a strong genotype-phenotype correlation, and 99% penetrance by the age of 60. NF2 is characterized by bilateral vestibular schwannomas (VS) (WHO grade I, comprised of neoplastic Schwann cells). Other manifestations include meningioma (intracranial, spinal, and optic nerve sheath), schwannomas at other sites (cranial nerves, spinal cord, peripheral nerves), ocular signs (posterior subcapsular lens opacities), ependymomas, and rarely, skin manifestations (café au lait macules).

Diagnostic criteria

There have been several diagnostic criteria proposed (NIH criteria 1987, revised 1991, and Manchester criteria 1992) (Evans et al., 1992; Evans et al., 2018). In 2011, new criteria were proposed to take into account MRI and molecular genetic testing (Baser et al., 2011) but most still use the Manchester criteria for diagnosis (**Box 38.1**).

Illustrative case

Case 38.3

A 33-year-old woman presents with falls, headaches, nausea, unsteadiness, and right sided tinnitus. Examination revealed swollen optic discs and computed tomography (CT) identified enhancing mass in right cerebellopontine angle with obstructive hydrocephalus. MRI (**Fig. 38.3**) confirmed bilateral VS and meningioma, diagnosed NF2. She underwent resection of large right-side VS, with ongoing surveillance of left side VS and meningioma.

Screening

Patients with a clinical diagnosis of NF2 should be offered genetic testing. If a mutation is identified, the children of affected parents should be offered genetic testing from birth, and clinical screening of at-risk individuals commenced. There is no standard screening protocol in the United Kingdom, but a suggested guideline is shown in **Box 38.2** (Evans et al., 2005).

Box 38.1 Diagnostic criteria for NF2—Manchester criteria

A. Bilateral vestibular schwannomas

B. First-degree family relative with NF2 and unilateral vestibular schwannoma or any two* of:
meningioma, schwannoma, glioma, neurofibroma, posterior subcapsular lenticular opacities

C. Unilateral vestibular schwannoma and any two of:
meningioma, schwannoma, glioma, neurofibroma, posterior subcapsular lenticular opacities

D. Multiple meningiomas (two or more) and unilateral vestibular schwannoma or any two of: schwannoma, glioma, neurofibroma, cataract

*'Any two of' refers to two individual tumours or cataract

Additional groups at risk of NF2 include (Evans et al., 2005): those with a first-degree family history, patients less than 30 years with unilateral VS or meningioma (approximately 10% with an isolated meningioma in childhood will ultimately be diagnosed with NF2), and patients with multiple spinal tumours (schwannoma or meningioma) or cutaneous schwannoma. Patients with a single VS in isolation have a low risk of NF2 (<1% if age >30 years) (Mohyuddin et al., 2002). Presymptomatic genetic testing is available for affected family members. It guides clinical screening, enabling early detection of tumours and improves outcome.

Clinical features

Bilateral vestibular schwannoma typically develop by the age of 30 years in 90–95% of patients (Parry et al., 1994). They present with hearing loss, usually unilateral at the time of onset, but progressing in most patients to deafness. They may also present with vestibular symptoms; tinnitus, dizziness, and imbalance. Unlike neurofibromas, schwannomas are encapsulated tumours composed of pure Schwann cells growing around the nerve, occurring wherever there are nerves with Schwann cells. The predilection for the eighth nerve in NF2 is not understood, but schwannomas of other cranial nerves also occur.

Meningioma occur in around half of NF2 patients, are multiple in 40% of patients, and may be cranial (including optic nerve sheath) and spinal. Intradural spinal tumours, most often dorsal root schwannomas, occur in between 26 and 90% of patients depending on case series (Evans, 2009). Low-grade ependymomas and gliomas also feature in NF2, primarily in the cervical spine and brainstem. Between 60% and 80% of patients have ocular manifestations of NF2 including posterior subcapsular opacities. Cutaneous lesions and café au lait spots occur in NF2 but are fewer and subtler than in NF1.

Management

Patients with NF2 should be managed in multidisciplinary specialist units, staffed with specialists in neurosurgery, otolaryngology, neurology, genetics, audiology, paediatrics, and hearing therapy (consider teaching the patient and family lip-reading and signing at an early age). The aim of NF2 management is to preserve hearing and maximize quality of life. The natural history of NF2-VS is poorly understood making management challenging. The surgeons require experience in managing VS and auditory rehabilitation with both cochlear and auditory brainstem implants. The patient should undergo routine clinical and radiological surveillance as outlined in **Box 38.2**. Treatment should be offered if evidence of growth, progressive hearing loss, or symptomatic tumours.

Bevacizumab, a monoclonal antibody inhibitor of vascular endothelial growth factor (VEGF), demonstrated hearing improvement and VS tumour regression in 50% of NF2 patients, but little effect on NF2-related meningiomas (Plotkin et al., 2012). Trials are ongoing to further evaluate its use in children and young adults (NCT01767792, 2013), and also in NF2-associated meningioma (Nunes et al., 2013).

Stereotactic radiosurgery has a role in poor surgical candidates however, there is controversy surrounding its use and microsurgery remains the accepted primary treatment modality. NF2-VS are more difficult to treat than their sporadic counterparts—typically presenting at a younger age, tending to be larger, multifocal, and with higher risks of recurrence and facial nerve injury. Timing of surgery

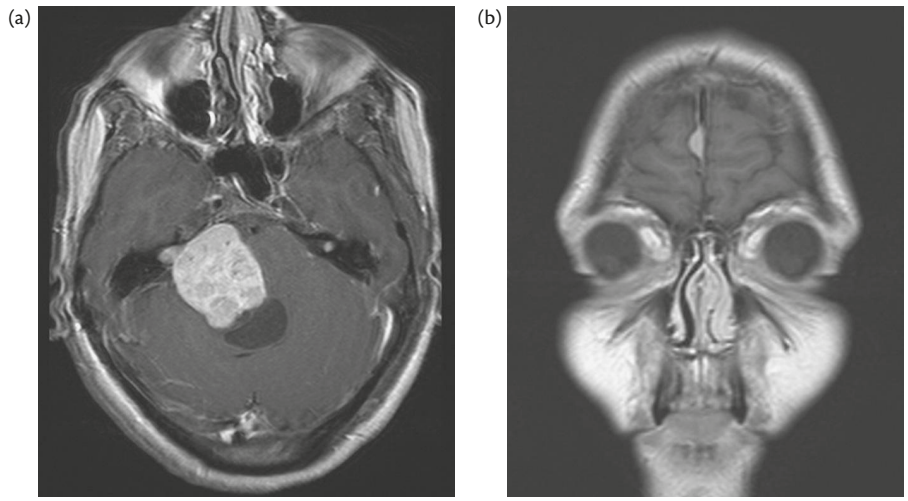

Fig. 38.3 (A) Contrast-enhanced T1-weighted MRI showing right cerebellopontine angle enhancing vestibular schwannoma and small left sided intracanalicular schwannoma. (B) Contrast-enhanced T1-weighted MRI showing enhancing durally based parafalcine meningioma.

is critical and multiple factors play a role in the decision-making process:

- Preservation of hearing and facial nerve function
- Size and growth pattern of the tumour (serial MRI can be used to assess progression)
- Hearing status and rate of deterioration

Box 38.2 Suggested screening guidelines

Initial cranial and spinal MRI age 10–12 years, unless severely affected family
Cataracts and other ocular abnormalities can affect vision in early life, and other tumours (particularly cranial meningiomas) can occur in the first 10 years of life. The initial MRI scan could be at 10–12 years of age, or earlier in severely affected families; it is rare for tumours to become symptomatic before that age.

Annual hearing test
Annual audiological tests, including auditory brainstem response, from the early teens may be useful, but all patients should be monitored with MRI as there is often tumour growth without audiological deterioration.

No tumours: MRI screening every 2 years, age <20 y, every 3 years >20 y
Surgery is unlikely to be more successful for tumours less than 6 mm in diameter than for larger tumours, but VS growth is higher in younger patients, so MRI screening every 2 years for patients less than age 20 and every 3 years for older patients should be sufficient for asymptomatic at-risk individuals without tumours.

Tumours: MRI screening every 1 year
Once tumours are present, MRI screening should be at least annual until the individual growth rate is established.

Spinal tumours are found frequently on MRI. Only 30% of patients with spinal tumours have symptomatic tumours that require a spinal operation, but a full annual neurological examination is a wise precaution, with spinal MRI every 2–3 years unless no tumours are present on the initial scan.

Reproduced with permission from DGR Evans, ME Baser, B O'Reilly, et al. Management of the patient and family with neurofibromatosis 2: a consensus conference statement, *British Journal of Neurosurgery*, Volume 19, Issue 1, 2005 © The Neurosurgical Foundation, reprinted by permission of Taylor & Francis Ltd, www.tandfonline.com on behalf of The Neurosurgical Foundation.

- Consideration of auditory rehabilitation device using either a cochlear implant or an auditory brainstem implant, and if so, when to insert (first surgery easier than revision—can be inserted even when serviceable hearing present, to be activated at later date)
- Extent of tumour resection—total removal only if the tumour yields easily (MRI can be used for surveillance of any residual tumour)

The management of other CNS tumours—meningioma, ependymoma, and other schwannoma, both cranial and spinal—follow the standard principle of active surveillance until evidence of progression or onset of symptoms when surgical resection can be considered.

Controversy

Stereotactic radiosurgery (SRS) has been proven to be an effective method of treatment for sporadic VS, with numerous studies demonstrating comparable, if not improved, results with microsurgery (tumour control rates between 92% and 98%, hearing preservation from 60% to 90%, facial nerve preservation 90% to 95%) (Golfinos et al., 2016). It is less effective in the context of NF2. Concerns surround the risks of malignant transformation, the development of secondary tumours and deleterious effect on surrounding structures (hearing loss and facial nerve damage). Although radiosurgical outcomes after treatment of sporadic VS have been studied, there remains a paucity of literature on SRS in NF2. NF2-VS are more difficult to treat due to their engulfing or infiltrating the eighth nerve more so than sporadic VS which more commonly displace and compress it; hearing and facial preservation is thus challenging whichever modality of treatment chosen. No studies directly compare microsurgical outcomes with SRS in NF2-VS. Several factors should be considered when deciding optimal management for NF2-VS.

Factors in favour of SRS include:

- Avoidance of complications of surgery—death, cerebrospinal fluid (CSF) leak, haemorrhage, meningitis, venous thromboembolism
- Tumours which may be technically difficult to surgically resect; often incomplete resection with higher risk of recurrence

- Avoidance of multiple operations in patients with multiple CNS tumours
- SRS can be performed in patients unfit for anaesthesia
- Good evidence in sporadic VS

Factors against SRS include:

- Risk of new malignant transformation of the VS.
- Theoretical risk of secondary malignancy (Plowman and Evans, 2000). Data is limited, but some suggests that this risk is very low (Rowe et al., 2007) (18 patients with >900 years of follow-up noted only two malignancies (1.7%)). Others argue (Evans et al., 2006) that most studies have short follow-up periods such that delayed presentations may be missed. One study presented a 10-fold malignancy risk in NF2 patients treated with radiotherapy (Baser et al., 2000).
- Poor long-term follow-up and outcome data.

The few studies that have looked at tumour control rates, hearing and facial preservation with SRS (Subach et al., 1999; Rowe et al., 2003; Mathieu et al., 2007; Phi et al., 2009; Sharma et al., 2010), have had variable follow-up durations (between 26 and 96 months) making comparison between studies difficult; outcomes for local control rates were between 66 and 98%, and serviceable hearing preservation between 33% and 66% (Mallory et al., 2014). No comparison has been made between the outcomes of microsurgery vs. SRS. As NF2 is a rare disease patient registration and prospective outcome collection may help define optimal treatment.

Tuberous sclerosis complex

TSC has a frequency of 1 in 6000–10 000 live births and a population prevalence of 1 in 20 000 (Sampson et al., 1989; O'Callaghan et al., 1998). It exhibits autosomal dominant inheritance due to mutations in two distinct tumour suppressor genes, TSC1 on chromosome 9q34 (Fryer et al., 1987) and TSC2 on chromosome 16p13.3 (Kandt et al., 1992), encoding hamartin and tuberin proteins. These form a complex which regulates cell growth and proliferation through the mTOR (mammalian target of rapamycin) pathway (Tee et al., 2002). TSC is characterized by hamartomas and benign neoplastic lesions affecting the CNS as well as skin, renal, cardiac, and pulmonary systems. Major CNS manifestations include cortical hamartomas (tubers), subcortical glioneuronal hamartomas, subependymal glial nodules and subependymal giant cell tumours (SGCTs). See Box 38.3.

Diagnostic criteria

See Box 38.3 for the diagnostic criteria for tuberous sclerosis complex (TSC).

Antenatal diagnosis can be made on fetal ultrasound and MRI, which show cardiac and brain lesions (Curatolo et al., 2008).

Illustrative cases

Case 38.4

A 3-year-old girl with no significant family history, was identified on fetal echocardiogram with cardiac rhabdomyoma. MRI brain at birth (Fig. 38.4A) identified lesions consistent with TSC. She had developmental delay with focal tonic seizures, simple renal cysts, a single renal angiomyolipoma, and regressing cardiac rhabdomyomas and MRI scans at age 3 showed developing features of TSC (Fig. 38.4B).

Case 38.5

A 6-year-old boy with multiple cardiac rhabdomyomas identified on antenatal 36-week ultrasound scan. Due to suspicion of TSC, neonatal MRI brain was performed which identified subependymal nodules and a large right subependymal lesion, likely SGCT (Fig. 38.5). He developed infantile spasms at 22 weeks. At 4 years he underwent resection of SGCT due to progressive enlargement on serial imaging. He has associated learning difficulties.

Screening

Individuals with suspected TSC should undergo brain imaging, EEG (in paediatric patients if seizures suspected or the patient has been diagnosed antenatally), assessment for TSC-associated neuropsychiatric disorder, renal and abdominal imaging, renal function blood tests, pulmonary function testing in adult women and symptomatic adult men, dermatology review if significant skin lesions,

Box 38.3 Diagnostic criteria for TSC

A. Genetic diagnostic criteria

The identification of either a TSC1 or TSC2 pathogenic mutation in DNA from normal tissue.
Between 10% and 25% of TSC patients have no mutation identified.

B. Clinical diagnostic criteria

Definite diagnosis: Two major features or one major feature with ≥2 minor features
Possible diagnosis: Either one major feature or ≥2 minor features

Major features

1. Hypomelanotic macules (≥3, at least 5-mm diameter) (best seen with a Woods' ultraviolet (UV) lamp)
2. Angiofibromas (≥3) or fibrous cephalic plaque (appear in 90% by age 4; hamartomas of cutaneous nerve elements typically arising in malar distribution sparing the upper lip)
3. Ungual fibromas (≥2)
4. Shagreen patch
5. Multiple retinal hamartomas
6. Cortical dysplasias*
7. Subependymal nodules
8. Subependymal giant cell tumour (SGCT)
9. Cardiac rhabdomyoma
10. Lymphangioleiomyomatosis (LAM)†
11. Angiomyolipomas (≥2)†

Minor features

1. 'Confetti' skin lesions
2. Dental enamel pits (>3)
3. Intraoral fibromas (≥2)
4. Retinal achromic patch
5. Multiple renal cysts
6. Non-renal hamartomas, e.g. hamartomatous rectal polyps

* Includes tubers and cerebral white matter radial migration lines.

† A combination of the two major clinical features (LAM and angiomyolipomas) without other features does not meet criteria for a definite diagnosis. When both are present together, other features are also required for the diagnosis.

Data from Krueger, D.A. & Northrup, H., Tuberous sclerosis complex surveillance and management: Recommendations of the 2012 international tuberous sclerosis complex consensus conference, *Pediatric Neurology*, Volume 49, Issue 4, pp. 255–65, Copyright © 2013 Elsevier.

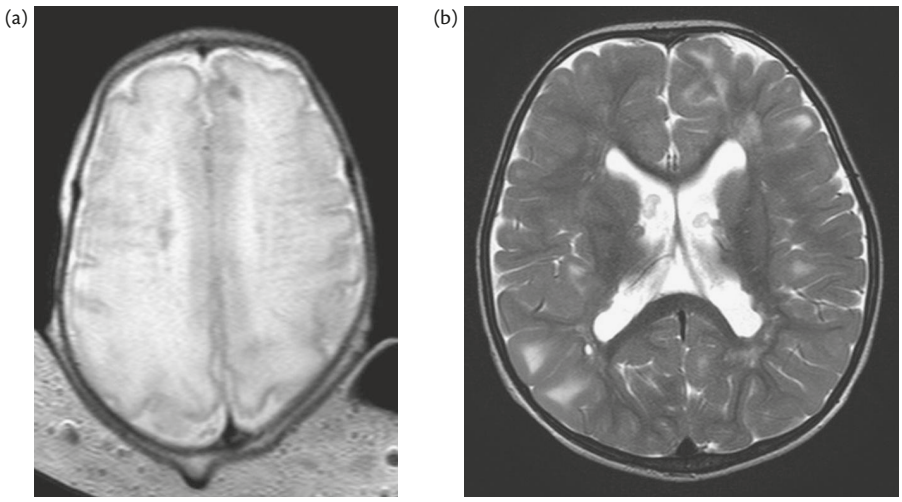

Fig. 38.4 (A) Axial T2-weighted MRI, age 3 days showing radial migration lines, left frontal (low signal) tuber. (B) Axial T2-weighted MRI, age 3 years showing multiple tubers (high signal) and scattered subependymal nodules along the lining of the lateral ventricles.

cardiac echocardiogram and electrocardiogram (ECG) in paediatric patients, ophthalmic and dental review. Once diagnosed, regular surveillance imaging and clinic review is recommended; if asymptomatic, patients should undergo brain MRI every 1–3 years from birth to age 25 years (Northrup and Krueger, 2013). The families of affected individuals should have full clinical assessment, and genetic testing and counselling should be offered.

Clinical features

Heinrich Vogt (1875–1936), a German neurologist, described a triad of three pathognomonic TSC clinical signs: seizures, learning disability, and skin lesions. This triad occurs in just 29% of patients and 6% lack all three (Schwartz et al., 2007). TSC is a multisystem disease with a wide variety of clinical features as defined in **Box 38.3**. Non-CNS lesions include cutaneous manifestations (see **Box 38.3**), renal cysts, angiomyolipomas, and renal cell carcinoma, pulmonary lymphangioleiomyomatosis, cardiac rhabdomyoma, and retinal hamartomas.

CNS lesions are identified in 90% of all TS patients (Curatolo et al., 2006):

- Cortical tubers—benign hamartomas, characterized by proliferation of glial and neuronal cells, and loss of cortical structure—large dysplastic neurons, giant cells, and bizarrely shaped astrocytes; variable in size and multiple in number.
- Subependymal nodules (SENs)—hamartomas, typically seen in the subependymal wall of the lateral ventricles; some protrude into the ventricular cavity (giving a characteristic 'candle guttering' appearance); typically calcified.
- Subependymal giant cell tumours (SGCTs) (aka subependymal giant cell astrocytoma SEGA)—WHO grade 1 tumour, displaying a mixed glioneuronal cell lineage; they are distinguished from SENs by progressive growth on serial imaging or if causing hydrocephalus; occur in approximately 10% of patients with TS.
- White matter linear migration lines—radial bands, radiating from the periventricular white matter to the subcortical region.
- Transmantle cortical dysplasia.

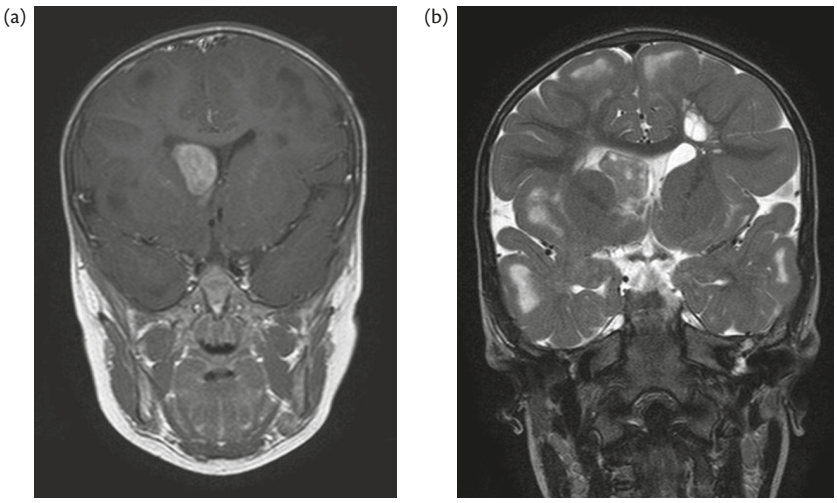

Fig. 38.5 (A) Coronal, contrast-enhanced T1-weighted MRI and (B) coronal T2-weighted MRI showing a SGCT in the right lateral ventricle as well as multiple subcortical tubers.

Management

TSC patients should be followed-up in a specialist multidisciplinary clinic with links to local services. Around 80–90% of patients have seizures; one-third will be managed successfully with medication. Those with refractory epilepsy may be suitable for surgery or vagal nerve stimulation. Surgery may be considered when a particular lesion is identified as the seizure focus. This requires thorough preoperative identification of the epileptogenic zone and consideration given to the extent of surgical resection (Fallah et al., 2015). Jansen et al. (2007) showed that 57% of children achieve seizure freedom postoperatively and another 18% experienced a reduction (>90%) in seizure frequency at one-year follow-up. Surgery should be considered for resection of tumours causing obstructive hydrocephalus, raised intracranial pressure, radiographic tumour progression, or development of new focal neurological deficits.

Controversy

The discovery of upregulation of the mTOR pathway upregulation in TSC-associated tumours presents new possibilities for treatment strategies. Sirolimus (aka rapamycin) is an immunosuppressant which binds to and inhibits the ability of mTOR to phosphorylate downstream targets. It has been approved as an immunosuppressant drug since 2001 and has been found to have application in the treatment of TSC (Jozwiak et al., 2006). Everolimus, a derivative of sirolimus, is effective in diminishing the volume of lesions in patients with renal angiomyolipomas, subependymal giant cell tumours (Franz et al., 2006) and sporadic lymphangioleiomyomatosis. It was approved by the FDA in the USA in 2010 for the treatment of TSC-associated SGCTs not amenable to surgical resection (Krueger et al., 2010). In 2013, the results of a double blind, placebo-controlled trial of everolimus to treat TSC-associated subependymal giant cell astrocytomas were published—the EXIST-1 trial (Franz et al., 2013). These also showed at least 50% reduction in the volume of the tumour as compared with placebo (Franz et al., 2013). Surgery may no longer be the treatment of choice for tumours associated with TSC.

Von Hippel-Lindau (VHL)

VHL has an estimated incidence of 1 in 36 000 live births and prevalence of 1 in 39 000–53 000 (Melmon and Rosen, 1964; Maher et al., 2011). It has autosomal dominant inheritance due to a mutation in the VHL tumour suppressor gene on chromosome 3p25 (Latif et al., 1993). The protein product regulates cell proliferation through the HIF (hypoxia inducible factor) pathway. 20% of cases arise from *de novo* mutations. VHL has marked phenotypic variability and over 90% penetrance by the age of 65 (Maher et al., 1990). It is a multisystem disorder characterized by the development of multiple haemangioblastomas (HGBs) of the central nervous system, retina, and other visceral tumours. Unlike other neurocutaneous syndromes, VHL is not typically associated with skin findings. Haemangioblastomas are composed of vascular and stromal cells.

Diagnostic criteria

See Box 38.4 for the diagnostic criteria for VHL.

In uncertain cases, genetic testing may be employed and is useful for management of the wider family. MRI brain imaging, renal ultrasound, abdominal CT, and urinary amine estimations are required to complete the evaluation.

Box 38.4 Diagnostic criteria for VHL

Confirmed family history

The presence of one single VHL tumour is sufficient for diagnosis (e.g. retinal or CNS HGB, clear cell RCC, phaeochromocytoma, pancreatic endocrine tumour, or endolymphatic sac tumour).

No family history

All of the tumours typically found in VHL disease can occur as a sporadic event.

Therefore, diagnosis requires the presence of two tumours:

either two CNS HGBs

or one CNS HGB and a visceral tumour (with exception of epididymal and renal cysts which are frequent in general population).

Illustrative case

Case 38.6

A 33-year-old man presented with headaches, dizziness, and unsteadiness. Imaging identified a posterior fossa lesion with local mass effect (Fig. 38.6). He underwent surgical resection; histopathology confirmed haemangioblastoma and serum VHL mutation. He also underwent cryotherapy for retinal angioblastoma, and nephrectomy for renal cell carcinoma (RCC). His pancreatic and epididymal cysts are under observation, together with ongoing CNS surveillance.

Screening

One-third of CNS HGBs are VHL-associated. VHL-HGBs tend to present 10 years earlier than sporadic lesions. Patients with a new diagnosis of CNS HGB should have a thorough family history and clinical review for VHL-associated manifestations, and whole neuro-axis imaging. If VHL is suspected, the patient should be referred to a specialist centre for further evaluation. Once the diagnosis is confirmed surveillance screening can be commenced. Screening may include annual ophthalmological assessment for retinal angioma beginning in early childhood, cranial MRI for haemangioblastoma and abdominal MRI for renal cell carcinoma and pancreatic tumours beginning in adolescence, and annual blood pressure monitoring and urinary studies for phaeochromocytoma (Maher, 2004).

Clinical features

CNS HGBs occur in 60–80% of VHL patients (Richard et al., 2000; Wanebo et al., 2003) most frequently in the cerebellum, spinal canal and, less frequently, brainstem and nerve roots. Retinal HGBs occur in more than 50% of patients, are often the earliest manifestation of the disease and can cause sudden visual loss. Other associated lesions include visceral cysts (renal, pancreatic and epididymal cystadenomas which are common but rarely compromise organ function), RCC, adrenal and extra-adrenal phaeochromocytomas, non-functioning pancreatic endocrine cancers, endolymphatic sac tumours and, occasionally, head and neck paragangliomas. RCC is the most common malignancy and cause of death, followed by CNS HGB (Maher et al., 1990).

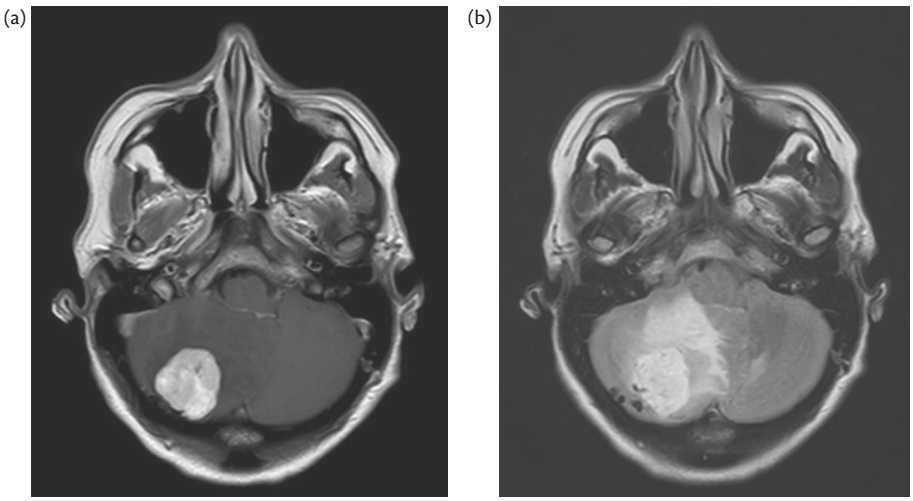

Fig. 38.6 (A) Contrast-enhanced, T1-weighted MRI showing solid enhancing HGB in right cerebellar hemisphere; (B) T2-weighted MRI showing solid lesion, associated flow voids and perilesional oedema, and local mass effect.

Management

VHL carries a lifetime risk of developing multiple organ tumours. Patients should be managed by a dedicated specialist VHL team. Surveillance should be undertaken to allow early detection and treatment of lesions. Complete surgical resection of accessible, symptomatic CNS HGBs is the mainstay of treatment. One study of 80 patients showed no recurrence after 61 months of follow-up (Jagannathan et al., 2008); others quote a recurrence rate of 17% at 53 months (Conway et al., 2001). Factors which influence the decision to proceed with surgery include neurological symptoms, evidence of growth on surveillance imaging (such that resection would be more difficult), or the presence of an enlarging cyst or syrinx (Lonser et al., 2003; Weil et al., 2003).

Preoperative work up should include MRI of the whole neuroaxis, investigation for phaeochromocytoma due to the risk of perioperative hypertensive crisis during anaesthesia, and consideration of preoperative embolization of the tumour.

When planning surgery for posterior fossa HGBs, consider external ventricular drainage and release of CSF, opening the cistern magna to further reduce CSF pressure, ultrasound-guided drainage of peritumoural or intratumoural cysts, intravenous mannitol, and/or furosemide and the use of transdural ultrasound to confirm the adequacy of bone removal for optimum exposure. The principle of resection of cystic HGBs is to remove the mural nodule in order to prevent recurrence of the cyst. The cyst wall itself does not need to be removed unless there is evidence of tumour within the cyst wall on MRI, or under direct vision at the time of surgery (Jagannathan et al., 2008). The standard principles of microsurgery should be applied to dissecting the tumour (i.e. define the plane between tumour margin and cerebellum circumferentially) and progressively dissect deeper tumour margins in layers. Vessels require coagulation and sharp division as they enter or leave the tumour capsule which is assisted by non-stick bipolar forceps. The tumour softens as the feeding supply is interrupted, and gentle retraction of the capsule becomes possible to enhance exposure and resection of the tumour.

VEGF is one of the downstream targets of the VHL protein. Sunitinib, a VEGF receptor inhibitor, is licensed for use in advanced metastatic renal cell carcinoma and has been tested for use in VHL-associated RCC. Its effect on CNS HGBs has not been proven, but research is ongoing (Jonasch et al., 2011). Stereotactic radiosurgery (SRS) may be considered for the management of surgically unresectable lesions. Few studies have yet determined the long-term safety and efficacy of the treatment (Asthagiri et al., 2010).

Controversy

SRS can be used to treat VHL-associated HGBs, less than 3cm^3 volume, tumours incompletely excised, or unresectable. It may minimize the number of surgical resections in an individual with multiple HGBs. Tumour control rates post-SRS range from 83% at 5 years, 61% at 10 years, 51% at 15 years (20 VHL patients with 44 HGBs) (Asthagiri et al., 2010) to 93% at 5 years, and 82% at 10 years (80 VHL patients with 335 HGBs) (Kano et al., 2015). Surgery, if without complication, is curative. Neurological status remains stable or improves following surgical resection (98% of patient improved at 3 months post-op cerebellar HGB resection (Lonser et al., 2003; Weil et al., 2003; Jagannathan et al., 2008).

Data from a retrospective review of 80 VHL patients showed new tumour development after SRS in 41% of patients at 67 months follow-up (rates of 7% at 1 year, 21% at 3 years, 43% at 5 years, 84% at 10 years) (Kano et al., 2015). This is comparable to new tumour formation in VHL without SRS (Wanebo et al., 2003; Ammerman et al., 2006).

As yet there are no reports of secondary malignancy or malignant transformation, but this should be considered. In a study of 186 patients with HGBs treated with SRS, only 13 (7%) developed adverse radiation effects, with one patient dying due to these side effects (Kano et al., 2015). However, this data was not defined as VHL or sporadic HGB patients. Patients with VHL are at risk of developing multiple HGBs and repeated radiotherapy is not always advisable.

Ataxia telangiectasia (AT)

AT is no longer classified as one of the neurophakomatoses. It has historically been included in neurosurgical texts due to its case report associations with some CNS tumours and with

angiographically occult capillary malformations. Unlike the other neurophakomatoses it is not associated with cutaneous or ocular manifestations, and it exhibits autosomal recessive inheritance. It is of most relevance to neurologists due to it causing cerebellar degeneration and progressive ataxia.

Uncommon brain lesions

Yizhou Wan, Hani J. Marcus, and Thomas Santarius

Introduction

In this chapter we discuss neurosurgical tumours, which are uncommon and have not been covered elsewhere.

Due to their rarity this chapter reviews what is known about these conditions and primarily discusses their diagnosis. The description of management is derived largely from published case series.

Choristoma

Choristoma is a mass of heterotopic tissue (i.e. 'normal' tissue) present in an abnormal location (Lee and Roland, 2013). The presence of histologically normal tissue differentiates these lesions from hamartomas, one example of which is dysplastic gangliocytoma of the cerebellum (L'hermitte-Duclos disease). Epidermoid and dermoid tumours are the most well-known intracranial choristomas and are the subject of a separate chapter. Several rarer choristomas have been found in the nervous system, such as intracranial pancreatic (Heller et al., 2010), salivary gland (Hintz et al., 2014), and neuromuscular tissue masses (Hebert-Blouin et al., 2012). Salivary gland choristomas located in the sella have been well-described (Hintz et al., 2014). Other common locations include major peripheral nerves, such as the brachial plexus and sciatic nerve for neuromuscular choristomas (Hebert-Blouin et al., 2013).

Neural choristomas are exceedingly rare and the most commonly found in the head and neck region, especially in the nose (*nasal gliomas)*. Other areas include the trunk and back, where they usually present as isolated asymptomatic masses (Downing et al., 1997). Patients can present from early childhood onwards and the mean age of presentation for neural choristomas is approximately 10 years of age (Hebert-Blouin et al., 2012).

Pathology

Histology of choristomas depends on their tissue of origin. Neural choristomas may comprise of a disorganized population of glial cells in a fibrous background, alternatively they may represent mature neural tissue resembling cerebral or cerebellar cortex (Downing et al., 1997). Neuromuscular choristomas (NMC) are composed of an admixture of mature striated and smooth muscle cells with nerve fibres, typically the sciatic and brachial nerves, although involvement of cranial nerves such as the optic, maxillary, oculomotor, facial and vestibulocochlear nerves have also been described (Hebert-Blouin et al., 2012).

Management

Clinical presentation depends on anatomical location. For example, salivary gland choristomas in the sella can cause hormone deficits whereas suprasellar extension can cause headaches or visual disturbances (Hebert-Blouin et al., 2012). NMCs may cause pain, weakness, and sensory changes when they produce a mass effect along the course of a peripheral nerve or result in sensory or motor deficits. Intracranially they are commonly found in the acoustic meatus or cerebellopontine angle, mimicking vestibular schwannomas on imaging (Boyaci et al., 2011). Radiological findings of NMC are non-specific and may be indistinguishable from schwannomas (Boyaci et al., 2011). Preoperative imaging is important to identify any potential connections between neural choristomas and the central nervous system (Downing et al., 1997). Malignant transformation of neural choristomas has never been reported (Newman et al., 1986).

Prognosis

The rarity of these tumours means that their natural history is not well elucidated. It can generally be thought of as a 'slow-growing' lesion and treatment can be conservative (Boyaci et al., 2011). Some authors have advocated complete resection (Awasthi et al., 1991).

Hamartoma

Hamartoma is a tumour made of tissue components normally found in that anatomical site, but the tissue architecture is disorganized. Cysts and pseudocysts will be described in other chapters, this section describes other lesions found in the central nervous system including, dysplastic gangliocytoma of the cerebellum (L'hermitte-Duclos disease), cortical glioneuronal hamartomas, and hypothalamic hamartomas. Common to all these lesions are that they may represent developmental malformations, but may be mistaken for more common tumour or cystic lesions.

Epidemiology

Since the first description in 1920 more than 230 cases of L'hermitte-Duclos disease (LDD) have been described in the literature. It can present from birth to the sixth decade with no gender predilection. It has been suggested that there is a genetic association between LDD and Cowden syndrome. Cowden syndrome is an autosomal dominant hamartoma-neoplasia complex presenting with neoplasia and hamartomas of the breast, thyroid, genitourinary tract, and endometrium (Nowak and Trost, 2002).

Among the CNS manifestations of tuberous sclerosis complex (TSC), an important diagnostic criterion is the presence of cortical glioneuronal hamartomas (tubers). TSC is an autosomal dominant multisystem disorder caused by mutations in genes encoding tuberculin and harmaline, proteins involved in cell proliferation and differentiation. They cause benign non-invasive lesions in any organ system (Curatolo and Maria, 2013). It occurs at a birth rate of 1 in 6000 (Kwiatkowski and Manning, 2005).

Hypothalamic hamartomas have a prevalence of 1 in 50 000 to 1 in 100 000 (Weissenberger et al., 2001).

Pathology

LDD is characterized by regional thickening of the cerebellar folia, caused by dysplastic replacement of cerebellar Purkinje and granular cells with hamartomatous overgrowth of hypertrophic ganglion cells (Wei et al., 2014). Microscopically there are abnormal ganglion cells in the granular cell layer with thickening and hypermyelination of the molecular cell layer, and absence of the Purkinje cell layer (Ozeren et al., 2014). There may also be the presence of calcification and ectatic vessels on histopathology but no pleomorphism or mitoses (Wei et al., 2014).

In TSC *cortical tubers* are characterized by proliferation of glial and neuronal cells and the loss of the six-layer cortical structure. Within tubers a variety of abnormal cells are found, predominantly, bizarrely shaped astrocytes, giant cells, and dysplastic neurons. A further characteristic finding is that of *subependymal nodules*, hamartomas growths which can protrude into the wall of the lateral ventricle near the foramen of Monroe. These can slowly grow into *subependymal giant-cell astrocytomas* (SEGAs), the most common cerebral tumours found in TSC (Curatolo and Maria, 2013).

Hypothalamic hamartomas are developmental disorders affecting the hypothalamic area between the infundibulum and the mammillary bodies (Striano et al., 2012).

Management

Patients with LDD are initially asymptomatic, but as the tumour slowly increases in size patients usually present with vague neurological complaints related to unilateral cerebellar dysfunction for as long as 15 years (Ozeren et al., 2014). Occasionally patients can present with acute decompensation from occlusive hydrocephalus (Nowak and Trost, 2002).

MRI is fairly characteristic and can be used to diagnose LDD, especially in the context of Cowden's disease. Enlarged cerebellar folia lose their secondary folding and lead to asymmetrical widening of the cerebellar hemispheres. The lesions are non-enhancing and display a characteristic pattern of isointense bands within a discrete lesion of hypointensity on T2-weighted imaging (Fig. 39.1). This indicates widened gyri and displaced sulci structure in expanded cerebellar cortex (Nowak and Trost, 2002).

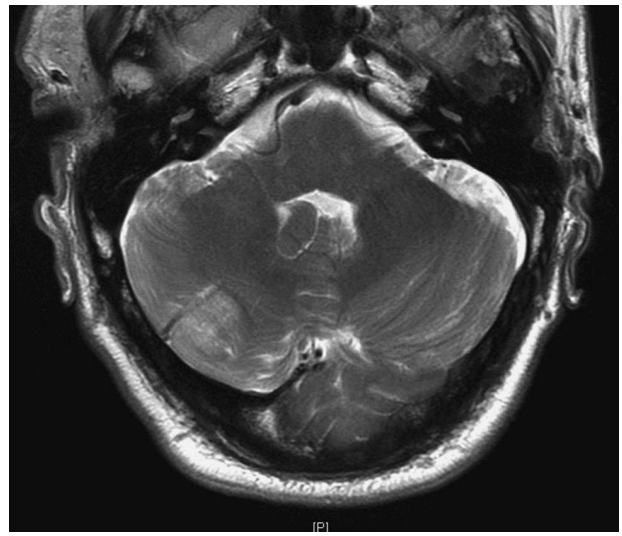

Fig. 39.1 L'hermitte-Duclos disease. Abnormal tissue involves the cerebellar cortex, appearing hyperintense on T2 with widening of cerebellar folia.

It may prove to be difficult for symptomatic LDD to be resected because the lesions blend into normal cerebellar parenchyma. Intraoperative MRI or/and intraoperative histological demonstration of a transition zone on histopathology maybe helpful.

The clinical manifestations of TSC are protean and related to the systemic effects of the condition. From a neurological perspective, the management focuses on controlling epilepsy. This generally occurs in the first year of life, evolving from focal seizures to infantile spasms. Subependymal giant-cell tumours are treated with mTOR pathway inhibitors or surgically (Franz et al., 2006).

Classically the hallmarks of hypothalamic hamartomas are gelastic seizures, developmental delay, and precocious puberty. MRI usually demonstrates a lesion with a vertical plane of attachment within the third ventricle and/or a horizontal plane of attachment on the underside of the hypothalamus (Fig. 39.2).

These lesions appear to have an intrinsic epileptogenicity (Maixner, 2006). Surgical resection has been reported to improve symptoms and seizure control (Palmini et al., 2002). Complete resection can be challenging and because it is difficult to predict the severity of a patient's epileptic course, the optimal timing of surgery is unclear (Maixner, 2006).

Prognosis

Due to the progressive growth of LDD lesions surgical resection is usually required but recurrence is common due to the difficulties in achieving a complete resection (Ozeren et al., 2014).

In TSC renal complications such as angiomyolipomas, renal cysts and renal cell carcinoma are the most frequent cause of the death (Curatolo and Maria, 2013).

Harvey et al. reported in their case series of 29 hypothalamic hamartoma patients that 15 patients achieved seizure-freedom and seven patients achieved 90% reduction in seizures over a follow-up of one to six years (mean 2.5 years). Complications of surgery included, injury to the optic tract, meningitis, communicating hydrocephalus and ischaemic infarction to the thalamus (Harvey et al., 2003).

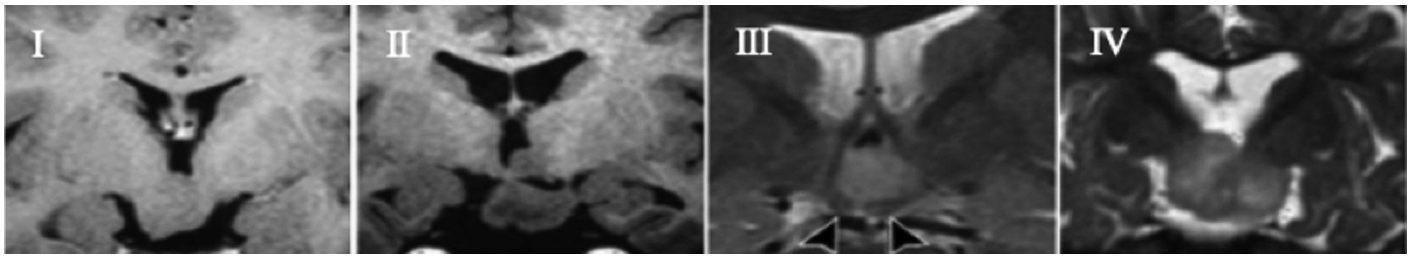

Fig. 39.2 Delalande classification of hypothalamic hamartomas: type I has a horizontal orientation; type II has a vertical orientation; type III has both a horizontal and vertical component; and type IV is a giant hamartoma.

Adapted from Endoscopic Treatment of Hypothalamic Hamartomas. *J Korean Neurosurg Soc.* 2017; 60(3): 294–300. doi: 10.3340/jkns.2017.0101.005, which is published under a Creative Commons License.

Pituicytoma, granular cell tumour (GCT), and spindle cell oncocytoma (SCO)

The 2007 WHO Classification of Tumours of the Central Nervous System describes a spectrum of benign (WHO grade I) non-adenomatous pituitary tumours including pituicytoma, GCT, and SCO (Louis et al., 2007; Covington et al., 2011).

Epidemiology

Non-adenomatous pituitary tumours are rare, with a recent meta-analysis identifying 112 cases in the literature (Covington et al., 2011). The average age at diagnosis is between 50 and 60 years, with a slight male preponderance for pituicytoma, and female preponderance for GCT and SCO (Covington et al., 2011; Pirayesh Islamian et al., 2012).

Pathology

Pituicytoma arises from pituicytes, specialized glial cells of the posterior lobe and the stalk of the pituitary gland (Zygourakis et al., 2015). Histologically, pituicytoma is characterized by elongated, bipolar spindle cells (Brat et al., 2007).

GCT arises from granular pituicytes, and are composed of polygonal eosinophilic granular cells that are strongly PAS positive due to abundant intracytoplasmic lysosomes (Orning et al., 2013). SCO also arises from pituicytes and are characterized by interlacing fascicles of spindled-to-epithelioid cells with mitochondrial accumulation seen on ultrastructural analysis (Zygourakis et al., 2015).

Management

The most common presenting symptom of patients with non-adenomatous pituitary tumours is visual disturbance (e.g. bitemporal hemianopsia) (Covington et al., 2011). Other symptoms include headache fatigue, and those related to hypopituitarism (e.g. decreased libido). Diabetes insipidus is rare.

Several features on MRI can aid diagnosis (Fig. 39.3) (Covington et al., 2011): pituicytoma may be considered if the lesion is purely intrasellar and clearly separate from the pituitary gland; GCT may be considered if the lesion is suprasellar or mixed supra- and intrasellar, and clearly separate from the pituitary gland; and SCO may be considered if the lesion is mixed supra- and intrasellar, but the mass cannot be separated for the pituitary gland. Compared to GCT and SCO, Pituicytomas more frequently demonstrate homogenous rather than heterogenous enhancement on T1-weighted images. (Covington et al., 2011).

In practice, these lesions may be difficult to distinguish from pituitary adenoma, and transsphenoidal surgical resection is generally considered safe and effective (Zygourakis et al., 2015). However, because these lesions are firm and may be highly vascular, some authors have advocated the use of preoperative embolization in

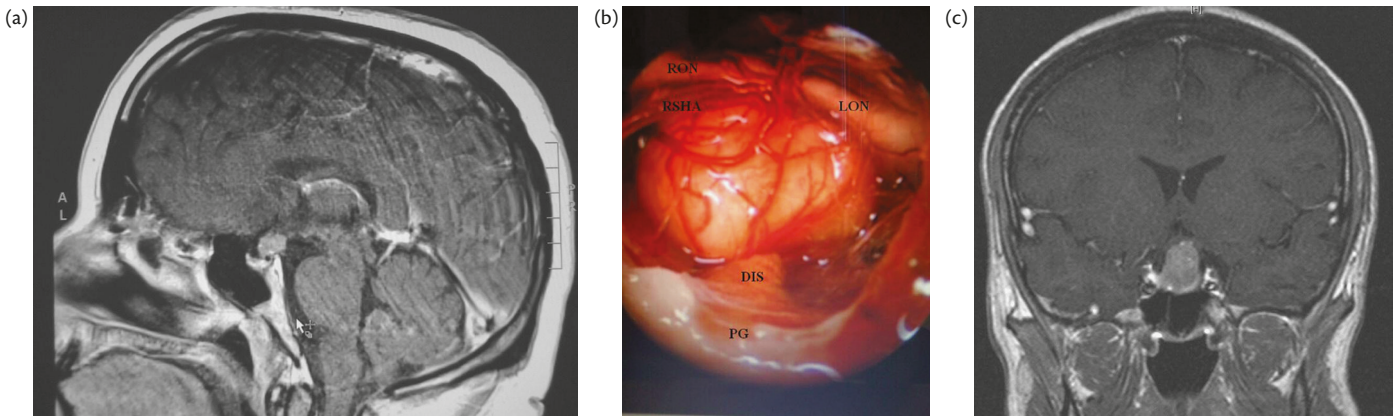

Fig. 39.3 Granular cell tumour (GCT) of the pituitary. (A) MRI (T1 with contrast) showing a GCT of the pituitary stalk. In this case the tumour is separate from the pituitary gland and the diagnosis of should be considered. (B) Transsphenoidal endoscopic approach—intraoperative photograph demonstrating the separation of the tumour from the pituitary gland as seen on the MRI. (C) Granular cell tumour of the pituitary—in this case not distinguishable from a much more common pituitary adenoma or the much rarer primary non-adenomatous pituitary gland tumours (i.e. pituicytoma and spindle cell oncocytoma, SCO).

selected cases (Wolfe et al., 2008). The role of adjuvant therapy remains unclear (Zygourakis et al., 2015).

Prognosis

Non-adenomatous pituitary tumours are generally benign and surgical resection may be curative.

Gangliocytoma

Gangliocytomas are usually considered alongside gangliogliomas as a spectrum of intra-axial tumours originating in the grey matter. Gangliocytomas differ from gangliogliomas by their noted absence of a glial component and consist of abnormal mature ganglion cells (WHO grade I).

Epidemiology

They account for 0.1–0.5% of all brain tumours and occur in children and young adults (Koeller and Henry, 2001).

Pathology

They are found in decreasing incidence in the temporal lobe, cerebellum, parieto-occipital region, frontal lobe, hypothalamus adjacent to the third ventricle and spinal cord (Koeller and Henry, 2001).

Intraoperative smear histology shows ganglion cells with vesicular nuclei and prominent nucleoli. One can differentiate between gangliocytoma and infiltrating glioma with entrapped neurons by the presence of variable-sized neoplastic ganglion cells which form clusters and have abnormal branching of apical dendrites.

Management

They present as a result of mass effect or seizures. There is possibly a long history of symptoms and it is important to consider their diagnosis because of their favourable prognosis postresection.

Non-enhanced CT demonstrates hyperattenuation and no vasogenic oedema. MRI appearances show low signal intensity on T1-weighted images and mixed signal intensity on T2-weighted images (Shin et al., 2002). These features make differentiation between gangliogliomas and gangliocytomas challenging.

Prognosis

Malignant transformation is uncommon, it is more likely to be seen with gangliogliomas and is due to the glial/astrocytic component showing increased cellularity, mitosis, and necrosis (Adesina and Rauch, 2010).

Paraganglioma

Tumours derived from chromaffin cells (themselves derived from neural crest cells) are known as paragangliomas regardless of their anatomical location. Intra-adrenal paragangliomas are called phaeochromocytomas. The most common location for extra-adrenal parasympathetic paragangliomas is in the head and neck. The most common location here is the carotid body at the bifurcation of the internal jugular and external jugular veins, where they are known as chemodectomas. Intracranially, paragangliomas occur in the region of the jugular foramen and glomus jugulare tumour is the most commonly used term to describe them. Glomus jugulare consists of one or more bodies, found in the aventitia of the dome of the jugular bulb. Glomus jugulare tumours can be found anywhere along the course of the internal jugular vein.

Epidemiology

The incidence of chemodectoma is less than 1 in 3000 (Gad et al., 2014). They are ten times more common in people living at high-altitudes (Athanasiou et al., 2007). This may be related to hypoxia-induced hyperplasia of the catecholamine-secreting chief cells (Knight et al., 2006). The mean age of onset is 45 years (Kotelis et al., 2009).

Glomus jugulare tumours are rare, comprising 0.6% of tumours in the head and neck. They are two to three times more common in women than they are in men (Lee et al., 2002).

Pathology

Chemodectomas are genetically heterogeneous. They can occur sporadically or as part of a neoplastic syndrome, such as multiple endocrine neoplasia II, neurofibromatosis I, and von Hippel-Lindau disease (Knight et al., 2006). Four different genetic susceptibility loci have been mapped in chemodectomas. They demonstrate autosomal dominant inheritance with age and hypoxia-related penetrance. Mutations in three of these genes encode for subunits of the enzyme succinate dehydrogenase complex (Knight et al., 2006).

Histology of chemodectoma demonstrates mostly chief cells, arranged in a characteristic pseudoalveolar pattern known to as 'cell balls' (Zellballen) (Athanasiou et al., 2007).

Histologically glomus jugulare tumours are composed of epithelioid or chief cells in a hypervascular stroma, surrounded by a thin capsular layer (Guild, 1953).

Management

Patients with chemodectomas typically present with a lateral neck mass, with or without involvement of the lower cranial nerves (8 to 12) (Knight et al., 2006).

Glomus jugulare tumours are slow-growing and there may be significant latency prior to diagnosis. Signs and symptoms include unilateral deafness, tinnitus, hoarseness, dysphagia, headache, and lower cranial nerve palsies (Watkins et al., 1994). In 10–20% of cases they can be multifocal and although generally benign, local invasion and metastasis to liver, lung, lymph nodes, and spleen have been reported. Preoperative workup should include MRI and CT to identify extent of bone involvement.

In contrast with phaeochromocytomas and extra-adrenal sympathetic paragangliomas, head and neck paragangliomas rarely produce significant amounts of catecholamine (Chen et al., 2010). This makes preoperative optimization of these patients less challenging from the neuroendocrine perspective.

Workup with imaging is crucial for surgical success as location renders chemodectomas technically challenging and biopsy is hazardous. Tumour enlargement typically splays the internal and external carotid arteries but does not lead to narrowing of their diameters (Wieneke and Smith, 2009). The differential diagnoses include vagal schwannomas and neurofibromas, glomus vagale tumours, and lymph node masses. Lymph nodes are not typically hypervascular, glomus vagale tumours occur more rostrally, and

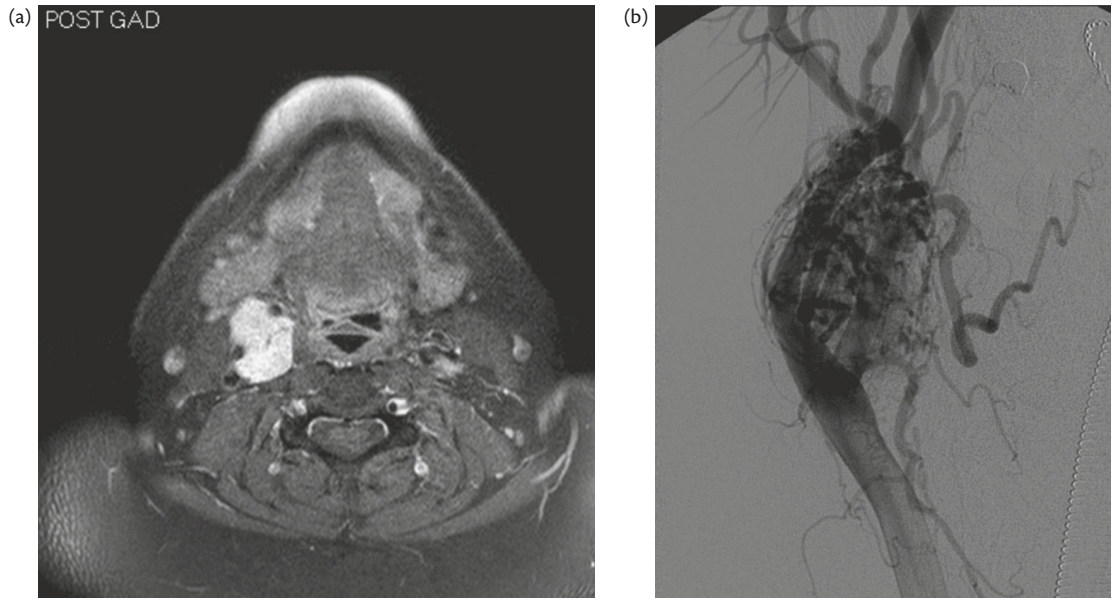

Fig. 39.4 Chemodectoma. A 59-year-old lady presented with right-sided otalgia. (A) T1W Axial MRI with gadolinium demonstrates splaying of the internal and external carotid arteries which differentiate paragangliomas from other lesions such as schwannomas and neurofibromas. (B)The lesion was resected with no complications after preoperative embolization demonstrated, extensive vascular supply from hypertrophic branches of the right ascending pharyngeal artery. ECA, external carotid artery; ICA, internal carotid artery; IJV, internal jugular vein.

vagal masses tend to displace both the carotid vessels together rather than to splay them (Fig. 39.4).

Larger tumours as much as 10 cm in diameter are more likely to encase the carotid artery. In these circumstances, neoadjuvant radiotherapy can be used to down-stage the tumours and improve resectability. Intraoperatively, internal carotid artery reconstruction with end-to-end anastomosis may be performed (Gad et al., 2014).

Historically, approaches to management of glomus jugulare tumours have been microsurgical. The median tumour doubling time has been reported to be four years or longer, but aggressive tumours exist and older patients may cope less well with its symptoms (Kemeny, 2009). Resection approaches depend on size and location and may include combined otological and neurosurgical approaches (Watkins et al., 1994).

Stereotactic radiosurgery's obvious advantages in terms of minimizing radiation damage to critical structures at the skull base have to be balanced against its limitations. Relative contraindications of radiosurgery include large tumours, typically a maximal of 3–4 cm field size and lack of radiological boundaries at the skull base. There have been no randomized control trials to directly compare radiosurgery against microsurgery but a meta-analysis of 19 retrospective studies demonstrated that radiosurgery is efficacious with 95% of a combined sample of 335 patients achieving clinical control (Guss et al., 2011).

Prognosis

The mortality and morbidity rate associated with resection of chemodectoma has been quoted at 1% and 33%, respectively (Gad et al., 2014). Cranial nerve injury, wound haematomas, and ischaemic stroke can occur. Although there is a low risk of distant metastasis, follow-up for possible lymph node metastases is indicated. Residue disease may also be controlled with radiotherapy.

Glomus jugulare tumours are typically indolent and, as the management goal is to provide long-term tumour control with low morbidity, a judicious use of stereotactic radiotherapy and modern microsurgery make achieving this goal possible (Fayad et al., 2009).

Langerhans cell histiocytosis

Langerhans cell histiocytosis (LCH), formerly known as histiocytosis X, is a heterogeneous group of tumours, typically affecting bone, characterized by a clonal proliferation of pathological cells with the characteristics of Langerhans cells (Abla et al., 2010). Langerhans cells are dendritic cells (antigen-presenting cells) that arise from the bone marrow and usually reside in the lymph nodes and skin.

The term 'eosinophilic granuloma' has been used to describe a single LCH lesion, 'Hand-Schüller-Christian disease' to describe multiple LCH lesions within one system, and 'Abt-Letterer-Siwe disease' to describe multiple LCH lesions within multiple systems (Arico et al., 2003).

Epidemiology

LCH typically occurs in children, with an estimated incidence of 4–4.5 cases per million per year (Chaudhary et al., 2013).

Pathology

The aetiology of LCH remains unclear. There are data to suggest that germ line mutations may predispose some patients to LCH. Approximately 1% of patients with LCH have an affected relative. Moreover, twin studies have found a considerably higher rate of concordance in monozygotic versus dizygotic twins (92% and 10%, respectively) (Abla et al., 2010). There are also data to suggest that viruses such as HHV6 may result in LCH, however most studies have failed to confirm this viral association (Abla et al., 2010).

Histologically the diagnosis of LCH rests on the presence of Langerhans cells within lesions, with accompanying macrophages, T-lymphocytes, eosinophils, and multinucleated giant cells. These Langerhans cells may be determined by the demonstration of CD1a on immunohistochemistry, or Birbeck granules on electron microscopy (Abla et al., 2010). The latter may now be more easily identified by immunohistochemical staining of langerin (CD207), an endocytic receptor which induces the formation of Birbeck granules (Valladeau et al., 2000).

Lesions associated with LCH are most commonly located within bone, particularly the skull. Within the central nervous system three patterns of lesions have been described (Grois et al., 2010):

1. Well-circumscribed granulomas within the brain's connective tissue with a predilection for the circumventricular organs.
2. Non-granulomatous neurodegenerative lesions mainly affecting the brainstem and cerebellum.
3. Granulomas in the pituitary stalk that invade the hypothalamus and show diffuse infiltration of the surrounding brain.

Management

The clinical symptoms and signs depend on the site and nature of LCH lesions. A single skull lesion is the most frequent presentation of LCH. Involvement of the hypothalamic-pituitary axis can result in diabetes insipidus in up to 25% of all patients (Grois et al., 2010). Non-granulomatous neurodegenerative lesions result in a highly variable presentation, ranging from mild abnormalities of the reflexes and subtle cognitive deficits, to pronounced ataxia or behavioural disturbance.

CT and MRI are indicated to investigate skull and brain lesions, respectively (Grois et al., 2010). CT of the skull may demonstrate lesions within the calvarium, with a characteristic bevelled edge. MRI of the brain may show enlargement of the pituitary stalk with potential extension to the hypothalamus (Fig. 39.5). MRI may also reveal radiological degeneration with symmetrical hyperintense signal changes on T2-weighted images and hypo- or hyperintense signals on T1-weighted images in the cerebellum, and sometimes changes in the basal ganglia and brainstem.

The evidence guiding the decision-making for LCH is limited. In unifocal skull lesions a simple curettage or even biopsy can provide diagnostic tissue and usually results in cure (Abla et al., 2010). The treatment of central nervous system lesions resulting in diabetes insipidus may include steroids or chemotherapy (Grois et al., 2010). Surgical resection and radiotherapy have also been used in lesions located in regions other than the hypothalamic-pituitary axis.

Prognosis

The prognosis of LCH is highly variable. Patients with lesions limited to a single system generally have a high chance of spontaneous remission and a favourable outcome. Patients with multiple systems affected may have a very much worse prognosis; those in whom high-risk organs (liver, spleen, or bone marrow) are involved, who fail to respond to therapy in the first 6 weeks, have a mortality rate as high as 35%.

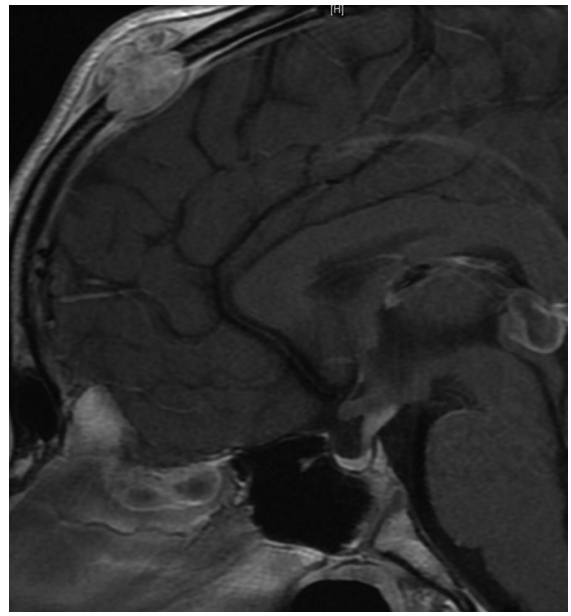

Fig. 39.5 Langerhans cell histiocytosis (LCH). A 14-year old boy presented with a lump on the forehead and chronic constipation. Subsequently diabetes insipidus and growth hormone deficiency were diagnosed and the MRI (T1 with gadolinium contrast) revealed a thickened and enhancing pituitary stalk and an enhancing lytic skull lesion. A biopsy of the skull lesion yielded a diagnosis of LCH. Further investigations uncovered involvement of the gut and chemotherapy according to LCH4 protocol was instituted.

Sarcoidosis

Sarcoidosis is a multisystem inflammatory granulomatous disease, typically affecting the lungs (Joseph and Scolding, 2007). The involvement of the central nervous system, termed neurosarcoidosis, is a rare but feared complication of the disease.

Epidemiology

The prevalence of sarcoidosis is approximately 40 per 100 000 (Joseph and Scolding, 2007). Less than 10% of patients with sarcoidosis exhibit symptoms and signs of neurological disease, though autopsy studies have suggested a significant proportion with subclinical disease. It is usually diagnosed between 20 and 40 years of age, and certain racial groups, such as Northern Europeans and West Africans, are at considerably higher risk of developing the disease.

Pathology

The aetiology of sarcoidosis remains unclear. Genetic studies have suggested that class I human leukocyte antigen (HLA)-B8 antigens and HLA class II antigens encoded by HLA-DRB1 and DQB1 alleles may predispose some patients to the disease (Vargas and Stern, 2010). Several environmental triggers have also been put forward including mould, metals, wood burning stoves, photocopier toner, and infectious agents such as mycobacterium tuberculosis and propionibacterium acnes.

Histologically sarcoidosis is characterized by non-caseating granuloma. Neurosarcoidosis most commonly affects the leptomeninges

at the base of the brain. Extension to the brain parenchyma may occur, and is usually associated with surrounding astrocyte activation and gliosis.

Management

Neurosarcoidosis presents most frequently with cranial nerve palsies, seen in 50–75% of patients. Such palsies are most commonly the result of basal meningitis, but may also be due to nerve granulomas, or raised intracranial pressure. Seizures are another common manifestation of neurosarcoidosis, often reflecting underlying mass lesions, and occur in about 10% of patients (Joseph and Scolding, 2007).

An enhanced MRI of the may show leptomeningeal enhancement with gadolinium. Multiple white matter lesions are seen in approximately 40% of patients (Joseph and Scolding, 2007). Large mass lesions may also be demonstrated, and can mimic neoplasia. Lumbar puncture may reveal raised protein (>2 g/litre), mild lymphocytosis, and possibly oligoclonal bands. Systemic investigations can also provide evidence of sarcoidosis including blood tests (elevated serum ACE, ESR, and calcium), and a chest X-ray or CT thorax (hilar and mediastinal adenopathy).

The first-line therapy for sarcoidosis are corticosteroids (Joseph and Scolding, 2007; Vargas and Stern, 2010). Long-term corticosteroid use is associated with considerable morbidity, particularly in patients with diabetes mellitus, hypertension, or osteoporosis. To this end, steroid-sparing immunosuppressive agents, including methotrexate and hydroxychloroquine, have also been used with varying success to manage sarcoidosis, though these too also carry risks of complications. In patients with drug-resistant sarcoidosis, case series have reported success with radiotherapy (Bruns et al., 2004). The role of surgery is limited to biopsy in equivocal cases, and the treatment of complications such as hydrocephalus.

Prognosis

Spontaneous remission of neurosarcoidosis has been reported but is very rare; most patients require long-term follow with therapy provided when disease exacerbation occurs.

Tumefactive multiple sclerosis

Multiple sclerosis (MS) is an autoimmune inflammatory disease affecting the central nervous system, characterized by lesions of demyelination and axonal loss. Tumefactive multiple sclerosis (TMS) describes the presence of MS lesions greater than 2 cm in diameter, often solitary, which may be mistaken for other space occupying lesions such as brain tumours on imaging (Hardy and Chataway, 2013).

Epidemiology

The prevalence of TMS has been estimated to be 1–2 per 1000 cases of MS (Hardy and Chataway, 2013). It is usually diagnosed between the ages of 20 and 40 years.

Pathology

The aetiology of TMS remains unknown. Tumefactive demyelinating lesions have been reported in diseases other than MS, including viral infections such as HIV, and as a side effect of treatment with drugs such as tacrolimus. Histologically, tumefactive demyelinating lesions are indistinguishable from other MS lesions. Active lesions consist of areas of demyelination with reactive astrocytes and myelin-containing foamy macrophages (Hardy and Chataway, 2013). Macroscopically, lesions are usually well circumscribed, with a predilection to the frontal and parietal lobes (Altintas et al., 2012).

Management

The presentation of TMS often resembles that of more sinister space occupying lesions, including symptoms and signs of raised intracranial pressure, seizures, and focal neurological deficits. Headache and vomiting are particularly common in children (Altintas et al., 2012).

An enhanced MRI brain is indicated to investigate TMS. Lesions up to 12 cm in diameter have been reported, but most range between 2 and 6 cm (Lucchinetti et al., 2008). There is usually associated cerebral oedema, though often less than that observed with malignancy. The majority of lesions enhance with gadolinium, and demonstrate a ring appearance (usually closed, but open ring is highly specific for TMS) (**Fig. 39.6**), which is thought to reflect an advancing area of active inflammation away from a more chronic non-enhancing core (Hardy and Chataway, 2013).

An unenhanced CT head may be helpful in distinguishing TMS from malignancy; regions that are hyperintense on an enhanced MRI brain, but hypodense on an unenhanced CT head, are more likely to represent TMS (Kim et al., 2009). Lumbar puncture may reveal unmatched (present in CSF but not in serum) oligoclonal bands. Systemic investigations are also important to exclude other pathologies such as vasculitis, granuloma, infection, or malignancy. These include blood tests and CT of chest, abdomen, and pelvis (Hardy and Chataway, 2013).

The treatment is with high-dose corticosteroids (Altintas et al., 2012). In patients in whom corticosteroids are ineffective, plasma

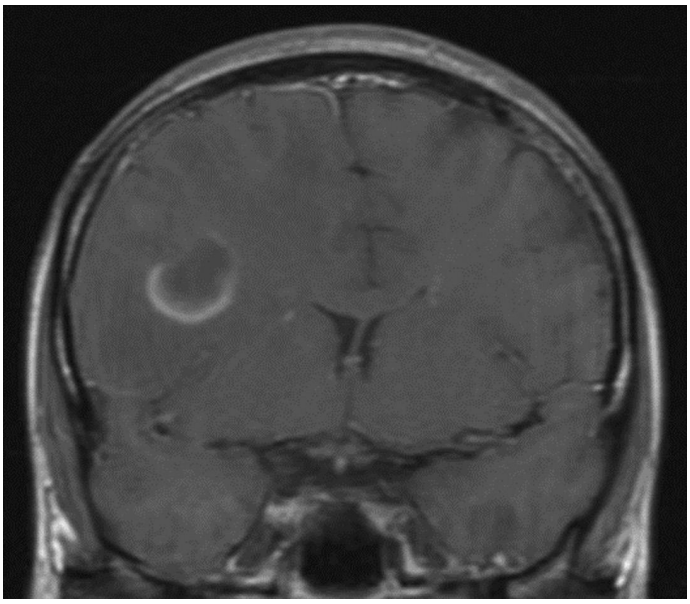

Fig. 39.6 Tumefactive MS plaque. An 'open ring sign' is relatively specific for multiple sclerosis. The enhancing component is thought to represent advancing front of demyelination, thus favouring the white matter side of the lesion. The open part of the ring will therefore usually point towards the grey matter. Stereotactic biopsy confirmed a diagnosis of MS.

Fig. 39.7 Melanocytoma. A middle-aged woman presented with headache. Dermatological and ophthalmological were unremarkable. An unenhanced CT brain showed a mixed density lesion with abnormal calcification, suggesting it was longstanding. A staging CT did not demonstrate lesions elsewhere, and she underwent a complete surgical resection. Histopathology confirmed melanocytoma and she remains well 5 years postoperatively.

exchange appears to be a reasonable second line agent. The anti-CD20 B cell monoclonal antibody rituximab has also been used with some success (Fan et al., 2012). Disease-modifying therapy such as interferon beta or glatiramer acetate may be also be beneficial in reducing the risk of recurrence, but this must be balanced against the risk of adverse events. The role of surgery is limited to biopsy in cases of diagnostic uncertainty, and the treatment of complications such as hydrocephalus.

Prognosis

Overall, the prognosis of patients with TMS does not appear to be worse than other patients with MS in general. Indeed, in the largest cohort of patients with TMS, the long-term prognosis was better than in matched controls with typical MS (Lucchinetti et al., 2008).

Primary CNS melanoma and melanocytoma

Primary melanocytic neoplasms of the CNS are a range of tumours characterized by a clonal proliferation of melanocytes of the leptomeninges, which are derived from the neural crest during early embryogenesis (Liubinas et al., 2010). These neoplasms include diffuse leptomeningeal melanocytosis (DML) or melanomatosis, melanocytoma, and primary malignant melanoma; the present discussion is limited to melanocytoma and primary malignant melanoma. As the highest concentration of meningeal melanocytes is in the spinal cord and posterior fossa and this is where these tumours occur most commonly (Goldgeier et al., 1984).

Epidemiology

The incidence of melanocytoma is approximately 1 per 10 million, and the incidence of primary CNS melanoma 1 per 20 million. The peak incidence is in the fifth decade, and there is a slight female preponderance (Liubinas et al., 2010).

Pathology

Histologically, the diagnosis of primary melanocytic neoplasms of the CNS rests on the identification of melanin in tumour cells or associated macrophages (Liubinas et al., 2010). Melanocytomas are low-grade lesions that do not invade the surrounding brain, although intermediate-grade melanocytomas are also recognized (Brat et al., 1999; Navas et al., 2009). Primary CNS melanoma is similar to melanoma arising in other sites, and may feature invasion, haemorrhage, or necrosis. Macroscopically, melanocytomas and primary CNS melanomas are solitary lesions that are generally extra-axial.

Management

The presentation of melanocytomas and primary CNS melanoma is that of other space occupying lesions, including symptoms and signs of raised intracranial pressure, seizures, and focal neurological deficits. Dermatological and ophthalmological examinations as well as CT staging must be performed to rule out a distant primary source.

Neuroimaging is indicated in suspected lesions. A CT brain often shows iso- or hyperdense lesions with or without abnormal calcification (Fig. 39.7), which enhance with contrast. An MRI brain may demonstrate lesions that are, unusually for tumours, hyperintense on T1-weighted images, hypointense on T2-weighted images, and enhance homogenously with gadolinium.

The treatment of melanocytoma and primary CNS melanoma is complete surgical resection. Radiotherapy may be indicated in incompletely resected melanocytoma, but malignant melanoma is relatively radioresistant. The role of chemotherapy is unclear, but it has been used as adjuvant therapy and in patients with recurrent disease (Cornejo et al., 2013).

Prognosis

Melanocytomas are generally benign and surgical resection curative. Primary CNS melanoma, however, is associated with a poor prognosis. Primary CNS melanoma may be prone to local recurrence or systemic spread, albeit less so than metastatic melanoma, with an average survival time approximately 6 years (Cornejo et al., 2013).

Intracranial lipomas

Epidemiology

These tumours are extremely rare with an incidence estimated at 0.06–0.46% of all intracranial tumours (Truwit and Barkovich, 1990). Older studies may however underestimate the true incidence due to

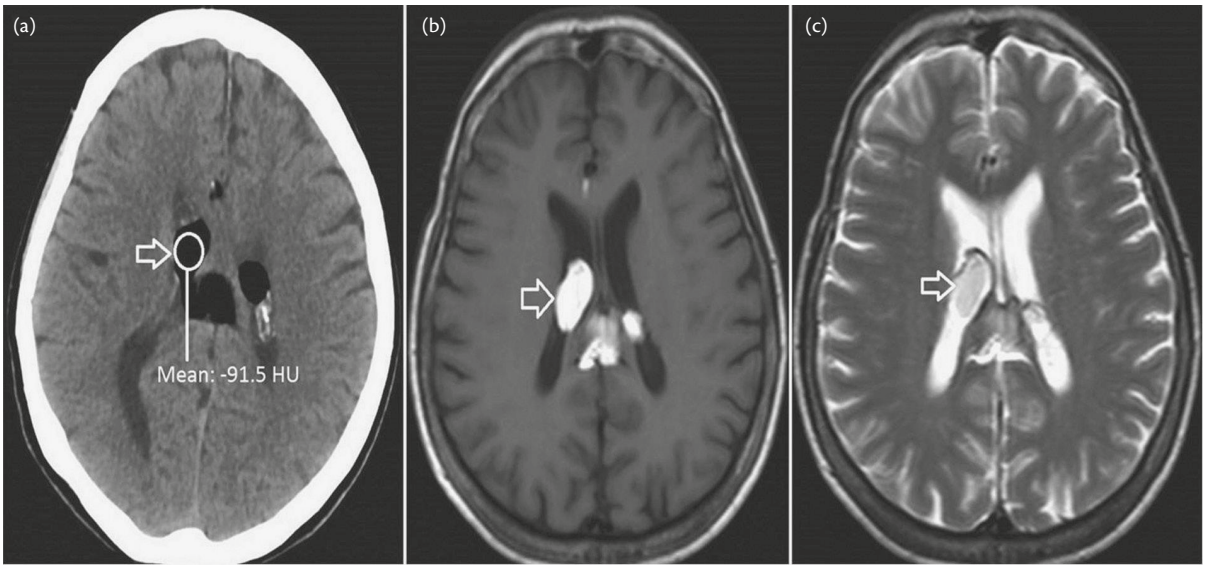

Fig. 39.8 Intracranial lipoma. (A) CT demonstrates a homogenously hypodense lesion in the lateral and third ventricle, approximately –100 Hounsfield units. (B) T1-weighted MRI showing a hyperintense mass lesion. (C) T2-weighted MRI also showing a hyperintense mass lesion.

increasingly widespread use of imaging. There does not appear to be any age or sex-differential in their distribution (Eghwrudjakpor et al., 1992). The youngest case reported is in a 3-day old child and the oldest in a 91-year-old woman (Cascino et al., 1958; Yalcin and Fragoyannis, 1966).

Pathology

Intracranial lipomas were first described by Rokitansky in 1856 following accidental discovery after an autopsy (Rokitansky, 1856). Merrill Sosman who was appointed roentgenologist to the Brigham Hospital in 1922 by Harvey Cushing made the first diagnosis in a living patient using pneumoencephalography (Sosman, 1946). These lesions are thought to be congenital malformations caused by maldifferentiation of the meninx primitiva during the development of the subarachnoid cisterns (Verga, 1929). They may interfere with cortical development near their location (Yildiz et al., 2006). Most commonly they are associated with corpus collosum dysgenesis or agenesis (Macpherson et al., 1987). Other reported abnormalities include, saccular or fusiform aneurysms, arteriovenous malformations and sagittal sinus and falcine sinus fenestrations (Futami et al., 1992; Sasaki et al., 1996). Macroscopically they do not exert a mass effect so nerves and blood vessels can run through them (Yildiz et al., 2006).

Management

In 45% of cases, lipomas are found in the interhemispheric region, in the pericallosal area. They are also frequently located in the dorsal mesencephalic area. Rarely, they have reported in the Sylvian fissure where they are associated with epilepsy (Yildiz et al., 2006). See Fig. 39.8.

Most commonly they are incidental lesions that appear hypodense on CT, hyperintense on T1-weighted images, and hyperintense on T2-weighted images. It is important to differentiate them from dermoids which frequently appear in the midline (Yildiz et al., 2006).

Prognosis

Lipomas are slowly progressing lesions so prognosis is good even with conservative management. Surgery may be considered for patients with medication-refractory seizures but tendency to adhere to surrounding neural tissue make radical resection hazardous (Yilmaz et al., 2006).

Controversies

A timely and accurate diagnosis is a guiding principle in the management of patients with brain tumours (Omuro et al., 2006). Making the diagnosis of uncommon brain lesions is inherently challenging, but this chapter has highlighted several elements that are important when investigating such lesions (Box 39.1). Considering the rarity of these lesions, their treatment is also invariably contentious. Unsurprisingly, there are no randomized controlled trials to

Box 39.1 Elements to consider when managing uncommon brain lesions

History	Onset in young adults History of subtle and transient neurological symptoms Personal or family history of autoimmune or inflammatory disease
Examination	Skin rashes Slit lamp findings
Investigations	Avoid empirical steroids unless significant mass effect MRI brain and spinal cord Lumbar puncture if not contra-indicated Anti-HIV and syphilis serology Whole-body CT scan Biopsy

guide surgical decision-making, and recommendations are therefore mostly based on case series.

Epidemiology of head injury and outcome after head injury

Nabeel Alshafai and Andrew Maas

Introduction

Traumatic brain injury (TBI) constitutes a major cause of death and disability. In low- and middle-income countries the incidence of TBI is increasing, subsequent to increased motorization. It is, however, particularly vulnerable road users (pedestrians, cyclists) where the risk is greatest. In higher-income countries, children, young adults, and elderly patients have the highest rate of TBI and a substantial increase in incidence of TBI in elderly patients as a result of falls has been noted. Nevertheless, TBI is a disease that affects the population of all ages and is referred to as 'a silent epidemic'. Knowledge of the epidemiology of TBI is essential to inform healthcare planning and to target prevention campaigns appropriately.

In this chapter we will summarize global TBI epidemiological perspectives and reflect on the burden that TBI imposes on health economics and society. We will review current classification systems, outcome measures, and prognostic models for TBI.

Definition

Many different definitions have been, and continue to be, used to describe TBI. This may cause confusion and ambiguity concerning an accurate diagnosis, leading to difficulties in comparing patient cohorts. In practice, it may be difficult to distinguish between symptoms of a mild TBI and the effects of alcohol intoxication or drug abuse. In elderly patients, a fall with some bruising to the scalp may be secondary to a primary cardiac event and it may be difficult to differentiate between a temporary loss of consciousness or dizziness due to the cardiac event and a mild TBI. Furthermore, some patients may present late and the diagnosis then needs to be established on basis of the case history, introducing a subjective element. A great need exists for objective parameters to confirm or exclude a diagnosis of TBI. Various new tools, including biomarkers, studies of eye movements, balance, are showing potential, but still need to be validated in large cohorts.

WHO defines TBI as an acute injury to the brain resulting from mechanical energy to the head from external physical (Carroll et al., 2004) force excluding injuries relating to illicit drug, alcohol, or substance, medication, or caused by other treatment or injuries (Andelic et al., 2012).

TBI has also been defined as: '*an alteration in brain function, or other evidence of brain pathology, caused by an external force*' (Menon et al., 2010). TBI has replaced the old term 'head injury' as it captures the importance of the brain injury (Roozenbeek et al., 2013), in addition to injuries purely affecting the scalp, skull, and face.

Aetiology

Motorized vehicles have been described as the most persistent killers. Preventive measures have been shown to be highly effective in reducing the number of TBI related to road traffic incidents, and combined with improved trauma care saves lives (**Table 40.1**). Legislation, seat belts, air bags, and helmet use have all contributed to increased safety. Prevention campaigns should target vulnerable road users who are unaware of traffic risks (e.g. the frail, or children) as well as vehicle drivers. While road traffic incidents remain the most common cause of TBI in low and middle-income countries, in Europe, falls are now a more frequent cause of TBI (Peeters et al., 2015). **Table 40.1** provides a summary overview of the most common causes of TBI. In the United States fire arm injuries exceeded road traffic incidents for the first time in 1990. In combat situations, blast injuries due to improvised explosive devices are a frequent cause of TBI. **Table 40.2** lists methods of reducing the impact of TBI.

Incidence

When we analyse the current epidemiological incidence studies, there appear to be a number of limitations, namely, deficient standardized epidemiologic reporting, the lack of age standardized incidence rates, the lack of data specific to mild and moderate TBI and the lack of data from lower- and middle-income countries. These challenges need to be addressed in future studies. An important point to bear in mind is poly-trauma and repeated head injuries in the same patient (first time vs. recurrent head injury) which is often overlooked and is crucial to understand the late consequences of such recurrent injuries.

In a systematic review of 28 European studies published over 24 years, an aggregate incidence rate of hospital admissions was 262 cases per 100 000 people annually (Peeters et al., 2015). A recent population-based study in New Zealand shows a much

Table 40.1 Common causes of TBI

Main causes of TBI
Road traffic incidents (44–80%)
Falls[$] (12–55%)
Violence[@] (7–17%) Fire arm (>50% suicide) (Aarabi et al., 2001)
Work and sports (4%)
Others

[$] *More recently, the leading cause in northern Europe, United States, and Australia specially in young children and elderly (>75-year-old)*

[@] *Higher risk population: male, young adults, non-white (56% African-American), unemployed at the time of the injury, unmarried, history of illegal substance use, history of law enforcement encounters, poverty, and low educational level.*

higher incidence rate of 790/100 000 (Feigin et al., 2013). The discrepancy between the high incidence rate reported in this study, with complete case ascertainment, and the lower rates based upon hospital admission data indicate that the latter approach grossly underestimates the total burden of TBI. Differences in reported incidence rates between countries are unlikely to reflect real differences, but rather result from differences in case ascertainment, the use of variable definitions and in some cases a focus on subpopulations.

Prevalence

Prevalence is the total volume of living people with TBI (existing and new cases) at a given point in time (point prevalence) or in a given period (period prevalence). In a meta-analysis in 2013 of 15 prevalence studies (Frost et al., 2013) (25 134 adults), Frost et al. found that 12% had experienced a TBI with loss of consciousness (male twice as much risk as female). McKinlay et al. looked at the paediatric age group (higher risk) and showed that over 30% of people had experienced at least one TBI before they are 25 years of age (McKinlay et al., 2008) These numbers appear high compared to estimates reported by the Center for Disease Control (CDC) in the United States, that 5.3 million people are currently living with TBI in the United States today.

Mortality

For Europe, an average mortality rate of 10.5–11.7/100 000 population has been derived, with a large range identified varying from 3.0 to 21.8/100 000, mainly determined by case mix (Peeters et al., 2015; Majdan et al., 2017). Table 40.3 presents an overview of mortality rates reported in the United States and Europe. Despite a rise in the incidence of TBI worldwide, some studies claim a decrease in mortality rate from TBI secondary to implementation and adherence to evidence-based guidelines and recommendations in the developed countries (Lu et al., 2005; Gerber et al., 2013). However, improved survival was not found when comparing mortality rates reported in observational studies over the past 30 years (Rosenfeld et al., 2012).

Another important point is that 'acute mortality' is not the only concern in TBI: TBI patients have been found to have a substantially elevated long-term risk for premature mortality. This includes: suicide, subsequent injuries, and assaults, even after adjustment for socio demographic and familial factors six months after injury (Fazel et al., 2014). There is a reduced average life expectancy of nine years following inpatient rehabilitation for TBI (McMillan et al., 2011). This varies according to age and severity. It has been found that after experiencing TBI, the annual mortality remains increased, up to sevenfold, for at least 13 years (McMillan et al., 2011).

Table 40.2 Reducing the IMPACT of TBI

Reducing the IMPACT of TBI
Strict limits in blood alcohol concentration
The use of seatbelts
Separate child restraint law
Firmly enforced speed limits
Compulsory helmets for motorcycle riders
Clinical care improved with faster communication
Better trauma systems
Increased availability of CT scanning
Improved intensive care unit (ICU) facilities and care
Others

Classification of TBI

Various approaches to the classification of TBI can be taken, these include classification by mechanism, clinical severity, burden of injury, the extent of structural damage, initial prognostic risk, and expected prognosis. Table 40.4 presents these different domains, which may be used for classification. We suggest that appropriate classification of TBI should not be restricted to a single domain but should incorporate a multidimensional perspective. Currently, no such multidimensional integrated system for classification exists, but this goal is being pursued in ongoing large-scale observational studies (Maas et al., 2017).

Mechanism of injury

Different mechanisms cause different types of injuries. In closed TBI, acceleration and deceleration forces may cause a typical picture of diffuse axonal injury in patients injured during road traffic incidents. A fall, in which the head hits a hard surface would typically result in focal contusional brain injury. Penetrating injuries caused by high velocity missiles, typically cause extensive damage along the missile track, while

Table 40.4 Different approaches to classification of TBI

Mechanism of injury	Clinical severity

CRASH and IMPACT prognostic models	

** AIS per body region: external (skin), head/neck (including brain injury), thorax, abdomen/pelvic contents, spine, and extremities*
ISS: Injury Severity Score (Baker et al., 1974)

the amount of kinetic energy transferred results in substantial distant damage. In crush injuries, dynamic forces are to a large extent absorbed by the skull and not all energy is transferred to the brain. As a consequence, skull injuries may be extensive while the brain injury may be less severe. In blast injuries, several mechanisms combine in damaging the brain. These include primary injury (due to pressure waves), secondary injury (collision with debris and other objects), tertiary (being thrown down by the blast and hitting the head against an object) or quaternary (heat and toxic injury).

Clinical severity

There is a wide spectrum of clinical presentation in TBI ranging from a hit to the head with symptoms of disorientation or alteration of consciousness that quickly resolve with or without amnesia, to complete loss of consciousness and coma. The Glasgow Coma Scale (Teasdale and Jennett, 1974) (GCS) has been adopted worldwide as instrument for assessing the level of consciousness. In GCS assessments the responses observed in three components (eye, motor, verbal scale) are recorded. For purposes of classification and research, a total sum score may be derived, ranging from 3 to 15; however, on an individual basis the importance of separating out the individual domains of the GCS cannot be overemphasized. The GCS scale is made up of entirely distinct components (E, V, M) and each 'score' is qualitative and discontinuous (i.e. a change from M2 to M3 is in no way related to a change from M4 to M5, let alone E3 to E4). It should be noted that especially early after injury the GCS may change over time, following resuscitation or as part of early recovery. Accurate assessments of one or more of the components of the GCS may be confounded by prior alcohol or substance use, prehospital use of sedation, paralysis, and intubation (Balestreri et al., 2004; Stocchetti et al., 2004). Indeed, the literature review revealed over 25 different TBI severity classification systems. Notwithstanding the limitations just mentioned, based on the GCS sum score, TBI is classified as mild, moderate, or severe (Fig. 40.1).

In addition to the GCS, multiple clinical approaches to the classification of TBI severity have been proposed. Many of these address specific subpopulations, but none have been shown to be convincingly superior to the GCS. We should recognize, however, that the GCS does not provide a granular classification for mild TBI, as it is not intended to capture more subtle changes such as 'an alteration in brain function'. Subtle and transient symptoms are reported, which may overlap with symptoms due to either post-traumatic stress disorders (PTSD) and/or postconcussion syndromes. This is an area of ambiguity at the present time and further research is required to distinguish the different diagnoses and the implications on patient outcome (Maas et al., 2017).

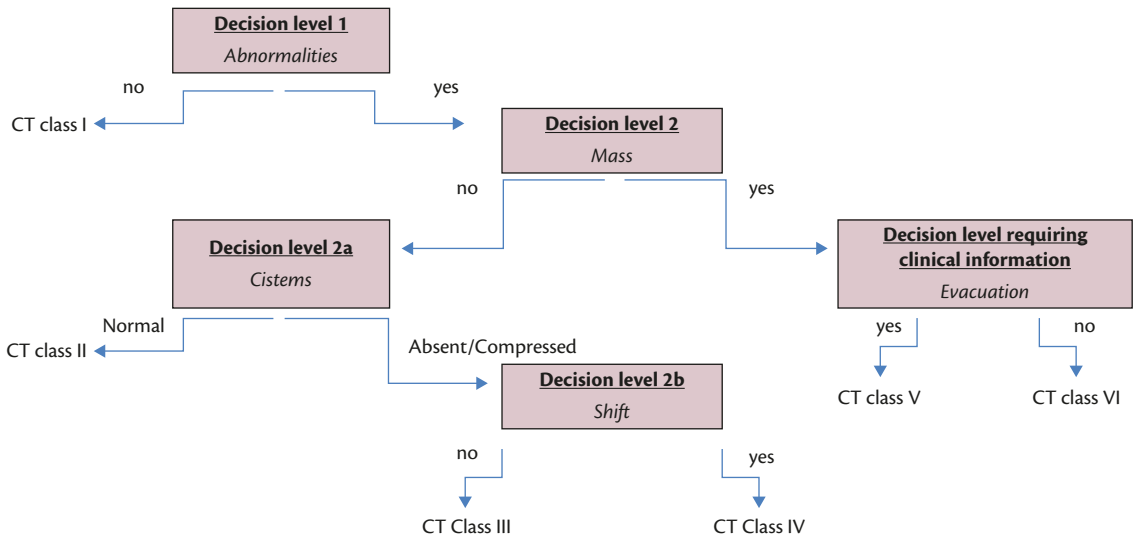

Fig. 40.1 Marshall CT classification presented in a tree structure.
Prediction of outcome in traumatic brain injury with CT characteristics: A comparison between the CT classification and combinations of CT predictors. Maas AIR, Hukkelhoven CWPM, Marshall LF, Steyerberg EW. *Neurosurgery* 2005, 57, 6, 1173–82.

Extracranial injuries (injury burden)

TBI is associated with extracranial injuries in about 35% of cases. The severity of injuries in six body regions is universally scored according to The Abbreviation Injury Score (AIS). In the AIS, severity is scored for six body regions: external (skin), head/neck (including brain injury), thorax, abdomen/pelvic contents, spine, and extremities. The severity score can range from 1 to 5 (1 is minor; 2 is moderate; 3 is serious; 4 is severe; 5 is critical; and 6 is likely unsurvivable). The Injury Severity Score (Baker et al., 1974) aims to summarize the total burden of injury by adding the quadratic scores of the three body regions with the highest score.

The extent of structural damage (CT classification)

The extent of structural damage is best assessed by neuroimaging. While MR examinations are more sensitive than computed tomography (CT), CT remains the primary procedure for diagnostic imaging because of its sensitivity for detecting intracranial hematoma and the speed, availability, and safety of examination. The extent of structural damage on the CT is commonly classified according to the Marshall Classification (Fig. 40.1) (Marshall et al., 1991). This provides a descriptive system which primarily differentiates between presence and absence of visible structural damage and differentiates between diffuse injuries (and a subclassification of these) and patients with mass lesions. Limitations of the Marshall Classification are that the scale is not ordinal, and that is does identify signs of raised intracranial pressure in patients with diffuse injury but not in those with mass lesions. Although the Marshall CT Classification was not developed from a perspective of prognosis, many studies have shown a clear association between the CT classification and outcome. The Rotterdam and Helsinki CT scores represent classification systems developed from a prognostic perspective (Maas et al., 2005; Raj et al., 2014).

Prognostic risk

A different approach to classification is by baseline prognosis. Many prognostic models for predicting risk of mortality or unfavourable outcome in patients with TBI have been developed. The two largest prognostic models, CRASH and IMPACT, have been extensively validated externally, show good performance, and aim to predict mortality and unfavourable outcome (https://www.crash2.lshtm.ac.uk and https://www.tbi-impact.org) (Perel et al., 2008; Steyerberg et al., 2008; Lingsma et al., 2013; Han et al., 2014; Majdan et al., 2014). The IMPACT models were developed on patients with moderate and severe TBI; the CRASH models also included patients with milder injuries. They were developed with data available upon admission, prior to provision of in-hospital care. They are therefore ideally suited for a baseline calculation of prognostic risk. Both approaches confirm that the largest amount of prognostic information is contained in a core set of three predictors: age, motor score, and pupillary reactivity. The IMPACT study group further evaluated the additional benefit of factors such as structural imaging (CT characteristics such as mass lesion, cerebral oedema, traumatic subarachnoid haemorrhage), secondary insults (hypoxia, hypotension) and laboratory data (glucose, haemoglobin). Additional predictive power was noted in more complex models however the model could only explain 35% of variance in outcome. Many other factors have been suggested as having prognostic importance, although not investigated within multivariate models to the rigour found in the CRASH and IMPACT models, including MRI burden of injury, comorbidities, Injury Severity Score, time to craniotomy of more than 4 hours, raised ICP, and autoregulatory indices.

Although useful for more reliably informing relatives of the anticipated outcome, it should be recognized that a prediction model is a population-based estimate and yields no more than a risk estimate with a substantial element of uncertainty, which can be expressed in the confidence interval. For this reason, the greatest application of prognostic analysis is not at the level of the individual patient, but rather at the 'group' level for quantifying and stratifying the severity of brain injury, as a reference for evaluating quality of care and for stratification and covariate adjustment in clinical trials (Maas et al., 2017).

It is worthy to add that recent studies are showing the superiority in early MR imaging as a prognostic tool in TBI, but there is still uncertainty about its discriminative predictive value and which acute phase lesion patterns correlate with long-term outcome (Haghbayan et al., 2014). Although a significant body of evidence has indicated that MRI is superior to CT in detecting most types of traumatic lesions, CT is currently used as a routine while the use of MRI is sporadic in the acute phase (Haghbayan et al., 2014).

There are several studies emphasizing the value of biomarkers as a tool for prognostications such as S100β protein and ApoE4 allele:

S100

S100β protein is a promising biomedical marker for the diagnosis, monitoring, and prognosis of TBI severity. Preoperative estimation of serum S100β in patients with TBI could be used as a prognostic predictor for postoperative survival and neurological outcome (Goyal et al., 2013) as well as being responsive to secondary insults. Measuring levels of S100β is useful in evaluating the severity of TBI and in the determination of long-term prognosis in patients presenting with moderate and severe injury (Mercier et al., 2013).

ApoE4

A current meta-analysis indicated that the ApoE4 allele might be associated with a poor prognosis in patients with severe TBI, but it may be used as a biomarker in predicting the prognosis of patients with TBI (Zeng et al., 2014). APoE4 allele presence influences recovery rate from severe TBI independent of other covariates (Alexander et al., 2007) and may also relate to the risk of subsequent cognitive decline.

Assessment of outcome: The Glasgow Outcome Scale (GOS) and beyond

Accurate characterization of outcome after TBI is essential, both from a clinical and research perspective. Historically, most TBI studies have used the Glasgow Outcome Scale or the extended version of the GOS to provide an overall global assessment of functional outcome after TBI (Table 40.5).

The GOS was initially described in 1975 as a global assessment of function following TBI (Jennett and Bond, 1975). While appropriate for more severe TBI, it was recognized that the scale was relatively insensitive at the upper levels and for this reason the Glasgow

Table 40.5 Glasgow Outcome Scale (GOS) and Glasgow Outcome Scale Extended (GOSE)

Scale	GOS	Scale	GOSE
1	Dead	1	Dead
2	Vegetative	2	Vegetative
3	Severe disability	3	Lower severe disability
	(Conscious but dependent)	4	Upper severe disability
4	Moderate disability	5	Lower moderate disability
	(Independent but disabled)	6	Upper moderate disability
5	Good recovery	7	Lower good recovery
	(Can resume normal activities)	8	Upper good recovery

GOSE:
Reproduced with permission from B Jennett, J Snoek, MR Bond, N Brooks, Disability after severe head injury: observations on the use of the Glasgow Outcome Scale, *Journal of Neurology, Neurosurgery & Psychiatry*, Volume 44, Issue 4, pp. 285–93, Copyright © 1981 BMJ Publishing Group Ltd.

Outcome Scale Extended (GOSE) was introduced. Alterations in major roles, independence in living and participation in social and leisure activities are assessed by the investigators and used to summarize the effects of diverse changes caused by injury. It should be recognized, however, that the GOSE remains a global approach to classifying outcome and that ceiling effects exist. TBI may cause problems in many domains: a wide variety of neuropsychiatric disturbances can be associated with functional impairments and low quality of life. Neuropsychological sequelae include: mood disturbances (Bombardier et al., 2010; Tanev et al., 2014); cognitive impairment; personality changes; and social and family effects.

An overlap may exist between sequelae of mild TBI and symptoms consistent with PTSD. The overlap of cognitive disruption between mild TBI and PTSD reflect the complex interplay of neurological, psychological, and physical factors in veterans with mild TBI and/or PTSD, and highlights the need for specialized evaluation and management (Benge et al., 2009; Brenner, 2011).

It has long been thought that quality of life measures are not appropriate for TBI as the neurocognitive sequelae might prevent accurate rating of the patient's perception of quality of life. However, this has been shown to be false. Patient-reported outcome measures in the sense of quality of life assessments are highly relevant to the field of TBI. Quality of life (QOL) measures may be generic; for example, the Short-Form-36 (SF36) or disease specific. A disease-specific measure QOL by a multidisciplinary working party and published as the Quality of Life after Brain Injury (QOLIBRI) scale. This scale provides a profile of health-related quality of life (HRQOL) in domains typically affected by brain injury. However, for more global assessments a summary measure may be preferable and as such the QOLIBRI-OS presenting a short six-item assessment was proposed. QOLIBRI was found to have moderate to strong relationships with QOLIBRI-OS, GOSE, Short-Form-36, Hospital Anxiety and Depression scale (Ware et al., 1993; Truelle et al., 2010; von Steinbüchel et al., 2010a; von Steinbüchel et al., 2010b). An important aspect is to capture the patient's own perspective on QOL (Dijkers, 2004). To date, outcome assessments have tended to be unidimensional, focusing on single domains. An alternative approach might be to combine these in multidimensional assessment scores. Much further work will however be required to determine which instruments are best suited for specific situations and to determine the weighting of different factors. Historical data on outcome differentiated by severity of injury, show that patients with severe TBI have a mortality rate of 36%, 5% are classified as vegetative, 15% have severe disability, 15–20% moderately disability, and 25% good recovery. Patients with moderate injury have been reported to have a mortality of 7%, vegetative classification of 1%, severe disability rate of 7%, moderate disability rate of 25%, and good recovery rate of 60%. Patients with mild injury have a very low mortality with a substantial majority designated as good recovery but nevertheless a high frequency of ongoing symptoms including headache, visual disturbance, dizziness, fatigue, and memory, concentration, and higher executive function impacting on family and social life and employment. With advances in treatment there is evidence that six-month outcome has improved in moderate and severely injured patients treated in specialist intensive care (increased in moderate disability and good recovery from 40.4% to 59.9%) (Patel et al., 2002).

Health economic cost

The economic cost of TBI management is tremendous and is a huge burden on society although, unfortunately, there are a paucity of studies that quantify this cost. Due to the long-term economic impact and burden of disability to family, work, and society, the average lifetime cost per person for TBI in the United States is estimated to be US$396 000. In the United States the Centre for Disease Control and Prevention estimates direct and indirect costs of TBI to be more than US$58 billion in total.

In most studies, the costs of non-hospitalized TBI were not considered at all. Feigin et al. performed a population-based TBI study and found out that 30% of cases were from non-hospitalized patients (Feigin et al., 2013). Although the cost of TBI is known to increase by severity (see **Table 40.6**), the unexpectedly large number of mild TBI in any population (95% of all TBI cases) means that the total cost of treating these cases is nearly three times that of moderate/severe TBI. The economic burden and overall outcome can be reduced by targeting both high cost injuries and population-based programmes aimed at reducing the incidence of lower cost mild injuries.

Conclusion

We have only uncovered the tip of the iceberg in TBI. There is a pressing need for further epidemiological studies with standardized criteria involving, specifically, lower income countries. This will have

Table 40.6 The cost of TBI is known to increase by severity especially with those requiring hospitalization and higher demand on rehabilitation services

TBI Grade	Mild	Moderate	Severe
Direct medical cost/person (US$)	21 160 (Farhad et al., 2013) to 35 954	25 271 (Farhad et al., 2013) to 81 153 (McGregor and Pentland, 1997)	57 637 (Farhad et al., 2013) to >100 000 (Faul et al., 2007)

a significant impact in relocating resources and better economic plans to reduce the healthcare burden on societies in the long run.

One critical area in TBI research that requires attention is the effects of risk factors and predictors of TBI outcome. Currently, a few prospective multicentre studies are undergoing. The two largest studies are the Transforming Research and Clinical Knowledge in TBI study (TRACK-TBI) to enrol 3000 patients and the Collaborative European Neuro-Trauma Effectiveness Research in TBI study (CENTER-TBI) (Maas et al., 2015) to enrol 5000 patients with controls, over the next five years, using an extensive standardized set of variables.

Pathophysiology of traumatic brain injury

John K. Yue, Hansen Deng, Ethan A. Winkler, John F. Burke, Catherine G. Suen, and Geoffrey T. Manley

Pathophysiology of primary brain injury

Head trauma is classified into two pathophysiological stages that differ in mechanism and necessitate distinct clinical treatments. Primary trauma is due to a mechanical load that translates into deformation of cerebral tissue (e.g. neurons, glia, axons, and blood vessels), which then initiate cellular responses that lead to disturbances in autoregulation and metabolism. The first signs of trauma range from rapid, indiscrete depolarization of cortical neurons as exemplified in concussion, to focal lesions due to blunt impact, to severe damage such as diffuse shearing of axonal integrity, to acute vascular disruptions in the form of haematomas.

Secondary injuries occur across a more protracted phase and include cerebral hypoxia, hypotension, swelling, and raised intracranial pressure (ICP). In a 2007 meta-analysis of 9205 moderate to severe TBI patients as part of the International Mission for Prognosis and Analysis of Clinical Trials in TBI (IMPACT) study, McHugh and colleagues reported that hypoxia, hypotension, and hypothermia are common on admission with observed prevalence of 20%, 18%, and 10% respectively (McHugh et al., 2007). Secondary insults, particularly when in combination during acute injury and hospitalization, correlate with poor outcome, and require imperative attention, stabilization, and surgical and/or medical management.

Biomechanics of closed head injury

Closed head injuries are cases when the cranium and dura mater remain intact after impact, with patients presenting with a range of neurologic signs and symptoms. Mechanical loading to 5% gelatine in the human skull caused focal lesions to areas of indentation or fracture, and diffuse shearing throughout the subcortex occurred during rotation (Holbourn, 1944). Extensive studies in animal models, human cadavers, computational simulations, and advanced imaging have since characterized traumatic brain deformation, but direct human measurements have traditionally been challenging to obtain as part of clinical studies.

The primary phase of trauma from TBI is defined through the nature of the mechanical load, the type of induced motion, and the duration and velocity of impact. Forces along different axes produce unique modes of stress upon the head (e.g. elongation, compression, bending, shear, and torsion) (Ommaya et al., 2002). Resultant injuries in TBI cannot be attributed to any single appellation. External force generally translates into an impact or impulsive load on the head, and in the real world can include both. Head motion can be translational or rotational, depending on the alignment of two axes: the axis of force application, and the axis between the centre of gravity of the head and the atlanto-occipital joint. Whether the head is fixed or free to extend/flex by the neck is an important determinant for injury mechanism.

Impact loading

Impact loading occurs from collision typically with a short duration of 3–7 ms measured in low velocity falls. Impact can result in a skull fracture and associated extradural haematoma as well as focal cerebral lesions. Contusions known as coup (directly below impact) or contre-coup (diametrically opposite to impact) are observed. High positive pressure is observed at the coup site, and the transmission of the force vector through the brain parenchyma generates a slapping effect to the contre-coup site. At the cellular level, high negative pressure at the contre-coup site, the development and subsequent collapse of cavitation bubbles known as contre cavitations, along with the brain parenchyma bouncing against inner posterior skull are associated with the contre-coup lesions. Elastic rebounding of the skull results in significant spikes in cerebrospinal fluid (CSF) pressure and worsen tissue damage. Intracerebral haematomas are frequently associated with contusions. In the early stage after trauma, a contusion is haemorrhagic and more severe at the crest of gyrus than in the sulcus. It is associated with swelling that subsides with time though discoloration remains.

Autopsy findings show higher incidence of coup and/or contre-coup contusions in the frontotemporal and basal regions of brain, irrespective of the primary impact site. Lagrangian strain tensor fields during occipital deceleration show anatomic constraints near the frontal base of

skull that must be breached in order for the brain to compress against the occipital bone, thus predisposing these regions for injury. The contre-coup lesion is associated with temporal and occipital impacts. Cerebral rotation during impact is also thought to be a significant contributing factor to contre-coup lesions, although definitive evidence on convulsional gliding have yet to confirm this theory.

Impulse loading

Impulse loading occurs due to inertial forces during translational or rotational motion. Within normal physiological circumstances, CSF pressure provides a considerable dampening effect on brain displacement during motion, and the lack of CSF is shown to significantly increase convolutional gliding and shear strain (Pudenz and Shelden, 1946). Brain displacement lags behind that of the skull and the affixed dura mater due to the inertial force of cerebral mass, and convolutional gliding occurs in varying degrees depending on the region of brain, inducing diffuse damage to white matter tracts. Relative to the region of the skull base near the sella and suprasellar space, the brain parenchyma is more mobile. White matter is stiffer than grey matter, thus more strain is distributed at the interface. Vascular, neural, and dural elements (e.g. distal internal carotid arteries, optic nerves, olfactory tracts, oculomotor nerves, and pituitary stalk) that tether brain to the base of skull experience are most susceptible to diffuse axonal injury (DAI) due to inertial effect. The splenium of the corpus callosum and dorsolateral brainstem can experience acute DAI due to a similar trajectory to that of the skull base, relative to the more compliant cerebral cortex.

Translational and rotational motions occur simultaneously to varying degrees. Purely translational motion of the head and neck generally does not produce acute subdural haematomas (SDH), diffuse petechial haemorrhages, or injuries to the cervical cord at linear acceleration of up to 1000 g. When linear acceleration is combined with angular motion of the head and neck, the aforementioned injuries are generated. During angular acceleration, there is a higher incidence of deep-seated haematomas in the basal ganglia in addition to DAI. Rotational insults, often seen in vehicular accidents, induce shear strain as axons and vessels are stretched or compressed beyond their physiologic limits and often result in acute SDH from tearing of subdural bridging veins.

When a single inertial load combines with a minor terminal impact load as in severe extension/flexion whiplash trauma, SDH, gliding contusions, and spinal cord injuries are prevalent. During angular acceleration, the rotational axis is at either the occipital condyles or the base of the neck, amplifying the rotational load and shearing potential. This correlates with sudden vehicular impacts, when translational motion is applied at the seat to induce inertial force onto the head and neck. Rear loading occurs when an applied force from behind causes the head to rotate back at the base of the neck, while front loading occurs when an applied force from the front causes the head to rotate forward.

Static or quasistatic loading

A less common type of mechanical load is static or quasistatic loading, in which gradual compression occurs with negligible velocity and acceleration—mechanistically similar to a closing elevator door. A steady load results in skull fractures and cerebral injuries that are deeper than cortical contusions from an impact load. In comparison to blunt impact trauma with relatively shorter duration and higher velocity, energy from crushing trauma tends to be transmitted to the foraminae and hiatus of the middle cranial fossa, causing in damage to the associated cranial nerves, sympathetic nerves, and intima of blood vessels.

TBI classification by morphology

Traditional approaches to TBI classification focus on the extent of injury (focal vs. diffuse) and the anatomical location of injury with respect to the meninges (extradural/extra-axial vs. intracerebral/intra-axial). The following section proceeds via the latter classification scheme, beginning with the extra-axial layer closest to the skull and proceeding inward to intracerebral tissue.

Extra- or epidural haematoma (EDH)

EDH overlays the dura mater and typically results from a fracture of the thin squamous part of the temporal bone which lacerates the middle meningeal artery. The resulting haematoma strips the dura from the inner table of the skull forming an ovoid mass that compresses the adjacent brain. The haematoma is constrained by the periosteum, which passes through the cranial sutures so these haematomas do not cross suture lines. Venous EDH is less common and results from the disruption of the dural venous sinuses at the vertex, posterior fossa, or the anterior aspects of the cranial fossa. Although less common, EDH may also be found in the frontal region, parietal region, or the posterior fossa in 25% of cases.

EDHs are far less common than subdural haematomas and account for approximately 2% of brain injuries. Although EDHs occur in all age groups, they are far more common in patients below 50 years of age and particularly in paediatric patients where they are primarily due to meningeal and diploic vein haemorrhage and the dura mater is tightly adherent to the paediatric skull. The relatively lower venous pressure and the strong dural adhesion to the skull are responsible for the variation and occasional subacute presentation of EDH in children. Radiographic progression of EDHs can be classified into three categories on computed tomography (CT) imaging: type I (acute), type II (subacute) and type III (chronic) occurring at presentation in 58%, 31%, and 11% of cases, respectively (Zimmerman and Bilaniuk, 1982). Type I is characterized as a dense haematoma with low density 'swirl' indicative of bleeding (i.e. a hypodense zone of active bleeding from the torn vessel into a dense organizing clot). The rise in pressure eventually produces tamponade of the bleeding site and progresses to type II—a homogenous, hyperdense, and organized clot. Type III is characterized by a low density collection due to blood resorption by perivascular tissue, along with a contrast-enhanced membrane consisting of neovascularity and granulation tissue.

The classic presentation of EDH, seen in 15–20% cases, is a patient who presents following a head trauma with transient loss of consciousness, progressing to a lucid interval, before deteriorating neurologically to a coma. The lucid interval represents recovery from the concussion, during which the patient may complain of severe headache on the ipsilateral side of the lesion accompanied by nausea, vomiting, and lethargy with subsequent decompensation into unconsciousness due to increased ICP secondary to the expanding EDH. The lucid interval is not specific to an EDH and was

originally described in cases of acute SDH. Neurological deterioration after EDH may be accompanied by contralateral hemiparesis, ipsilateral oculomotor nerve paresis, decerebrate rigidity, arterial hypertension, cardiac arrhythmias, respiratory disturbances, and if uncorrected, apnoea and death.

Subdural haematoma (SDH)

SDH results from tearing of bridging veins that cross the subdural space to communicate with the venous sinuses or from disruption of superficial pial arteries on the brain surface. SDH is not limited by dural attachment and extends over the cortical surface in the typical biconcave pattern over the tentorium cerebelli or into the interhemispheric fissure. SDH is classified as acute, subacute, and chronic. Acute SDH presents as a crescent-shaped hyperdense collection. Subacute SDH is isodense with symptomatic improvement and typically presents between 7 and 21 days. Chronic SDH (CSDH, >21 days postinjury) is hypodense and may not present symptomatically until the collection has expanded significantly and signs of compression appear (Sambasivan 1997).

Acute SDH is associated with stereotypic motor disorders, impaired oculomotor reflexes, and following transtentorial herniation of the uncus of the temporal lobe, unilaterally fixed and dilated pupils. Arterial bleeds are associated with larger clots near the Sylvian fissure. Postoperative complications include reaccumulation of the haematoma and infection at the accessed site (e.g. osteomyelitis, meningitis, ventriculitis).

Acute traumatic SDH has high reported mortality rates of 22% to 66%. While a lesion surgically evacuated within four hours to reduce the risk of disability, conservative methods may be considered for patients with shallow haematomas in a good clinical state. The Brain Trauma Foundation guidelines recommend specific criteria based on thickness, midline shift, and GCS for intervention, however, these must be viewed in the context of the individual patient, their premorbid state, the length of history and any associated injuries (Chesnut, 1997). Historically, patients undergoing decompression within four hours show a 30% mortality rate, compared with 90% for patients surgically evacuated after four hours (Seelig et al., 1981). More recently series with rapid surgical intervention show a lower overall mortality rate between 8% and 10% (Bajsarowicz et al., 2015). Other predictors include extent of neurologic deficit, sex, and postoperative ICP. Rapid diagnosis and time to surgical evacuation remain of highest prognostic importance after acute SDH. The issue of decompressive craniectomy at the time of subdural haematoma evacuation is currently being investigated in a randomized control trial (RESCUE-ASDH). Currently, the decision to remove the bone flap at the time of surgery (primary decompressive craniectomy) is based on the injury burden on the brain (e.g. the presence of large contusions), the severity of injury assessed clinically and by mechanism of injury and most importantly the degree of intraoperative swelling at the time of surgery.

Chronic subdural haematoma

Chronic subdural haematoma (CSDH) can be thought of as a distinct pathological entity as it often presents in a specific demographic (elderly patients or those with cerebral atrophy) as a specific clinical syndrome. The presumed pathology is a minor head injury that leads to a small haematoma from tearing of the stretched bridging veins that span the subdural space and are therefore unsupported in those with cerebral atrophy. The initial small volume haematoma may be asymptomatic and the initial insult is often forgotten. In a subset of patients, an inflammatory neomembrane forms and potentiates ongoing haemorrhage and swelling of the enclosed haematoma by breakdown of blood products and the development of an osmotic gradient across the neomembrane. The chronicity of this process leads to a clinical presentation several weeks after the initial injury, with an SDH hypodense to brain. The haematoma may nonetheless show areas of acute haemorrhage from repeated haemorrhages, presumably from the inflammatory neomembrane.

Clinical features of CSDH are headache, hemiparesis, speech disturbance (dominant hemisphere) or behavioural disturbances (e.g. emotional outbursts, lack of concentration, manic and depressive states), and ultimately coma if large and untreated. Bilateral CSDH are more likely to progress to coma rapidly and consequently are treated at a smaller absolute volume. CSDH occur most commonly on the cerebral convexity but can occur in the interhemispheric fissure, over the tentorium cerebelli and rarely the posterior fossa.

Treatment can be with burr hole drainage (one or two to aid lavage of the haematoma), by mini-craniotomy or via closed drainage systems. The risks of intervention include infection of the subdural space, seizures, and recurrence. Proliferating microcapillaries in the capsule of SDH are implicated in bleed recurrence due to marked mitotic potential of endothelial cells and vascular permeability. There is level 1 evidence that recurrence can be reduced by the placement of a soft drain into the subdural space for 48 hours (Santarius et al., 2009).

Subarachnoid haemorrhage (SAH)

SAH is a frequent finding in closed head injuries as a result of direct damage to cortical vessels. It correlates with poorer outcome and more severe injury, although in most cases it appears be a reflection of a greater degree of violence at injury rather than being directly responsible for secondary injury. Nevertheless, in a subset of patients traumatic SAH may also contribute to secondary insults (e.g. cerebral swelling, hemodynamically significant vasospasm, and disturbances of metabolism and autoregulation due to reduced adaptive thresholds of the brain to additional physiological shifts). Posttraumatic vasospasm can be observed as early as two days postinjury and reaches maximum intensity between five to seven days (Weber et al., 1990).

Cortical SAH is associated with progression of adjacent cerebral contusions, suggestive of subarachnoid bleeding in the vault as an early sign of cortical microbleeding and significant intraparenchymal brain damage. In TBI patients matched by GCS, age, sex, and the presence of intracranial mass lesions after blunt head injuries, traumatic SAH patients spend more time in the intensive care unit (ICU), are less likely to be discharged home, and are 1.5 times more likely to die during acute hospitalization. In penetrating TBI there is a significant correlation between SAH and poor outcome.

Intraventricular haemorrhage (IVH)

IVH is found in 1.5–3.0% of all head trauma and predominantly in severe TBI. Damage to the septum pellucidum, choroid plexus, and subependymal veins in the fornix are seen in post-mortem exams in patients with primary IVH. The incidence of primary IVH, referring to isolated bleeding confined to the ventricular system, is low. An estimated 21% of patients with IVH attain functional recovery

(Glasgow Outcome Scale (GOS) moderate disability or good recovery) due to presence of concomitant intracranial injuries. In infrequent cases of isolated IVH, more improvement in GOS is possible. In general, the small sample sizes make it difficult to interpret the specific prognostic significance of IVH as opposed to the associated TBI.

Cerebral contusions

Cerebral contusions are focal or multifocal and located in cortical or subcortical regions from direct impact or an acceleration/deceleration injury. Contusions appear as a bruise to the surface from damaged small arteries, veins, or capillaries. Herniating contusions occur when tissue is displaced from one cranial compartment to another typically along the margin of the falx cerebri, the tentorium, or the foramen magnum leading to compression of the herniating tissue. Intermediary contusions are subcortical lesions affecting the corpus callosum, basal ganglia, hypothalamus, and brainstem.

Cortical impact murine models demonstrate that cerebral oedema peaks at 24 hours coincident with a marked reduction of cerebral blood flow (CBF) to contused cortex. CBF normalizes after day seven post-trauma, during which focal areas of hyperaemia appear adjacent to regions of low flow. Studies of the human brain after non-penetrating head injury show contusions being more severe in the frontal and temporal lobes and in patients who do not experience lucid intervals (Adams et al., 1985). Cellular analyses of excised contusions from emergency craniotomies corroborate necrosis as the predominant finding and apoptosis as part of the secondary injury cascade. Tumour necrosis factor increases immediately and rapidly in CSF during acute neuronal degeneration and gradually decreases within a few hours. Neutrophils and macrophages accumulate with elevated chemokines to sustain the cerebral inflammatory cascade. ICP can become elevated due to cerebral swelling and delayed haematoma formation in the pericontusional area, thus requiring ICP monitoring regardless of the need for surgical intervention. Unilateral lesions portray better prognosis while bilateral lesions can be delayed in clinical presentation. This secondary deterioration in clinical state can be delayed as long as 10 days following injury and requires careful counselling of patients and their relatives on discharge. Hyponatraemia can exacerbate this risk and serum Na must be monitored before considering discharge, as the syndrome of inappropriate antidiuretic hormone secretion can coexist in the context of TBI.

Diffuse axonal injury (DAI)

DAI is caused by angular acceleration leading to damage of axonal integrity. Diffuse brain injury is seen in up to 50% of TBIs and spans a range of outcomes from concussion to coma and vegetative state. Classically, DAI is defined as diffuse damage in the cerebral hemispheres, corpus callosum, brainstem and cerebellum (Gennarelli et al., 1982). Long-tract structures (axons and blood vessels) are especially at risk. This is graded on MR as: Grade I (parasagittal white matter of the cerebral hemisphere) Grade II (Grade I plus focal lesion in the corpus callosum), and Grade III (Grade II plus focal lesion in the cerebral peduncle) (Table 41.1). Grade I and II typically show marked improvement in GCS within 2 weeks while Grade III requires ~2 months for recovery, suggestive of prolonged loss of consciousness or coma with DAI involving the brain stem.

Strictly, a definitive diagnosis of DAI is established by immunostaining for β-amyloid precursor protein (β-APP) at autopsy and identifying axonal retraction balls in the deep white matter. *In vivo* diagnosis is challenging as it may present microscopically and in combination with one or more type of brain injuries including: contusion, anoxia, and intracerebral haemorrhage. Although there is ample data implicating DAI in moderate or severe TBI, its involvement in mTBI is difficult to prove histologically as patients rarely die from their injuries. Minor degrees of axonal injury may provide the pathophysiologic basis for deficits experienced during and after mTBI/concussion. Alternatively, functional and metabolic disturbances may be responsible with little structural axonal injury (Vespa et al., 2005).

Table 41.1 Diffuse axonal injury grading

DAI grade	Pathology
I	Grey-white matter interface (commonly parasagittal white matter of frontal lobes, periventricular temporal lobes)
II	Focal lesions in corpus callosum (commonly posterior body and splenium) in addition to Grade I lesions
III	Brainstem (commonly rostral midbrain, cerebellar peduncles, medial lemnisci, and corticospinal tracts) in addition to Grade I and II lesions

GRE: T2-weighted gradient-recalled-echo (GRE) magnetic resonance (MR) technique
SW: Susceptibility-weighted (SW) magnetic resonance (MR) technique.
Data from Tong KA, et al, Hemorrhagic shearing lesions in children and adolescents with posttraumatic diffuse axonal injury: improved detection and initial results, *Radiology*, Volume 227, Issue 7, pp. 332–9, 2003

Mild TBI/Concussion

The United States (US) Centers for Disease Control and Prevention (CDC) defines mild TBI (mTBI)/concussion as a transient neurological disturbance caused by rapid linear and/or rotational acceleration and deceleration forces, resulting in a disruption in cerebral structural or vascular physiology. The American Congress of Rehabilitation Medicine (ACRM) defines mTBI by one or more of the following: loss of consciousness (LOC), loss of memory immediately before or after the incident, alteration in mental state, or focal neurologic deficit that may or may not be transient. The U.S. Department of Veterans Affairs and Department of Defense (VA/DOD) provide similar clinical guidelines while specifying that presence of intracranial lesions classify the patient with, at minimum, moderate TBI.

An estimated 75% of TBI patients are classified as 'mild', which is likely an underestimate as most of these patients do not present to the emergency department. Current classifications of concussion centre on the impairment of neurological function, the disturbance of vision, memory, or equilibrium, alteration of consciousness (AOC), and/or LOC. The diagnosis of concussion is largely appropriate for the non-penetrating head trauma that results in one or more of the following: confusion/disorientation, LOC less than 30 minutes or post-traumatic amnesia (PTA) less than 24 hours in duration, transient focal neurological deficits, and/or seizure, with a GCS of 13–15 upon acute medical evaluation; however, multiple concussion grading scales currently exist without definitive consensus. The lack of evidence in imaging studies, perhaps due to lack of sensitivity, is a challenge to the clinical diagnosis of mTBI/concussion. Recent efforts in utilization of magnetic resonance imaging (MRI), including MR Spectroscopy, for TBI diagnosis has shown promise in identifying a subset of patients with structural changes post-mTBI.

The pathophysiology of mTBI/concussion begins with a sudden change in momentum of the head, causing mechanical stretching or compression of the partially tethered brain against the cranial vault,

initiating diffuse neuronal firing, discharge, and axonal shearing. Neurocognitive deficits tend to occur with minimal detectable pathology and can resolve over time. However, even patients with GCS score 13–15 present with acute and subacute glucose metabolic disturbances on positron emission topography (PET) and require careful assessment for postconcussive risks (Giza and Hovda, 2001). Cerebral microdialysis immediately following mTBI/concussion contains elevated levels of excitatory amino acids and ionic fluxes throughout hemispheric regions, the hippocampus, and the brainstem. Specifically, there is a sharp increase of extracellular K^+ through voltage-gated channels. Studies using electroencephalogram (EEG) demonstrated that postconcussive EEG was excitatory and epileptiform in nature comparable to generalized seizures. Likewise, during this period the sensory evoked potential was completely lost (Shaw, 2002). In early stages after mTBI/concussion, increased glucose utilization and hyperglycolysis sustain the indiscriminate neuronal depolarization and firing, but can also restore the disturbed membrane potential. Later, diffuse neuronal suppression (e.g. spreading depression) takes effect. Spreading depression is characterized by near-complete breakdown of ion gradients, loss of electrical activity, and vasoconstriction, which can trigger infarct growth and initiate cascades leading to apoptotic cell death (Dreier, 2011).

Physiological disturbances persist after mTBI/concussion and increase susceptibility to further injury. After the initial hypermetabolism, hypometabolism and reduction in CBF may persist for up to 4 weeks. Additional excitation (e.g. direct cortical stimulation or recurrent concussion) prolongs cellular recovery and induced cell death due to inability to match increased metabolic demand in part due to decoupling between neuronal activation and CBF after concussion. Dependent on the severity of impact, intracellular accumulation of Ca^{2+} also remains elevated, which impairs mitochondrial metabolism and initiates programmed cell death. In the surviving cells, reduction in cellular plasticity is associated with neurotransmission changes, particularly in subunits of *N*-methyl-D-aspartate (NMDA) receptors.

Penetrating brain injury (PBI)

Compared with blunt TBI, PBI is less prevalent and associated with worse prognosis, occurring when a non-blunt projectile breaches the cranium and dura mater. CSF leaks are common and may require surgical intervention. When a projectile also induces an exit wound, it is termed a perforating brain injury. The projectile crushes soft brain tissue in its path and generates bone fragments at impact, which can require surgical debridement. The shape and kinetic energy of projectile $E = 1/2mv^2$ (E = energy, m = mass, v = velocity) are associated with the degree of tissue damage. A high velocity projectile generates waves of compression and re-expansion (cavitation wave) and inflicts focal shearing damage, parenchymal contusions, and haematomas. CT provides clear characterization of in-driven bone fragments, missile trajectory, extent of tissue damage, haematomas, and mass effects. Cerebral angiography is recommended due to the high risk of vascular injury. High risk factors include a penetrating track crossing the ventricle, involving both hemispheres, crossing the geographical centre of the brain or associated vascular injury. Seizure control following PBI is a key part of clinical management.

Cerebral metabolism and autoregulation

The brain is responsible for the greatest overall resting energy expenditure by organ at approximately 22%, compared with the liver 21%, the heart 9%, and the kidneys 8%. The brain is 2% of overall weight while accounting for 20% of basal cardiac output and 20% of resting O_2 consumption. The cerebral metabolic rate of oxygen ($CMRO_2$) remains relatively constant in healthy adults at approximately 3.5 ml O_2/100 g/min and may be as high as 5.2 ml O_2/100 g min in children aged 3–12 years. Glucose is the primary source of ATP in the brain and approximately 50% of energy generated from cerebral metabolism is utilized for synaptic activity (i.e. neurotransmitter production, release, and uptake); 25% is for maintaining for electrochemical gradients, and the remaining 25% is for molecular transport, biosynthesis, and other processes.

Aerobic metabolism is the primary process in the brain through which glucose is efficiently converted to 36–38 molecules of ATP by glycolysis, the citric acid cycle, and aerobic oxidation. Glucose metabolism is disturbed after TBI. There is a significant increase in anaerobic glycolytic turnover and elevated level of extracellular lactate in cerebral circulation as neurons and astrocytes convert glucose to two molecules of ATP and two molecules of lactate. Hyperglycolysis contributes to prolonged elevated lactate/glucose ratio, CSF lactic acidosis, and compromised mitochondrial function via calcium-mediated interference. The duration of hyperglycolysis and lactate accumulation may reflect the extent of injury and worse prognosis. See **Figure 41.1**.

$CMRO_2$, cerebral metabolic rate of glucose (CMRG), and CBF are common measurements utilized in neurophysiology. In healthy adults, $CMRO_2$ is 3.3 ml/100 g/min, CMRG is 5.5 mg/100 g/min, and CBF is 54 ± 12 ml/100 g/min. In comatose patients with TBI, $CMRO_2$ is reduced to between 1.2 and 2.3 ml/100 g/min and is associated with GCS score and recovery outcome. Storage of glucose and oxygen by neurons and astrocytes is limited, therefore continuous CBF is essential to ensure survival. Arteries and arterioles 30–300 um in diameter can alter their resistance to control cerebral circulation. There is a linear relationship between $CMRO_2$ and CBF consistent with the notion of diffusion-limited oxygen delivery. Flow-metabolism coupling is the process by which blood flow changes in relation to the metabolic demands of cerebral tissue, largely influenced by the changes in tissue CO_2. PaO_2 does not affect CBF except in patients with drastically reduced PaO_2 below 50 mmHg. Cerebral metabolism declines after TBI with corresponding decreases in CBF.

Pressure and viscosity

The Hagen-Poiseuille law of laminar flow in a cylindrical tube is utilized to describe cerebral blood flow in relation to cerebral perfusion pressure (CPP), vessel diameter, and blood viscosity. CBF= k[CPP × d(4)]/(8 × l × v), where k is a constant, d is artery diameter, l is artery length, and v is blood viscosity. CBF is maintained at 50 ml/100 g/min in the adult to facilitate constant metabolic supply to the brain, provided that CPP is in the range of 60–160 mmHg (Cipolla, 2009). CPP is calculated as the difference between mean arterial pressure (MAP) and ICP.

CBF is also maintained via autoregulation (**Fig. 41.2**). Cerebral vasculature possesses myogenic capacity to dilate or contract to counteract deviations in wall tension (that reflect the CPP) to maintain

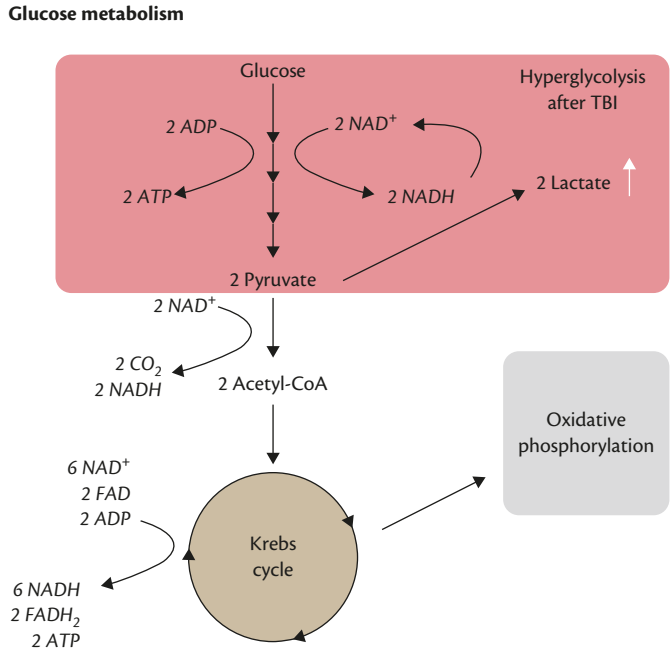

Fig. 41.1 Glucose metabolism can be divided into three distinct processes. Glycolysis is the conversion of glucose into pyruvate. This generates two ATP molecules (net) and does not require oxygen if coupled with conversion of pyruvate into lactate (anaerobic respiration). The Kreb's cycle is a circular biochemical pathway that consumes the carbon skeletons from acetyl-coenzyme A and generates reducing equivalents (nicotinamide adenine dinucleotide (NAD)-H and flavin adenine dinucleotide (FAD)-H), carbon dioxide, and two ATP molecules. The final step of oxidative phosphorylation utilizes the reducing equivalents generated in the preceding steps to generate a hydrogen ion gradient across the mitochondrial membrane which drives a proton ATPase that generates an additional 34 ATP molecules, giving a total of 38 ATP molecules per molecule of glucose (aerobic respiration).

constant flow. Outside the normal CPP 60–160 mmHg, vessels become either maximally dilated or experience forced dilation (i.e. 'pressure breakthrough'). Autoregulation is impaired or absent in the majority of severe TBI patients at some point in their clinical course. When autoregulation is lost, the brain becomes vulnerable to systemic pressure disturbances leading to secondary insults (e.g. ischaemia from reduced CBF or swelling from excess CBF). Severe TBI patients are more prone to secondary injury from low CPP. Thus, flow-metabolism and autoregulation are distinct mechanisms allowing the cerebral circulation to meet local metabolic demand and to stabilize against systemic pressure disturbances.

Changes in whole blood viscosity, largely determined by haematocrit and serum fibrinogen, affect CBF and induce an autoregulatory response under normal physiological circumstances. An increase in viscosity decreases metabolic supply to the brain and causes arterial dilation, while a decrease in viscosity increases metabolic supply and causes arterial constriction. Following acute cerebral infarction, increased haematocrit and fibrinogen are associated with reduced CBF, and that changes in blood viscosity may have important hemodynamic effects on cerebral circulation as well during acute stress.

CO_2 reactivity

CO_2 reactivity is the process by which partial pressure of arterial CO_2 ($PaCO_2$) affects CBF and the cerebral vasculature. Within the normal range of $PaCO_2$ between 20 and 60 mmHg, every 1 mmHg fluctuation results in 2% to 3% change in CBF. Hypercarbia (hypoventilation) results in vasodilation and increased CBF, while hypocarbia (hyperventilation) has the inverse effect. This is mediated through changes in pH of the perivascular space via carbonic anhydrase, and this forms the basis of the acetazolamide challenge. The normal response to acetazolamide administration (e.g. 1 g intravenous) is vasodilation and augmentation of CBF to 30–60% over

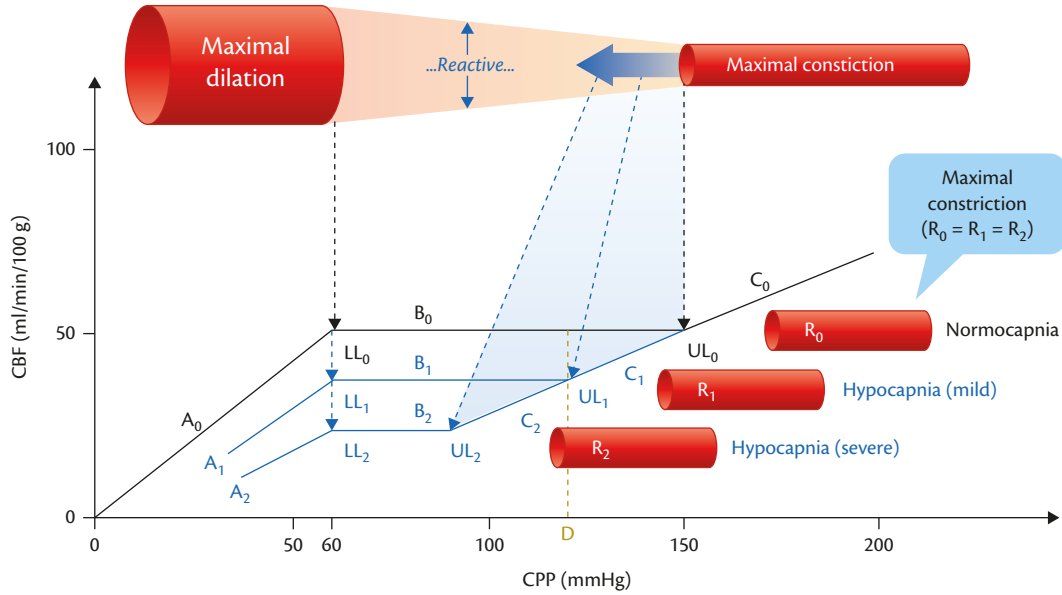

Fig. 41.2 Cerebrovascular autoregulation (A, autoregulation) is the mechanism by which a constant blood flow (B, blood flow) is maintained in the face of variations in systemic blood pressure. Over a range of blood pressures CBF is constant, however above (UL, upper limit) and below (LL, lower limit) this range the vessels are maximally vasoconstricted or vasodilated (respectively) and changes in blood pressure are transmitted as changes in CBF. This risks ischaemia below LL and exacerbates intracranial hypertension above UL.

Therapeutic hyperventilation (C_0–2) in order to reduce intracranial pressure leads to vasoconstriction (R_0–2). This has two potentially damaging effects. Firstly, CBF is reduced risking ischaemia. This can be mitigated by using a measure of intracranial oxygenation. Secondly, the autoregulatory range is reduced, making it more difficult to target an appropriate CPP. This can be mitigated by using a metric of autoregulation such as pulse reactivity index (PRx).

10–15 minutes. A failure to vasodilate in response to acetazolamide implies maximal vasodilation, usually resulting from chronic ischaemia. Hyperaemia and metabolic acidosis in CSF are associated with the acute phase of TBI, typically in the first 24 hours, and patients with persistent loss of CO_2 reactivity risk high mortality or severe neurological compromise. While CO_2 reactivity causes changes in both CBF and $AVDO_2$, autoregulation affects CBF with $AVDO_2$ maintained relatively constant. Hyperventilation and control of $PaCO_2$ are important therapeutic interventions in the management of raised ICP, however this requires cerebral oxygenation monitoring to ensure that excessive arterial vasoconstriction does not inflict ischaemia.

Secondary injury after severe head trauma

Complex neurochemical pathways after TBI disrupt cerebrovascular circulation and inflict secondary injuries that may last from minutes to weeks, and treatment of secondary injuries is essential to maximizing patient outcome. Though not all these mechanisms are fully understood, the International Mission for Prognosis and Clinical Trials in TBI (IMPACT) database identified hypoxia and hypotension to be present in 20% and 18% of TBI patients, respectively (Murray et al., 2007). Repeated investigations have consistently identified five clinical variables that are correlated with morbidity and poor outcome: arterial hypotension, reduced CPP, elevated ICP, hypoxemia, and pyrexia.

Glutamate-mediated excitotoxicity

Mitochondria play an essential role in cerebral energy metabolism, calcium homeostasis, and reactive oxygen species generation. As early as one-hour post TBI, mitochondrial oxidative phosphorylation can fail, resulting in reduction of ATP production, failed energy-dependent membrane ion pumps, and disrupted homeostasis in neural cellular metabolism. Depressed ATP production increases the rate of glycolysis, elevating lactate production, and potential accumulation in the CSF and extracellular fluid of the injured brain. High lactate levels can further contribute to neuronal dysfunction by inducing acidosis, membrane damage, altered blood brain barrier permeability, and cerebral oedema. Activation of intracellular digestive enzymes (i.e. peroxidases, proteases, phospholipases) and caspases lead to structural damage at the subcellular level, DNA degradation, and neuronal death (i.e. necrosis and apoptosis).

The relationship between excessive Ca^{2+} influx and glutamate-triggered injury is well supported, resulting in uncoupling of mitochondrial electron transfer from ATP synthesis and overactivation of calpains. Glutamate-mediated excitotoxicity activates NMDA receptors, triggering neuronal depolarization with an unchecked influx of calcium into mitochondria. Mitochondrial dysfunction becomes the main cause of energy failure of damaged tissue, as ion pumps are unable to restore membrane potentials. Experiments indicate that Ca^{2+} loading at L-type voltage-sensitive channels is non-toxic, but Ca^{2+} loading at NMDA receptors is neurotoxic. The production of toxic reactive oxygen species (i.e. nitric oxide, superoxide, and hydrogen peroxide) is also contingent on NMDA receptor activation, therefore NMDA receptors are key drivers of excitotoxicity after head injury. These cellular changes lead to cerebral oedema, elevated ICP, vascular compression, and ultimately herniation (Lucas and Newhouse, 1957). When assessing causes and treatments for ischaemia and abnormal oxygen measurements such as cerebral perfusion pressure and jugular venous oxygen saturation, mitochondrial dysfunction should be considered, as maintenance of adequate perfusion may not improve clinical outcome due to underlying mitochondrial impairment. A pragmatic definition of mitochondrial dysfunction is an inability to efficiently carry out oxidative phosphorylation of ADP in the presence of adequate oxygen and metabolic substrate.

Elevated extracellular glutamate is important in mediating both traumatic and ischaemic brain injury. Interstitial glutamate is shown to increase by several mechanisms: BBB damage and extravasation of glutamate to region of impact, membrane damage, and microporation, upregulation of complexin I and complexin II enhancing exocytosis, and glutamate transporter impairment. Beta-lactam antibiotics (e.g. ceftriaxone) are potent stimulators of glutamate transporter (GLT1), which is the astroglial protein responsible for inactivating synaptic glutamate. Beta-lactams increase brain expression of GLT1 and its functional activity, which decreases glutamate neurotoxicity to provide neuroprotective potential in ischaemic injury and neuronal degeneration (Rothstein et al., 2005). Calcium-induced mitochondrial matrix swelling and ruptured outer mitochondrial membranes uncouple the respiratory chain and further impair ATP production. The unregulated influx of calcium and membrane rupturing also induces the opening of the mitochondrial permeability transition pore (mPTP), causing an apoptotic cascade. Cyclosporin A, an immunosuppressant investigated for its ability to inhibit mPTP opening in TBI patients, has demonstrated neuroprotective effects against mitochondrial swelling, membrane breakdown, and ionic homeostatic imbalance (Okonkwo et al., 1999).

Perturbations in cerebral metabolism

TBI damages mitochondrial functionality to propagate neurodegeneration and limit neuroregeneration. Severe TBI induces a sudden shift from aerobic metabolism to hyperglycolysis/anaerobic metabolism with high glucose turnover, contributing to cerebral acidosis. Even when sufficient oxygen is present, hyperglycolysis has been demonstrated in 56% of patients through findings using PET within 1 week following TBI. Acidosis shifts the haemoglobin oxygen-dissociation curve to the right and may increase O_2 supply to injured brain tissue. Elevated CSF lactate level after TBI typically normalizes within 12 hours of injury, except following cerebral ischaemia and diffuse cerebral swelling. The hypothesized role of lactate in injured brain energetics is controversial, and has changed from metabolic waste to supplemental fuel, neuroprotection, and signalling molecule in cortical neurons. Intracerebral microdialysis catheters (Fig. 41.3) allow for biochemical analysis of changes in extracellular neurotransmitters and metabolites during the secondary stage of TBI. The microdialysis measured lactate/pyruvate ratio is a marker of anaerobic metabolism and correlates with outcome after TBI. (Timofeev et al., 2011). Increase in the lactate/pyruvate ratio can be due to cerebral ischaemia or mitochondrial dysfunction. In patients with elevated cerebral lactate/pyruvate ratio (LPR), microdialysis demonstrates that exogenous lactate therapy significantly increases cerebral glucose levels. This correlates with previous evidence that lactate is directly oxidized to pyruvate in the

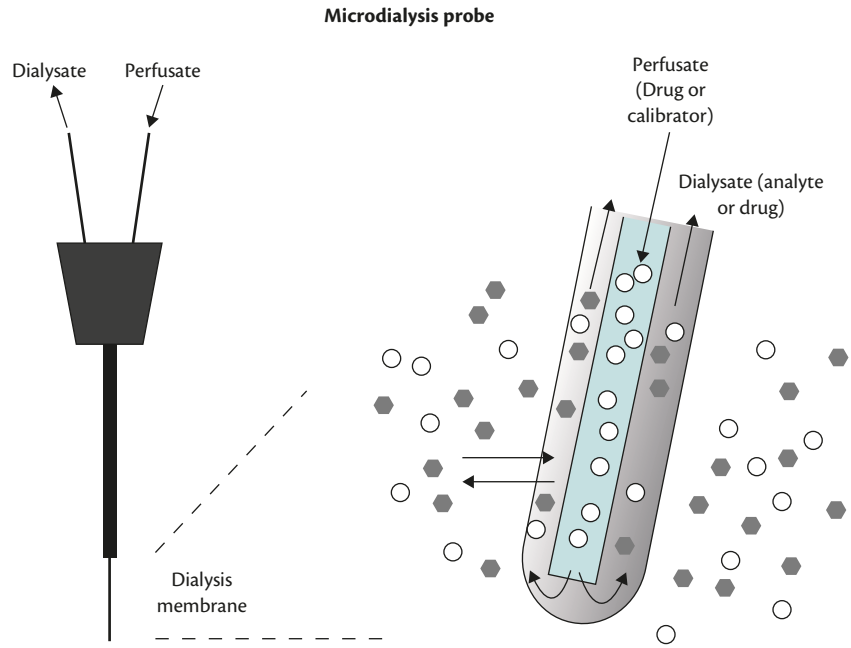

Fig. 41.3 Microdialysis is a technique for sampling the brain extracellular space. An invasive probe is inserted into the brain substance and perfused with fluid (perfusate) at ultralow flow rates (typically 0.3 μl/minute). A semipermeable membrane at the tip of the catheter allows substances to diffuse into the catheter and are recovered in the exiting fluid (microdialysate). For clinical purposes, the commonest analytes are glucose, lactate, pyruvate, glutamate (an excitotoxic neurotransmitter) and glycerol (a measure of cellular membrane breakdown). The ratio between lactate and pyruvate (LPR, lactate-pyruvate ratio) provides a measure of the balance between anaerobic and aerobic respiration (Fig. 41.1). An LPR more than 25 is regarded as pathological and correlates with poor clinical outcome in TBI.

mitochondria of neurons and astrocyte to contribute to cerebral aerobic metabolism (Lazaridis and Andrews, 2014).

Increased activity of the pentose phosphate pathway (PPP) after severe TBI contributes to elevated cerebral glucose uptake exceeding $CMRO_2$ and lactate production (Fig. 41.4). Infusion of isotype glucose after TBI increased PPP activity by 19.6% compared to 6.9% in controls. The PPP products (NADPH, ribose 5-phosphate, and erythrose 4-phosphate) that upregulate fatty acid synthesis, DNA repair and replication, and amino acid and neurotransmitter production are processes that are stimulated after brain injury (Dusick et al., 2007). NADPH is used to produce reduced forms of glutathione and thioredoxin, cofactors for glutathione peroxidases, and peroxiredoxins that combat oxidative stress after acute injury. The PPP does not use oxygen as substrate and does not produce ATP, but rather serves as an antioxidant that contributes to the shift in glucose metabolism from glycolysis to PPP in ischaemic brain tissue.

In TBI patients, 30% patients are found to have $CMRO_2$ values profoundly reduced under non-ischaemic conditions from normal value of 3.3 ml/100 g/min to 1.2–2.3 ml/100 g/min. While $CMRO_2$ after TBI correlate with GCS and is a strong predictor for neurologic outcome, reduced $CMRO_2$ does not necessarily result from ischaemia nor directly cause patient decline. Causes of patient decline include the severity of primary and secondary injuries and the level of consciousness. Studies of severe TBI with mean GCS of 6 report a 25% incidence of reduced oxidative metabolism and persistent metabolic crisis (elevated LPR >40) despite absence of ischaemia, which suggest LPR as an indicator of widespread mitochondrial dysfunction causing metabolic depression following TBI, further impairing brain capacity to meet metabolic demands in coping with secondary insults. While very low $CMRO_2$ indicates irreversible cell injury, LPR may be utilized as a sensitive marker of reversible mitochondrial dysfunction in regions with no observable tissue damage. Published studies using ^{15}O PET demonstrate a metabolism threshold of 37.6 μmol/100 ml/min resulting in irreversible injury.

Loss of autoregulation and pressure reactivity index

As previously mentioned, vascular autoregulation is a myogenic mechanism where wall tension directly results in vascular smooth muscle constriction. An increase in MAP leads to vasoconstriction within 5 to 15 seconds to decrease cerebral blood volume (CBV) and ICP, while a decrease in MAP leads to vasodilation and increase in ICP. Autoregulation may be disrupted on the days following injury with the magnitude and risk of disruption depending on the severity of injury. Quantifying vascular reactivity is clinically important after TBI when cerebral vasculature can become unreactive. Slow wave fluctuations in MAP and ICP lasting 30 seconds to several minutes are common in ventilated patients after head injury. These changes are continuously monitored and their relationship is calculated as pressure reactivity index (PRx) between –1 and +1 (Czosnyka et al., 1997). A negative correlation indicates good vasoreactivity (ICP declines as a result of arterial vasoconstriction when MAP increases) and autoregulatory protection, but a positive correlation indicates the loss of autoregulation and worse prognosis. In large series of patients, a PRx of less than 0.3 correlates with good outcome on dichotomized GOS.

PRx is frequently compromised on the first day after TBI, and the loss of autoregulation in the first 48 hours has strong indication for additional secondary injury including cerebral hypoxia and further ischaemic insults. Preserved autoregulation is a crucial protective

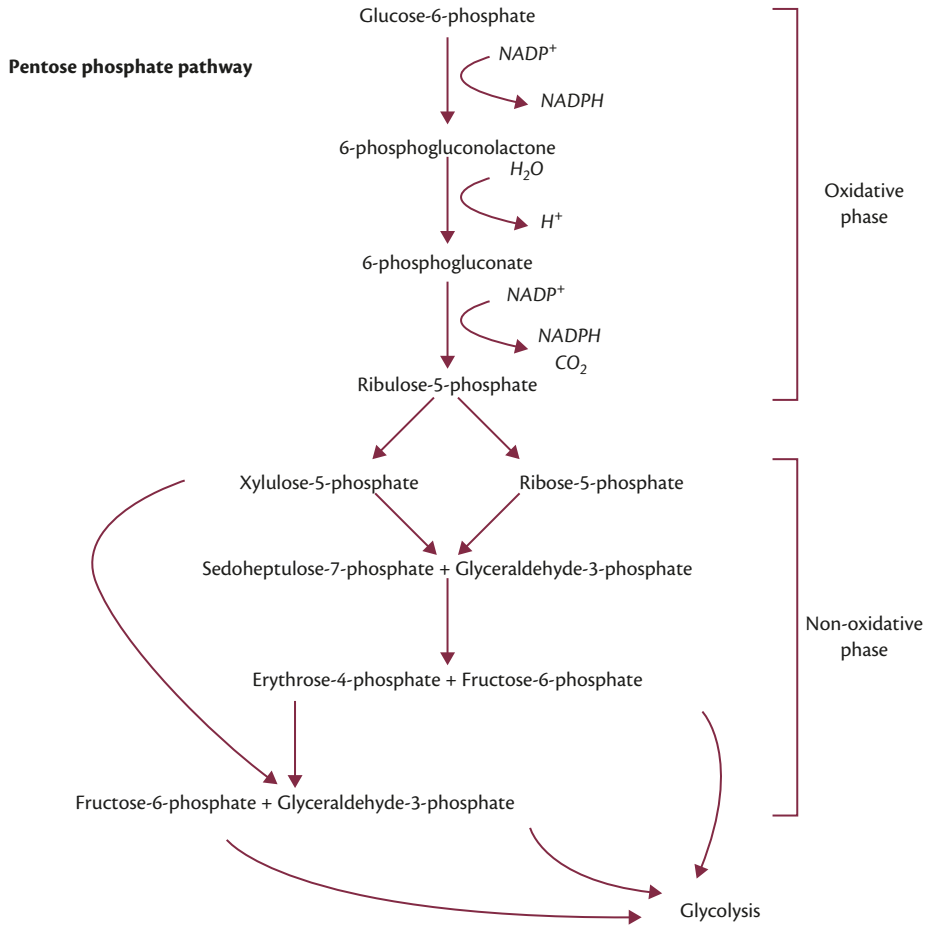

Fig. 41.4 Pentose phosphate pathway. The pentose phosphate pathway (PPP) is an alternative pathway for glucose utilization and is found to be upregulated following TBI. It provides several biochemical substrates that are potentially protective, and this is an actively explored research avenue.

mechanism against transient MAP derangements. In addition to being a strong predictor of outcome, PRx is an important clinical tool in guiding posttraumatic treatment and CPP management. PRx changes dynamically with CPP making it possible to define the CPP threshold at which PRx is minimized to maximize autoregulatory protection: this has been termed 'CPP optimal' ($CPP_{opt)}$. Continuous PRx monitoring in TBI patients determines a real-time CPP_{opt} dependent on the severity of injury, and deviation from the CPP less than CPP_{opt} appears to increase risk of mortality while CPP more than CPP_{opt} appears to discriminate between good and poor outcome on dichotomized GOS. It is yet to be determined whether targeting CPP_{opt} is a valid therapeutic target.

Raised intracranial pressure

The Monro-Kellie hypothesis explains that under normal conditions the total volume of the intracranial cavity remains constant and is formed from three main components: blood (CBV, both arterial and venous), fluid (CSF) and cerebral parenchyma. An increase in one compartment normally results in compensation in another through translocation of CSF and venous blood to maintain constant ICP. When compensatory mechanisms are exhausted, an exponential increase in ICP occurs. Patients with ICP below 20–25 mmHg have significantly better outcomes. Raised intracranial pressure (>20–25 mmHg) can induce ischaemia and hypoxia by reducing CPP (MAP–ICP); as CBF is directly proportional to CPP, the presence of hypotension, elevated ICP, and hypoxia can severely limit cerebral supply after TBI.

Oedema is common after TBI and can be attributed to three distinct mechanisms: vasogenic, cytotoxic, and osmotic. Structural damage due to breakdown of BBB endothelium causes intravascular flow of protein-rich exudate into the brain interstitium, increasing extracellular volume without cell swelling. Second, intracellular volume can accumulate without BBB disruption. Ion influxes and increased membrane permeability of neural cells cause cytotoxic oedema and cellular swelling. Cytotoxic oedema is the most common brain oedema and results in decreased interstitial volume. Third, necrotic tissue is hyperosmolar, causing osmotic-gradient driven fluid accumulation in the cell. Not surprisingly, oedema causes increased ICP and secondary ischaemic events that further exacerbate structural integrity and tissue damage.

In the management of post-traumatic cerebral oedema, hyperosmolar agents such as mannitol or hypertonic saline be administered to lower ICP. However, it is important to note that once the BBB is compromised, mannitol may exacerbate vasogenic cerebral oedema. Bolus mannitol can initiate more than 10% ICP reduction among 86% of patients with intact autoregulation, whereas ICP reduction was observed in only 35% of patients with impaired autoregulation (Muizelaar et al., 1984). When autoregulation is lost,

osmotic agents may increase CBF without compensatory vasoconstriction and thus the desired reduction in ICP may not be achieved. Other potential mechanisms of mannitol action include acting as a free radical scavenger, improving microvascular flow by dehydrating endothelial cells and reducing haematocrit as well the osmotic load. Despite intensive therapeutic measures, intractable ICP is the primary cause of 46% of TBI deaths.

Cerebral blood flow disturbances

In an uninjured brain, changes in CPP between 60 and 160 mmHg have only minor effects on CBF. Following trauma and autoregulatory impairment, CBF becomes increasingly dependent on CPP and minor fluctuations can instigate further ischaemic injury. As previously mentioned, CPP = MAP–ICP, and CBF = CPP/CVR, where CVR is cerebrovascular resistance. Secondary elevation in ICP may worsen CPP and decrease CBF. CBV is defined as millilitres of blood per 100 g cerebral tissue, and can be calculated based on measures of CBF using stable xenon and mean transit time after injection of contrast material. CBF is reflective of CBV under normal conditions, but acutely after trauma there is a dissociation between CBF and CBV due to physiological disturbances. Because metabolism decreases after severe head injury, determining $AVDO_2$ is necessary for accurate interpretation of CBF and diagnosing hypo- or hyperperfusion. CBF is generally low during the first 6 hours after injury and increase significantly in the first 24 hours. A low CBF is generally not associated with a high $AVDO_2$, and is more likely a sign of low oxidative metabolism rather than ischaemia. High CBV does not always correlate with cerebral swelling in severe TBI; other factors besides hyperaemia contribute to cerebral swelling and refractory hypertensive ICP. In patients without acute hyperaemia, CBF consistently correlates with functional recovery (i.e. the lowest CBFs exist in patients with the most severe disabilities).

More recent studies that combine oxygen 15-labelled positron emission tomography (^{15}O PET) with fluorine 18-labelled fluoromisonidazole (^{18}F FMISO) further characterize macrovascular and microvascular ischaemia in early TBI (Veenith et al., 2016). Comparison of ischaemic brain volume (IBV) and hypoxic brain volume (HBV) demonstrates that the diffusion hypoxia barrier in HBV is associated with microvascular collapse, whereas IBV represents macrovascular ischaemia and irreversible damage. Traumatic contusions show reduced CBF and $CMRO_2$, but similar CBV and oxygen extraction fraction (OEF) as controls. In pericontusional regions with no identifiable tissue dysfunction, $CMRO_2$ is lower, but CBF, CBV, and OEF are similar to the controls. Classic reasoning dictates that with reduced $CMRO_2$, OEF increase to compensate. However, recent studies using DTI showed that surrounding contusions there is a frequent rim of low diffusion coefficient consistent with cytotoxic oedema, which may explain the minimal change in OEF because of widespread microvascular failure and selective neuronal loss.

Hyperaemia

Hyperaemia, also known as vascular engorgement or luxury perfusion, results from disruption of flow-metabolism coupling when CBF exceeds $CMRO_2$ requirements. Increased CBV often indicates posttraumatic hyperaemia which in conjunction with elevated ICP portends poor recovery. While acute hyperaemia is frequently associated with hypertensive ICP (>20 mmHg), subnormal flow indicates intact flow-metabolism coupling rather than ischaemia. Hyperaemic ICP patients are often younger, present with low mean GCS (≤6), risk effacement of basal cisterns and refractory hypertension, and demonstrate gross loss of autoregulation. Of note, CBF is functionally coupled to CMRG and not $CMRO_2$, thereby luxury perfusion may be an appropriate metabolic response to hyperglycolysis after injury. Historically, hyperventilation was initiated to decrease CBF and subsequently ICP, however this approach has been tempered by the risk of inducing ischaemia. After brain injury, CBF may no longer accurately reflect CBV due to disruption in normal physiology, and in patients with acute SDH, elevated ICP, and ischaemia, CBV is half of normal value. Therefore, multiple aetiologies may contribute to intracranial hypertension and cerebral swelling after severe head trauma.

Cerebral ischaemia

Ischaemic injury consists of the infarct core and the penumbra. The core undergoes hypoxia-induced loss of cellular homeostasis and necrosis, while the penumbra's apoptotic processes can be targeted for therapeutic intervention. Cerebral ischaemia occurs when CBF does not meet cerebral metabolic demands (e.g. low CBF and high $AVDO_2$). Assuming flow-metabolism coupling is intact, jugular bulb oximetry is frequently utilized in the ICU to estimate the adequacy of CBF from its inverse relationship to $AVDO_2$. While normal $AVDO_2$ ranges from 4 to 9 ml 100 ml^{-1}, low CBF and ischaemic state increase oxygen extraction and increase $AVDO_2$. Transcranial doppler non-invasively measures the blood flow velocity of basal cerebral arteries in order to estimate CBF, with the caveat that haemorrhage can cause vasospasm which increases flow velocities irrespective of CBF. Ischaemia is often seen in acute SDH and diffuse cerebral swelling and inadequate metabolic supply to the brain after TBI is predictive of high morbidity and disability. PET has demonstrated that previous definitions of hyperaemia and ischaemia based on CBF and oxygen are inaccurate, and maintaining oxygen delivery may not be sufficient to prevent secondary injury. Mitochondrial dysfunction after TBI decreases oxygen demand, and the transition to hyperglycolysis increases lactate accumulation. Thus, decreased CBF can be misinterpreted as ischaemia, and the maintenance of adequate perfusion (CPP >70 mmHg) may not result in improvement due to impaired mitochondrial ATP synthesis.

As mentioned earlier, in normal physiology, $AVDO_2$ remains relatively constant while CBF changes in accordance to $CMRO_2$/CMRG. When autoregulation is lost in TBI and the ability of CBF to meet metabolic demands is impaired, $AVDO_2$ may increase to improve O_2 extraction in the cerebral circulation. $AVDO_2$ is capable of increasing from baseline value 6.7 ml/100 ml to a maximum 13 ml/100 ml. The normal CBF threshold at which $AVDO_2$ compensation occurs is 18 ml/100 g/min, and can rise to 20 ml/100 g/min following TBI due to decreased oxidative metabolism. ^{15}O PET shows that diffusion barrier ischaemia (increased oxygen diffusion gradient from vasculature to interstitium) is due to microvascular disturbances such a perivascular oedema surrounding traumatic lesions causing decreased partial pressure of oxygen in brain tissue (PbO_2).

In addition to caspases and other proteins directly causing neuronal death, three distinct mitogen-activated protein kinase (MAPK) inflammatory pathways contribute to ischaemic injury: extracellular signal-regulated kinase (ERK) pathway, c-Jun-N-terminal protein

kinase (JNK) pathway, and the p38 pathway. Emerging research on the use of biomarkers has yielded several markers of importance to neuronal, glial, and axonal damage. Neuron-specific enolase is a glycolytic enzyme predominantly in neurons. S100B is a calcium binding protein predominantly in astroglia. Myelin basic protein is in white matter and a marker for axonal damage. Recent studies have found these to be important biomarkers of pathological processes involved in cerebral ischaemia and neuroinflammation following TBI and reflecting the time course of secondary injury.

Cortical spreading depression and epilepsy

Cortical spreading depression (CSD) is a pervasive wave of ionic homeostasis failure that transiently interrupts cortical function. It is characterized by EEG depression, pial vasodilation, and a slow negative potential shift following severe head trauma and ischaemia (Leao, 1947). Spontaneous peri-infarct depolarizations (PID) propagate to normal cerebral tissues and take on the characteristics of CSD. Electrocorticographic (ECoG) recordings show spontaneous depressions accompanied by stereotyped CSDs spreading across the cortical mantle at 3.3 mm/min; ECoG background activity recovers spontaneously or 2 to 5 hours later (Fabricius, 2006). Propagating depolarization waves in neuronal and glial cells cause an increase in oxidative metabolism, compensated by increased CBF and metabolic activity; hence CSD does not cause neuronal injury in the normal brain when flow-metabolism is intact. Haemodynamic disruption and flow-metabolism decoupling are frequent phenomena after head injury, thus CSD may incur additional energy demand that cannot be metabolically compensated for by the injured brain.

CSD alters BBB permeability via matrix metalloproteinase (MMP) activity. MMPs consists of neutral proteases implicated in wide range of processes: the opening of the BBB; immune cell infiltration of neural tissue; shedding of cytokine and cytokine receptors; direct cellular damage; and neuronal development and plasticity. CSD increases MMP-9 activity, which leads to the breakdown of BBB and oedema formation. Neuronal expression of MMP-9 and MMP-2 is implicated in neurotoxicity after ischaemia and trauma, increasing the susceptibility to cerebral haemorrhage. CSD occurs more frequently in the younger acutely injured patients, and may be attenuated with glutamate receptor inhibitors, specifically NMDA receptor antagonists. CSD and PID contribute to the increase of final infarct volume in a step-wise fashion as part of additional secondary insults and stress-induced changes in the penumbra of primary lesions.

Seizures

Acute seizures (both convulsive and non-convulsive) are well documented secondary insults that may be due to neurochemical disarray and can exacerbate tissue damage and worsen clinical recovery. EEG monitoring demonstrates that the majority of seizures do not have overt motor manifestations and require continuous monitoring of seizure activity. ECoG recordings can distinguish the hallmark slow potential change of CSD from seizures; while CSD and seizures frequently occur together, there is no correlation between the two phenomena in regard to time, space, and intensity (Fabricius, 2006). Following moderate to severe TBI, seizures occur in more than 20% of patients in the first week; peak incidence is bimodal with an early peak at 29 hours and later peak at 140 hours, with mean duration of 2.8 minutes and a tendency to cluster. At these respective peaks for seizure activity, ICP is secondarily elevated, with the ictal ICP being higher than interictal ICP. Elevated ICP and the risk for swelling due to seizure may be attributed to prolonged increases in CBF, extracellular oedema, and glutamate accumulation in the interstitium.

Epileptiform activity is known to further stimulate glycolysis and neurochemical changes that may further stress neuronal integrity. Microdialysis LPR is higher for TBI patients with seizures (compared to without), and during the ictal periods (compared to interictal periods). Increased LPR is associated with prolonged metabolic stress, therefore seizure control is a therapeutic target for minimizing metabolic stress postinjury. Pericontusional regions, in particular in the frontotemporal region, are electrically active and capable of epileptiform activity. Patients with severe TBI are predisposed to seizures. Strong risk factors include the presence of a brain contusion and/or subdural haematoma, and early evacuations of mass lesions may be associated with reduced seizure activity (Annegers et al., 1998). Focal seizures with secondary generalization occur in 78% of reported seizures after severe TBI.

Beta-amyloid deposition and apolipoprotein E interaction

TBI is shown to trigger pathological production and accumulation of amyloid-(Aβ) peptides in the cerebral cortex, particularly localized to contusional and pericontusional regions (Roberts et al., 1991). Cleavage of amyloid precursor protein (APP) produces apolipoprotein E (ApoE) and Aβ, and the polymorphism of the ApoE gene determines the risk for plaque deposition: ApoE ε4 carries greater risk, while ApoE ε3 (more frequent) and ε2 (rare) both reduce the risk for Aβ burden. Of the three isoforms, ApoE ε4 binds the least avidly to cytoskeletal proteins that would promote neurite growth and neuroprotective effect. Rather, ApoE ε4 binds more avidly to Aβ and promotes aggregation into amyloid fibrils. Studies using intracranial microdialysis measured higher levels of Aβ in patients with DAI compared to focal injuries, and thus Aβ accumulation may also depend on the injury type. Long-term axonal degeneration and intra-axonal Aβ deposition in the brain parenchyma is likely due to continued neurodegeneration and secondary insults. *In vitro* studies support evidence of ApoE-Aβ interactions where TBI patients with ApoE ε4 allele have more Aβ deposition in the hippocampus and frontal cortex.

In the acute phase postinjury, decreased ELISA measurements of Aβ concentrations and apolipoprotein E (ApoE) in the CSF occur. Their levels gradually increase over time to correlate with improved neurologic outcome. There is reduced Aβ production immediately following neuronal trauma, and the decreased ApoE level is possibly due to increased utilization of ApoE-lipid complexes for repair as part of a coordinated response to neuronal injury. ApoE can be neuroprotective against cerebral ischaemia, and intraventricular infusion of ApoE reduced neuronal damage after ischaemia in animal models via clearance of lipid and cholesterol debris. ApoE facilitates anti-inflammatory effects through downregulation of microglia and cytokine release (Kay et al., 2003). Aβ plaques from TBI are similar to the hallmark pathology found in early stages of Alzheimer's disease. Long-term follow-up of patients with TBI also correlated with incidence of Alzheimer's disease, with ApoE isotype as a key predictor. Notably, follow-up 6 months after TBI reported 57% of patients possessing the ApoE ε4 allele to have unfavourable outcome (GOS: dead, vegetative state, or severe disability) compared to 27% of patients with the ApoE ε2 or ε3 allele.

Future directions

Successful implementation of the TBI Common Data Elements (CDEs), along with demonstration of their utility in generating novel classification approaches with robust statistical power, informed the refinement of the NIH/NINDS CDEs, version 2 (Hicks et al., 2013), and generated the impetus for the concurrent 22-nation Collaborating European NeuroTrauma Effectiveness Research in TBI (CENTER-TBI) study in the EU and 11-site TRACK-TBI study in the US (Manley and Maas 2013). These had the goals of enrolling close to 10 000 combined patients using the CDEs in order to provide novel multidimensional approaches to TBI classification, establish evidentiary benchmarks for quality of care, and generate large, well-curated TBI data repositories to enable and ensure legacy research opportunities.

Conclusion

While risk reduction of primary neurological trauma is mainly preventative in nature, understanding the sequelae of TBI in order to clinically manage and/or pre-empt secondary injuries is paramount in current neurosurgical and neurocritical care. Preventing potential complications in TBI patients who 'talk and deteriorate' emphasizes the crucial concept that a primary injury can readily induce pathophysiologic conditions for compounded secondary damage. Finally, TBI is recognized more as a disease process rather than a single event; the inherent heterogeneity of injury types and severities highlight the critical need to converge upon a classification scheme using a consensus definition of pathoanatomic injury—measurable through validated clinical, neuroimaging, and serum biomarkers similar to current standard approaches in heart disease, cancer, and diabetes. Large-scale international TBI trials using validated common data standards to accelerate advances in classification and prognosis are currently underway.

Intensive care management of head injury

Matthew A. Kirkman and Martin Smith

Introduction

Traumatic brain injury (TBI) is a leading cause of death and disability in adults under 40 years of age. Outcome is determined by the severity of the primary injury and several mediators of secondary injury, including intracranial hypertension, systemic hypotension, and hypoxia, pyrexia, and hypo- and hyperglycaemia. The monitoring, prevention, and management of factors that lead to secondary brain injury are the cornerstones of the intensive care management of TBI.

Early management of head injury

The initial approach to head injury focuses on prompt and systematic assessment and management in line with standard prehospital and Advanced Trauma Life Support protocols (**Fig. 42.1**). Resuscitation and early management is a crucial stage at which mortality and morbidity after severe TBI can be influenced (Boer et al., 2012). The prevention or immediate correction of hypoxaemia and hypotension, rapid diagnosis and evacuation of an expanding intracranial haematoma, and treatment of raised intracranial pressure (ICP) are key determinants of outcome. Minimizing time to stabilization and definitive treatment is of the essence. Although airway management and ventilation are crucial interventions in comatose TBI patients and those with a deteriorating conscious level, the role of prehospital endotracheal intubation and who should perform it remains controversial (Boer et al., 2012). Unless the patient is alert and cooperative, the cervical spine should be immobilized while awaiting imaging and/or formal clinical assessment. Life-threatening extracranial injuries should be stabilized prior to transfer.

Management of polytrauma in the context of head injury

TBI is often associated with extracranial injuries, including spinal trauma (see **Chapter 64**), which can complicate brain-directed therapy. Timely and appropriate intervention to stabilize or treat extracranial injuries is critical to prevent prolonged haemorrhagic shock, systemic inflammatory response syndrome, and multiple organ failure.

A particular challenge in patients with multiple injuries is balancing the competing interests of hypotensive resuscitation and its' potential to limit ongoing blood loss and speed time to resuscitation with the risk of worsening associated brain injury. It is recommended that systolic blood pressure be maintained more than 90 mmHg at all times in patients with TBI. However, if a lower blood pressure is required during the treatment of life-threatening haemorrhage, the duration of hypotension should be as short as possible and other physiological variables optimized to maximize cerebral oxygen delivery. In particular, hypocarbia must be avoided.

ICP monitoring is recommended during multiple surgical procedures and/or prolonged sedation for extracranial injuries when the opportunity for clinical assessment is limited (Stocchetti et al., 2014).

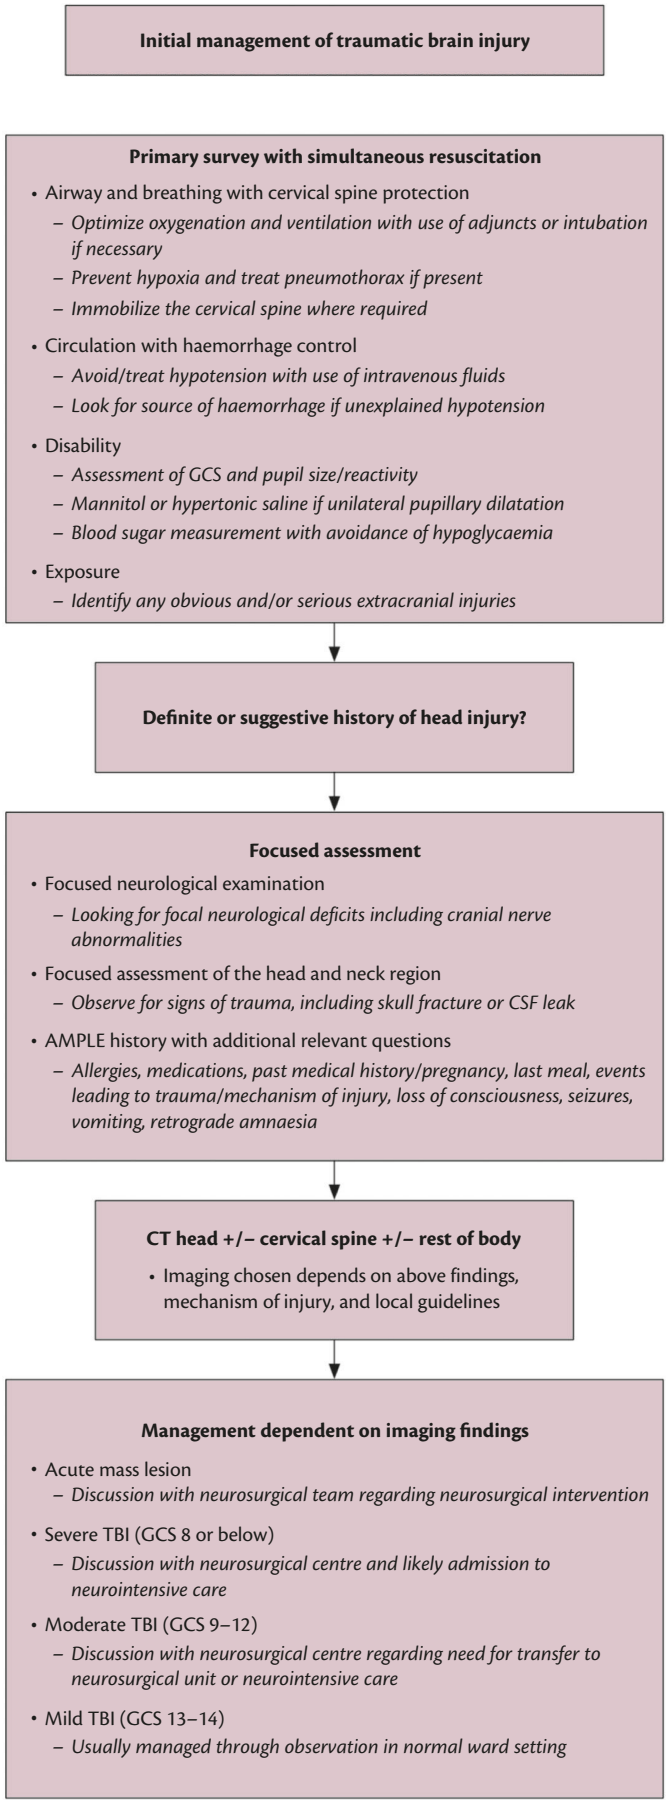
General principles for the intensive care management of head injury

All patients with severe TBI should be managed in an intensive care unit (ICU) offering immediate access to multidisciplinary clinical neuroscience teams and other relevant specialties, supported by appropriate imaging and investigational facilities. Patients with mild or moderate TBI may also require admission to the ICU for a variety of indications (**Box 42.1**).

The intensive care management of TBI is complex and involves meticulous general intensive care support to optimize systemic physiology, and interventions targeted to the injured brain (**Table 42.1**). In addition to the continuous monitoring and assessment of cardiorespiratory functions common to all critically ill patients, several techniques are available for global and regional brain monitoring (see next).

Cardiorespiratory function

A single episode of hypoxaemia (PaO_2 <8 kPa or SpO_2 <90%) or hypotension (systolic BP <90 mmHg) is strongly associated with poorer outcomes after severe TBI, and the combination of the two is more deleterious than either insult alone (McHugh et al., 2007). Prevention or rapid reversal of hypoxia and hypotension is essential in patients with severe TBI. However, therapeutic hyperoxia is associated with adverse effects, including free radical formation



Initial management of traumatic brain injury
Primary survey with simultaneous resuscitation
• Airway and breathing with cervical spine protection
– Optimize oxygenation and ventilation with use of adjuncts or intubation if necessary
– Prevent hypoxia and treat pneumothorax if present
– Immobilize the cervical spine where required
• Circulation with haemorrhage control
– Avoid/treat hypotension with use of intravenous fluids
– Look for source of haemorrhage if unexplained hypotension
• Disability
– Assessment of GCS and pupil size/reactivity
– Mannitol or hypertonic saline if unilateral pupillary dilatation
– Blood sugar measurement with avoidance of hypoglycaemia
• Exposure
– Identify any obvious and/or serious extracranial injuries
Definite or suggestive history of head injury?
Focused assessment
• Focused neurological examination
– Looking for focal neurological deficits including cranial nerve abnormalities
• Focused assessment of the head and neck region
– Observe for signs of trauma, including skull fracture or CSF leak
• AMPLE history with additional relevant questions
– Allergies, medications, past medical history/pregnancy, last meal, events leading to trauma/mechanism of injury, loss of consciousness, seizures, vomiting, retrograde amnaesia
CT head +/– cervical spine +/– rest of body
• Imaging chosen depends on above findings, mechanism of injury, and local guidelines
Management dependent on imaging findings
• Acute mass lesion
– Discussion with neurosurgical team regarding neurosurgical intervention
• Severe TBI (GCS 8 or below)
– Discussion with neurosurgical centre and likely admission to neurointensive care
• Moderate TBI (GCS 9–12)
– Discussion with neurosurgical centre regarding need for transfer to neurosurgical unit or neurointensive care
• Mild TBI (GCS 13–14)
– Usually managed through observation in normal ward setting

Fig. 42.1 Management algorithm for immediate management of traumatic brain injury.

Box 42.1 Indications for intensive care unit admission of head-injured patients

- Severe traumatic brain injury (defined as a postresuscitation Glasgow Coma Scale score ≤8)
- Clinical or radiological evidence of raised intracranial pressure
- Need for mechanical ventilation due to:
  - Decreased conscious level
  - Evidence of brainstem dysfunction
  - Acute respiratory failure (e.g. due to neurogenic pulmonary oedema)
  - Episodes of apnoea
  - Generalized tonic-clonic seizures or status epilepticus
  - Any other cause of a compromised or threatened airway
- Cardiovascular instability requiring intensive haemodynamic monitoring and management
- Need for invasive neurological and systemic monitoring
- Management of systemic organ support such as renal and cardiac dysfunction
- Postoperatively following neurosurgical interventions
- Multisystem trauma

and pulmonary injury, and normobaric hyperoxia does not result in clinically significant improvements in brain oxygen metabolism. Although there is some evidence that hyperbaric oxygen reduces mortality, there is little evidence of improved functional outcome in survivors (Bennett et al., 2012). Routine hyperoxia beyond that which is necessary to maintain key oxygenation targets is therefore not recommended.

Hypotension should be corrected initially with intravenous fluid resuscitation, but a vasoactive agent is required if adequate blood

Table 42.1 General aspects of the critical care management of severe head injury

Ventilation	• PaO_2 >11 kPa • $PaCO_2$ 4.5–5.0 kPa • lung protective ventilation strategies (tidal volume 6 ml/kg ideal body weight, PEEP 6–12 mmHg and recruitment manoeuvres) as brain-directed therapy allows • PEEP to maintain oxygenation (PEEP (≤12–15 cm H_2O does not have adverse effects on ICP and may reduce ICP if oxygenation is improved) • ventilator 'care bundle' to minimize risk of pneumonia – head-up positioning – oral hygiene – peptic ulcer prophylaxis – venous thromboembolism prophylaxis – daily sedation holds if ICP allows
Cardiovascular	• MAP > 90 mmHg • target euvolaemia with isotonic crystalloids • vasopressors/inotropes if insufficient response to fluid
ICP and CPP targets	• CPP 60–70 mmHg • ICP <22 mmHg
Other	• normoglycaemia • normothermia • seizure control • enteral nutrition • thromboembolic prophylaxis

CPP, cerebral perfusion pressure; ICP, intracranial pressure; MAP, mean arterial pressure; PEEP, positive end-expiratory pressure.

pressure cannot be achieved with fluid resuscitation alone. Overly aggressive fluid resuscitation is detrimental, and euvolaemia is the primary cardiovascular goal (Gantner et al., 2014). Intravascular volume should be maintained with isotonic crystalloids, and 0.9% saline is a justified choice despite a lack of evidence of superiority. Albumin is associated with increased mortality, possibly secondary to an associated increase in ICP (Cooper et al., 2013). Despite interest in the use of hypertonic saline (HS) solutions for fluid resuscitation after TBI, no outcome benefits over isotonic crystalloids have been reported.

There is no reliable evidence that one vasopressor is superior to another, but norepinephrine has a predictable and consistent effect on systemic blood pressure and cerebral haemodynamics, and is widely used.

Glycaemic control

Hyperglycaemia exacerbates secondary neuronal injury and is associated with worsened outcomes after severe TBI. 'Tight' glycaemic control with intensive insulin therapy can precipitate cerebral hypoglycaemia and metabolic crises after TBI (Vespa et al., 2012). Moderate serum glucose control is therefore recommended, maintaining serum glucose concentration between 7 and 10 mmol/litre, and avoiding hypoglycaemia (serum glucose <4.4 mmol/litre) and large swings in glucose concentration (Kramer et al., 2012).

Temperature control

Pyrexia (variably defined as core body temperature exceeding 37.5°C to 38.5°C) occurs in more than 50% of TBI patients on the ICU, and is independently associated with worse outcome. Causes are multifactorial and include infection and hypothalamic dysfunction. Despite the availability of treatment options including antipyretic medications, and surface and intravascular cooling devices, high-quality evidence of outcome benefits following cooling to normothermia is lacking. Despite this, targeted normothermia or mild hypothermia (35.5–37°C)—increasingly referred to as targeted temperature management (TTM)—is often recommended in TBI management.

TTM has many potential neuroprotective actions including stabilization of the blood-brain barrier, ICP reduction, and inhibition of inflammation and intracellular calcium overload. Compelling preclinical evidence of benefit has not translated into positive outcome effects of TTM in large-scale randomized clinical trials (RCTs), although several single-centre studies have shown benefit. In contrast to previous systematic reviews, a 2014 meta-analysis including RCTs and observational studies demonstrated some evidence of benefit for TTM in terms of overall reduction in mortality and poor outcome (Crossley et al., 2014). However, the majority of included trials were of low quality and this may overestimate the effectiveness of TTM versus standard care. In particular, there is significant heterogeneity between studies in the timing of onset and duration of TTM, target temperature, and timing and rate of rewarming. Rewarming is the most dangerous phase of TTM, and must be carried out in a controlled manner (0.1–0.25°C per hour) to minimize the risk of rebound intracranial hypertension and hyperkalaemia. Disappointingly, a recent RCT failed to find a benefit of TTM over fever control alone, despite inducing TTM as soon after injury as possible, maintaining target temperature (32–34°C) for at least 72 hours, and rewarming slowly (<1°C per day) (Maekawa et al., 2015). Other adverse effects of TTM include shivering, and abnormalities in blood glucose, electrolyte levels, and fluid balance.

Moderate TTM effectively reduces raised ICP and is often incorporated into ICP management protocols (see next), despite a lack of evidence of improved outcomes. The recent international multicentre Eurotherm3235 RCT, which randomized 387 TBI patients with intracranial hypertension (ICP >20 mmHg) resistant to first-tier treatments (including mechanical ventilation, sedatives, and head of bed elevation) to either standard care or hypothermia to 32–35°C plus standard care, was suspended early because of worse functional outcomes and higher mortality rates in the hypothermia group (Andrews et al., 2015). Because this study used hypothermia as a second-tier therapy it does not address adequately whether TTM benefits refractory elevated ICP in patients with TBI. Use of stage 3 treatments (barbiturates and decompressive craniectomy) was higher in the control group (54%) than in the hypothermia group (44%), but data on the amount of mannitol and hypertonic saline used in each arm of the study were not recorded. Given these and other limitations, this trial is unlikely to significantly alter the use of TTM in TBI, although it does highlight the need for further, high-quality RCTs of TTM after TBI.

Anaemia

Around 50% of patients with severe TBI develop anaemia that can activate hypoxic cell signalling pathways and adversely affect cerebral oxygen delivery. The outcome effects of anaemia and precise haemoglobin (Hb) threshold for brain tissue injury are uncertain. However, it seems unlikely that the restrictive transfusion approaches used in general critical care can be extrapolated to patients with TBI because of the increased susceptibility of the injured brain to ischaemia. An RCT of erythropoietin and two transfusion thresholds (Hb concentrations 70 g/litre and 100 g/litre) found that neither administration of erythropoietin nor maintenance of Hb more than 100 g/litre improved neurological outcomes at six months after TBI, but the latter was associated with more adverse events particularly thromboembolism (Robertson et al., 2014). It is currently recommended that haemoglobin concentration should be maintained more than 90 g/litre in the acute phase after TBI, and aggressive transfusion practices avoided (LeRoux, 2013).

Coagulopathy

Acute traumatic coagulopathy develops in over one third of patients with isolated TBI, and is associated with worsened outcomes (Epstein et al., 2014). Both hypocoagulable and hypercoagulable states can exist, with release of large amounts of tissue factor, altered protein C homeostasis, and platelet dysfunction. Management relies on the correction of coagulation abnormalities with combinations of fresh frozen plasma and prothrombin complex concentrate according to local protocols. There are no specific guidelines for reversal of coagulopathy in TBI.

The antifibrinolytic agent tranexamic acid, when given within three hours of injury, reduces mortality in bleeding trauma patients without increasing adverse events. An ongoing prospective RCT (CRASH-3, http://www.isrctn.com/ISRCTN15088122) is investigating whether the same benefits apply after TBI.

Seizures

Seizures are common following TBI and cause elevations in ICP, cerebral ischaemia, and excessive neurotransmitter release. Post-traumatic seizures (PTS) are classified as early (occurring within 7 days) or late (after 7 days), and are associated with adverse outcomes. Prompt seizure detection and treatment improves outcome, although the use of prophylactic antiepileptic drugs (AEDs) is controversial. Some guidelines recommend a short course (7 days) of AEDs to reduce the incidence of early PTS, but there is no evidence that this improves outcomes or reduces the risk of post-traumatic epilepsy. There is also no evidence to support the use of AEDs for prophylaxis of late onset PTS, which should be managed like any new onset seizure. Phenytoin has historically been the first-line drug for prophylaxis and treatment of PTS, but levetiracetam appears to be of equal efficacy, has fewer side effects, and does not require monitoring of plasma drug levels.

Patients with TBI, particularly those with depressed skull fracture, penetrating injuries, and large cortical contusions/haematomas, are at risk of developing non-convulsive seizures (NCSz). AED prophylaxis does not prevent the development of NCSz, and the effect of treatment on outcomes remains to be elucidated. Electroencephalography (EEG) is recommended to exclude seizures in TBI patients with unexplained and persistent altered consciousness (Claassen et al., 2013).

Venous thromboembolism

Severe TBI is a significant risk factor for the development of venous thromboembolism. Graduation compression stockings or intermittent pneumatic compression stockings are recommended (unless lower limb trauma prevents their use) until the patient is ambulatory, despite no clear evidence of efficacy. Low molecular weight heparin or low dose unfractionated heparin can reduce the rates of deep vein thrombosis (DVT) and mortality respectively, but the timing of chemoprophylaxis is controversial. Concerns about associated risks of intracranial haemorrhage must be balanced against the significantly higher risk of DVT if chemoprophylaxis is withheld for seven days after injury. Based on evidence from over 5000 TBI patients, it has been recommended that chemoprophylaxis should be started after 72 h in patients at medium or high risk of haematoma expansion, and after 48 h in those with low risk of haematoma expansion and absence of expansion (Abdel-Aziz et al., 2015).

Nutritional support

TBI is associated with a hypermetabolic state and excessive nitrogen wasting, and full caloric replacement should be achieved by day five, and at the latest by day seven, postinjury (Carney et al., 2017). A recent meta-analysis found that early feeding (defined in most studies as within 48 hours of admission) was associated with a significant reduction in mortality, poor outcomes, and infectious complications (Wang et al., 2013).

Electrolyte and endocrine disturbances

Disorders of sodium homeostasis are common after TBI, and both hypo- and hypernatraemia have adverse effects on the injured brain. A systematic approach to diagnosis and treatment is essential (Table 42.2).

Endocrine failure after TBI is related to direct injury to the hypothalamic-pituitary axis (HPA), intracranial hypertension-related hypothalamic ischaemia, and inflammation-related primary gland failure. HPA dysfunction leading to adrenal insufficiency occurs in up to 50% of patients with severe TBI, and the effects can be long-lasting and affect recovery into the chronic phases of rehabilitation. Acute screening for pituitary insufficiency using standard stimulation/response tests should be considered in all at risk patients and those with unexplained hyponatraemia or hypoglycaemia, or a persisting requirement for high-dose vasopressors. The effect of hormone replacement on outcome is not well studied but hydrocortisone should be considered in the presence of refractory hypotension, and may be supplemented with a mineralocorticoid if hyponatraemia persists (Powner et al., 2006).

Non-neurological organ system dysfunction

Non-neurological organ dysfunction, particularly involving cardiorespiratory systems, is common after TBI and an independent

Table 42.2 Characteristics and treatment of sodium disturbances after head injury

Finding	SIADH	CSWS	CDI
Plasma volume	Raised	Lowered	Lowered
Sodium balance	Positive/equal	Negative	Equal
Water balance	Positive	Negative	Negative
Serum sodium	Low	Low	High
Serum osmolality	Lowered	High/normal	High
Urine sodium	High	High	Normal
Urine osmolality	High	Normal/high	Low
Management	• electrolyte-free water restriction—initially to 1000–1500 ml/day—if cardiovascular status allows • demeclocycline—inhibits renal response to ADH • ADH-receptor antagonists—inhibit binding of ADH to renal receptors	• volume and sodium resuscitation • fludrocortisone may limit sodium loss	• replace fluids to maintain normovolaemia • DDAVP if high urine output (>250 ml/h) continues

ADH, antidiuretic hormone; CDI, central diabetes insipidus; CSWS, cerebral salt wasting syndrome; DDAVP, 1-deamino-8-D-arginine vasopressin; SIADH; syndrome of inappropriate ADH secretion.

Normal values: plasma osmolality 278–305 mmol/kg; plasma sodium 135–145 mmol/litre; urine osmolality 350–1000 mmol/kg; urine sodium 20–60 mmol/litre or 100–250 mmol/24 h.

contributor to morbidity and mortality. Whether early recognition and prompt intervention improves outcomes is less clear. Systemic complications may occur because of neurogenic causes such as brain injury-related catecholamine and neuroinflammatory responses that can lead to neurogenic stunned myocardium syndrome and neurogenic pulmonary oedema, or as a complication of brain-directed therapies such as acute lung injury (ALI) secondary to cerebral perfusion pressure (CPP)-guided therapy, or TTM-related infection. Pneumonia is particularly common after TBI, occurring in up to 80% of ventilated patients. The management of systemic organ dysfunction and failure presents a significant challenge because optimum treatment for the failing systemic organ system may have potentially adverse effects on the injured brain and *vice versa*. For a detailed discussion of the aetiology and management of non-neurological complications the reader is referred elsewhere (Berthiaume and Zygun, 2006).

Intracranial and cerebral perfusion pressure monitoring and management

Monitoring and management of ICP and CPP are crucial aspects of the critical care management of severe TBI. ICP monitoring allows measurement of absolute ICP, calculation of CPP, identification and analysis of pathological ICP waveforms that predict the development of intracranial hypertension, and derivation of indices of cerebrovascular pressure reactivity. CPP is calculated as the difference between mean arterial pressure (MAP) and ICP, and is modifiable through this relationship. The Brain Trauma Foundation (BTF) recommends interventions when ICP exceeds 22 mmHg (although some centres use a threshold of >20 or >25 mmHg) and maintenance of CPP between 60 and 70 mmHg (Carney et al., 2017).

Intracranial pressure

The indications for ICP monitoring are highlighted in **Box 42.2**, which emphasizes differences between 2014 expert consensus recommendations and the 2016 BTF guidance. Stocchetti et al. (2014) advise that comatose TBI patients with normal CT scans do not require ICP monitoring whereas the latest BTF guidelines continue to recommend monitoring in such patients in the presence of specific high-risk characteristics despite the absence of high-quality evidence to support such a recommendation (Carney et al., 2017). This difference in emphasis likely relates to the fact that modern scanners are more able to identify lesions that were previously undetectable, thereby reducing the likelihood of the subsequent development of raised ICP secondary to evolution of occult lesions.

Technical aspects

ICP is most commonly measured through an intraventricular catheter or parenchymal microtransducer device. Other techniques, such as subarachnoid or epidural devices, are less accurate and rarely used. Ventricular catheters measure global ICP (cerebrospinal fluid (CSF) pressure in the lateral ventricles) and permit therapeutic drainage of CSF. There is a risk of catheter-associated ventriculitis, which increases with the length of time since catheter insertion. This can be reduced (but not abolished) by the use of antibiotic-impregnated or silver-coated catheters. Parenchymal microtransducer ICP monitoring systems are easy to insert and usually placed ~2 cm into brain parenchyma through a cranial access device or at craniotomy when they can also be sited in the subdural space. While intraventricular catheters have historically been considered the 'gold standard' for ICP monitoring, intraparenchymal devices provide equivalent pressure measurement and are safer, with lower risk of device-related complications such as haematoma and infection (Smith, 2008).

Several non-invasive ICP monitoring techniques have been developed, including transcranial Doppler (TCD) ultrasonography-derived pulsatility index and ultrasound or CT measurement of optic nerve sheath diameter. Although lacking the risks of invasive methods, these techniques currently fail to measure ICP sufficiently accurately for routine clinical use.

Management of raised intracranial pressure

The burden of intracranial hypertension (the time spent with ICP above a defined threshold—usually 20–25 mmHg) is associated with adverse outcomes after TBI. ICP-lowering strategies are usually administered in a stepwise manner, starting with first-line, safer interventions such as head-up positioning and sedation (**Fig. 42.2**). Higher risk treatment options, including hyperventilation, TTM, barbiturates and surgical decompression, are reserved for patients with multimodal brain monitoring evidence of brain hypoxia of cerebral metabolic distress, or those at imminent risk of cerebral herniation.

Sedation

Most sedative agents have beneficial effects on ICP and CPP, but there is no convincing evidence of advantage of one agent over another (Roberts et al., 2011). Propofol is widely used, usually in combination with infusion of a short acting opioid. It effectively reduces cerebral metabolic rate and ICP, and allows readily titratable sedation levels and rapid wake-up. The alpha-2 agonist dexmedetomidine has shown some promise for sedation after brain injury but there are no RCTs in patients with TBI.

Neuromuscular blocking agents do not reduce ICP, although they may prevent increases during endotracheal suctioning and other interventions. They should not be used routinely because of the increased risk of extracranial complications including pneumonia and ICU-acquired weakness.

Hyperventilation

Hyperventilation effectively reduces ICP secondary to cerebral vasoconstriction in response to reduced $PaCO_2$. It can therefore precipitate or worsen global and regional cerebral ischaemia because of critical reductions in cerebral blood flow (CBF) (Stocchetti et al., 2005). As such, hyperventilation should be used only as a temporizing measure and avoided in the first 24 hours (when CBF is often significantly reduced) and as a prophylactic intervention. Concomitant cerebral oxygenation monitoring is recommended during hyperventilation to identify impending ischaemia.

Osmotic therapy

Mannitol (0.25–1.0 g/kg) is a standard of care for the acute treatment of elevated ICP (Carney et al., 2017), but has never been subject to a randomized comparison against placebo. Side effects include initial fluid overload, subsequent hypotension, metabolic acidosis, and electrolyte imbalance, all of which can adversely affect the injured brain. Repeated administration may result in unacceptably high

Box 42.2 Indications for intracranial pressure monitoring in traumatic brain injury, from the Brain Trauma Foundation guidelines and expert consensus recommendations

Brain Trauma Foundation guidelines (2016)

- All salvageable patients with severe TBI* and an abnormal cranial CT scan
- All salvageable patients with severe TBI and a normal scan and two or more of the following:
  - age more than 40 years
  - unilateral or bilateral motor posturing
  - systolic blood pressure <90 mmHg

Note: These recommendations have been carried over from the previous (3rd) edition of the BTF guidelines, despite not being supported by current standards of evidence.

Expert consensus recommendations (2014)

- Comatose** TBI patients with an initial CT scan showing minimal signs of injury (tSAH, petechiae) that subsequently worsen (e.g. development of contusions, or compression or absence of basal cisterns)
- Comatose TBI patients with cerebral contusions when interruption of sedation to check neurologic status is dangerous, or when the clinical examination is unreliable
- Comatose TBI patients with large bifrontal contusions and/or haemorrhagic mass lesions close to the brainstem irrespective of initial Glasgow Coma Scale (GCS)
- Following a secondary decompressive craniectomy to assess the effectiveness of surgery in terms of ICP control and guide ongoing management
- After evacuation of an acute supratentorial intracranial hematoma in salvageable patients at increased risk of intracranial hypertension, including those with:
  - GCS motor score ≤5
  - pupillary abnormalities
  - prolonged/severe hypoxia and/or hypotension
  - compressed or obliterated basal cisterns
  - midline shift >5 mm or exceeds thickness of an extra-axial clot
  - additional extra-axial haematomas, parenchymal injuries (such as contusions), or swelling
  - intraoperative brain swelling
- It should also be considered in polytrauma cases as highlighted earlier
- *Not* in comatose TBI patients with a normal initial CT***

*ICP, intracranial pressure; CPP, cerebral perfusion pressure; CT, computed tomography; GCS, Glasgow coma scale; TBI, traumatic brain injury; tSAH, traumatic subarachnoid haemorrhage. * defined as a GCS score of 8 or below. ** defined as a GCS of 8 or below after haemodynamic and respiratory stabilization and in the absence of anaesthetic or paralysing agents. ***in such cases a second CT scan is recommended, urgently if the patient deteriorates neurologically.*

Management of raised intracranial pressure
ICP >20–25 mmHg?
Initial options
• Elevate head of the bed
• Ensure the neck is in a neutral position
• Avoid unnecessary pressure on the neck (e.g. from collar or endotracheal tube ties)
• Optimise ventilation to precent hypercarbia
• Sedation
• Analgesia
• Paralysis
• Surgical removal of mass lesions (e.g. subdural or extradural haematoma)
ICP remains >20–25 mmHg?
Further treatment options
• Ventriculostomy
• Inotropes
• Mannitol
• Hypertonic saline
• Loop diuretics
• Therapeutic hypothermia
ICP remains >20–25 mmHg?
Further treatment options
• Barbiturates
• Decompressive craniectomy
• Decompressive laparotomy/thoractomy

Fig. 42.2 Management algorithm for raised intracranial pressure.

serum osmolality (>320 mOsm/litre), neurological complications, and acute kidney injury.

HS may have a more profound and long-lasting effect on ICP compared with mannitol, but outcome benefits over mannitol have not been demonstrated (Diringer, 2013). Clinical outcome studies are inconsistent in terms of dose, concentration, frequency, and mode (bolus or continuous infusion) of HS administration, and the optimal osmolar load to lower elevated ICP is undefined. HS has multiple theoretical beneficial effects on the injured brain in addition to its osmotic action, including vasoregulatory, immunological, and neurochemical actions; it also expands intravascular volume, potentially augmenting CPP.

Although previously believed to be only a by-product of anaerobic metabolism, there is some evidence that lactate can act as a preferential fuel in the injured brain. Preliminary clinical data suggest that hypertonic lactate solutions spare cerebral glucose, improve cerebral energy metabolism, and effectively reduce elevated ICP (Bouzat and Oddo, 2014). Further data are required before its routine use can be recommended

Barbiturates

A Cochrane review has confirmed that the use of barbiturates in patients with TBI does not reduce mortality, and increases the risk of hypotension by 25% (Roberts and Sydenham, 2012). The adverse cardiovascular effects of barbiturates are likely to offset any benefit on CPP of ICP reduction. Barbiturates continue to be used in the treatment of refractory intracranial hypertension when first- and second-tier therapies have failed to control ICP, although in some centres there is a preference for decompressive craniectomy over barbiturates in this situation.

Surgery

The role of decompressive craniectomy, CSF drainage, and other neurosurgical interventions in the management of intracranial hypertension are discussed in **Chapter 43**.

Evidence for intracranial pressure monitoring and management

It is well recognized that intracranial hypertension is detrimental, but there is little evidence that monitoring and managing ICP improves outcomes. A meta-analysis of 14 studies including 24 792 patients with severe TBI concluded that ICP monitoring-guided management of intracranial hypertension had no significant mortality benefit overall compared to treatment without ICP monitoring, although mortality was lower in patients who underwent ICP monitoring in studies published after 2012 (Yuan et al., 2015). There has been only one randomized study evaluating the utility of ICP monitoring in TBI. The Benchmark Evidence from South American Trials: Treatment of Intracranial Pressure (BEST-TRIP) compared treatment guided by ICP monitoring with care based on imaging and clinical examination in the absence of ICP monitoring, and found no difference in three- or six-month outcomes (Chesnut et al., 2012). Patients in the ICP monitoring group received significantly fewer days of ICP-directed treatment (hyperventilation, HS/mannitol, and barbiturates), although the length of ICU stay was similar. This is in contrast to other (observational) studies, which have demonstrated an increased burden of brain-directed therapy in patients in whom treatment is guided by ICP monitoring,

BEST-TRIP has been criticized on several counts, but its findings reinforce the notion that assessment of ICP is integral to managing severe TBI. The evaluation and diagnosis of intracranial hypertension, whether through monitoring ICP directly, or indirectly through assessment of clinical and imaging variables, was fundamental to patient management in both groups.

Cerebral perfusion pressure

Guidelines recommend that CPP should be maintained between 60 and 70 mmHg (Carney et al., 2017), through manipulation of MAP with fluid resuscitation and vasopressors/inotropes or treatment of raised ICP, with evidence that both lower and higher values are associated with deleterious outcomes. CPP more than 70 mmHg is associated with increased risk of ALI related to overly aggressive fluid resuscitation or vasopressor therapy, and CPP less than 50 mmHg with cerebral hypoperfusion. An alternative approach, the Lund concept, targets a lower CPP (50 mmHg) to minimize increases in intracapillary hydrostatic pressure and intracerebral water content in an attempt to avoid secondary increases in ICP (Grände, 2006), but it does not have a strong evidence base and is not universally accepted. Rather than a single threshold for CPP, it is likely that 'optimal' values can be identified at the individual level using multimodality neuromonitoring (Kirkman and Smith, 2014).

Multimodality neuromonitoring

Monitoring multiple physiological variables is more accurate in the prediction of cerebral hypoxia-ischaemia than measurement of one variable alone (Bouzat et al., 2015) (**Table 42.3**). In particular, ICP monitoring should be regarded as one part of a multimodality neuromonitoring strategy rather than a monitoring modality in isolation (Kirkman and Smith, 2012).

Cerebrovascular reactivity

Cerebrovascular reactivity, a key component of cerebral autoregulation (CA), is often impaired after TBI, rendering the brain more susceptible to secondary ischaemic insults. Monitoring and correlation of spontaneous slow waves in ABP and ICP allows calculation of a pressure reactivity index (PRx) which can be used as a continuous bedside assessment of CA. A negative value for PRx, when ABP is inversely correlated with ICP, indicates normal CA, and a positive value a non-reactive cerebrovascular circulation. PRx may be used to guide therapy and identify optimal CPP after TBI (**Fig. 42.3**) (Aries et al., 2012).

An oxygen reactivity index (ORx) has also been described as the moving correlation between brain tissue oxygenation ($PbtO_2$) and ABP, as have non-invasive alternatives using the correlation between ABP and TCD-derived blood flow velocity and several near infrared spectroscopy (NIRS)-derived variables (Kirkman and Smith, 2012).

Cerebral blood flow monitoring

TCD is a non-invasive technique allowing real-time assessment of cerebral haemodynamics at the bedside. Although it measures relative changes in CBF rather than absolute values, it can be used to detect impaired CBF and assess cerebrovascular reactivity after TBI. Quantitative measurement of absolute regional CBF is possible

Table 42.3 Neuromonitoring techniques used in traumatic brain injury

Technique	Monitored variable(s)	Indications in TBI	Advantages	Disadvantages
Intracranial pressure				
Intraparenchymal or subdural microsensor	• ICP • CPP • Autoregulatory indices	• To allow CPP optimization through derivation of PRx and ORx	• Relatively easy insertion • Low procedural complication rate • Low infection risk	• *In vivo* calibration not possible • Measures localized pressure • Small zero-drift with time
Ventricular catheter	• As above	• As above, plus: • To allow therapeutic drainage of CSF	• Measures global ICP • Therapeutic CSF drainage • *In vivo* calibration possible	• More difficult insertion • Risk of procedure-related haemorrhage • Risk of catheter-related ventriculitis
Cerebral blood flow				
Transcranial Doppler ultrasonography	• Blood flow velocity • Pulsatility index • Autoregulatory indices	• May detect cerebral hypoperfusion and facilitate early goal-directed therapy	• Noninvasive • Can be used on an intermittent or continuous basis • Good temporal resolution	• Measures relative (not absolute) CBF • Operator dependent • Failure rate in 5–10% of patients (absent acoustic window) • Little evidence base in TBI
Cerebral oxygenation				
Jugular venous oximetry	• Jugular venous oxygen saturation • Arterio-venous oxygen content difference	• To evaluate the adequacy of cerebral perfusion and oxygen delivery • To supplement ICP/CPP-guided therapy • To assist titration of medical and surgical therapies to guide ICP/CPP therapy	• Global assessment of balance between CBF and metabolism	• Non-quantitative assessment of cerebral perfusion • Insensitive to regional ischaemia • Risk of extracranial contamination of samples
Brain tissue pO_2	• Brain tissue oxygen partial pressure • Oxygen reactivity	• As for jugular venous oximetry, plus: • To allow CPP optimization through derivation of ORx	• Regional assessment of balance between CBF and metabolism • Continuous • Ischaemic 'thresholds' defined	• Minimally invasive • Measures oxygenation within a small region of interest • One hour 'run-in' period limits intraoperative applications
Near infrared spectroscopy (cerebral oximetry)	• Regional cerebral oxygen saturation • Autoregulatory indices	• As for jugular venous oximetry, plus: • Detection of intracranial haematoma	• Noninvasive • Real time • Multisite measurement	• rScO2-derived 'ischaemic' threshold not defined • Readings affected by the presence of intracranial haematoma and 'contamination' of signals by extracranial tissue • Little evidence base in TBI
Cerebral microdialysis	• Glucose • Lactate, pyruvate, and LPR • Glycerol • Glutamate • Multiple biomarkers for research purposes	• To detect cerebral ischaemia, hypoxia, cellular energy failure, and glucose deprivation • To predict the development of secondary injury before it is detectable clinically or by other monitoring modalities • To optimize CPP • To assist titration of medical therapies such as systemic glucose control	• Assessment of cerebral glucose metabolism • Detection of hypoxia/ischaemia • Assessment of non-ischaemic causes of cellular bioenergetic dysfunction	• Focal measure • Thresholds for abnormality unclear • Not continuous • Labour-intensive
Electrophysiology				
EEG	• Seizures • Diagnosis-specific EEG patterns • Some evidence that detection of SDs might be possible	• To detect convulsive and non-convulsive seizures • To diagnose characteristic EEG patterns to facilitate prognostication	• Noninvasive • Detection of non-convulsive seizures • Correlates with cerebral ischaemic and metabolic changes	• Skilled interpretation required • Affected by anaesthetic and sedative agents
ECoG	• Cortical SDs	• To detect spreading cortical depolarizations	• Currently the only method to identify SDs accurately	• Highly invasive • No evidence that treatment of SDs improves outcome • Little evidence base in TBI and thus currently remains a research tool

using a thermal diffusion flowmetry probe, but clinical data using this technique are limited.

Cerebral oxygenation monitoring

Maintenance of ICP and CPP within established thresholds for normality does not guarantee against brain tissue hypoxia (Oddo et al., 2011). Cerebral oxygenation monitoring is therefore often used to assess the balance between cerebral oxygen delivery and utilization, and the adequacy of cerebral perfusion.

Jugular venous oximetry

Jugular venous oxygen saturation ($SvjO_2$) monitoring was the first bedside monitor of cerebral oxygenation, and formed the basis of our understanding of cerebral oxygenation changes after brain injury.

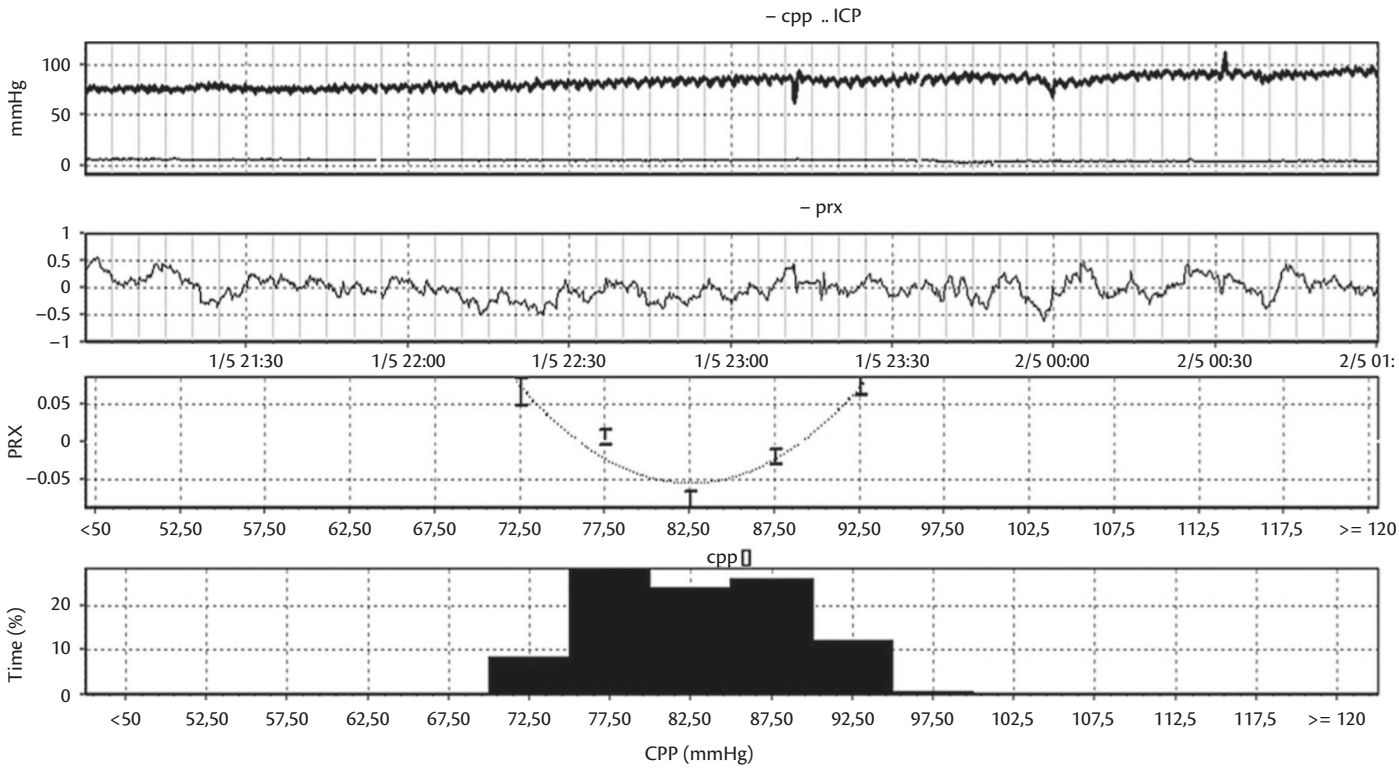

Fig. 42.3 Screenshot from ICM+ software panel (Cambridge Enterprise, Cambridge, UK) with 4 h trend charts. Determination of the PRx can guide therapy and allow identify optimal CPP at the individual level (CPPopt). *First chart*: CPP and ICP; *second chart*: PRx; *third chart*: PRx/CPP plot for evaluating CPPopt; and *fourth chart*: percentage of the 4-h time period spent within a given CPP interval.

The ICM+® brain monitoring software developed at the University of Cambridge was used to generate this image.

Maintenance of $SvjO_2$ more than 50% after TBI is recommended in BTF guidelines (Carney et al., 2017), but no interventional trials have confirmed a direct benefit of $SvjO_2$-directed therapy on outcome and in any case $SvjO_2$ monitoring is being superseded by other modalities.

Brain tissue oxygen partial pressure

$PbtO_2$ monitoring is considered the 'gold standard' bedside monitor of cerebral oxygenation, and recommended after severe TBI (Le Roux et al., 2014). It is a complex and dynamic variable resulting from interaction of all factors affecting cerebral oxygen delivery and demand (oxygen metabolism), the relative proportion of arterial or venous vessels in the region of interest, and tissue oxygen diffusion gradients. It is therefore a biomarker of cellular function rather than simply a monitor of hypoxia/ischaemia. $PbtO_2$ is a regional monitor and the probe is typically placed in tissue immediately surrounding a hematoma or contusion to monitor 'at risk' brain regions.

Normal brain $PbtO_2$ is reported to lie between 2.7 and 4.7 kPa (20–35 mmHg), and the ischaemic threshold usually defined as 1.33–2.0 kPa (10–15 mmHg). However, $PbtO_2$ values are best considered within a range rather than as a precise threshold and ischaemia defined by both duration and depth of hypoxia. Guidelines recommend interventions to maintain $PbtO_2$ more than 2.7 kPa (>20 mmHg) (Le Roux et al., 2014).

Observational studies suggest a potential benefit of supplementing ICP/CPP-guided management with $PbtO_2$-directed therapy after TBI (Nangunoori et al., 2012). In addition to systemic blood pressure, $PbtO_2$ is affected by several other factors including PaO_2, $PaCO_2$, and haemoglobin concentration, and which intervention or combination of interventions should be used to reverse brain tissue hypoxia is contentious. In fact, it appears that the responsiveness of brain tissue hypoxia to a given intervention is the prognostic factor, with reversal of hypoxia being associated with reduced mortality (Nangunoori et al., 2012). RCT data are urgently needed to confirm any benefits of $PbtO_2$ monitoring, and the results of the Brain Tissue Oxygen Monitoring in Traumatic Brain Injury (BOOST2) study are awaited (https://clinicaltrials.gov/ct2/show/NCT00974259).

Near infrared spectroscopy

Near infrared spectroscopy-based cerebral oximetry provides continuous and non-invasive monitoring of regional cerebral oxygen saturation ($rScO_2$), with high temporal and spatial resolution, and the possibility simultaneous measurement over multiple regions of interest. The 'normal' range of $rScO_2$ is reported as 60–75% but there is substantial intra- and interindividual variability, and $rScO_2$ values are best used as a trend monitor. There has been limited investigation of the utility of NIRS after TBI where its application is confounded by the optical complexity of the injured brain (Ghosh et al., 2012). NIRS-derived variables have been investigated as a non-invasive assessment of cerebral autoregulatory status, but its role in the broader monitoring of TBI is undefined.

Cerebral microdialysis

Cerebral microdialysis (CMD) allows bedside analysis of biochemical substances in brain tissue extracellular fluid. The catheter is usually placed in 'at risk' tissue so that biochemical changes in the area of brain most vulnerable to secondary insults can be monitored. Glucose, lactate, pyruvate, lactate:pyruvate ratio (LPR), glycerol and glutamate are the variables most commonly measured clinically, and each is a marker of a particular cellular process associated with glucose metabolism, hypoxia/ischaemia, or cellular energy failure. CMD measures the supply of substrate and its cellular metabolism, so it is a monitor not only of cerebral ischaemia but also of non-ischaemic causes of cellular energy dysfunction. It may identify cerebral compromise at the cellular level before it is detectable clinically or by other monitored variables.

Elevated lactate:pyruvate ratio (LPR) more than 40 combined with low brain glucose (<0.7–1 mmol/litre) suggests severe hypoxia/ischaemia and correlates with poor outcome after TBI (Timofeev et al., 2011). Although the clinical utility of CMD is debated, expert consensus guidance for its use has recently been published (Hutchinson et al., 2015).

Electroencephalography and electrocorticography

EEG is used to diagnose and guide therapy in patients at risk of, or having, seizures or status epilepticus. Continuous EEG (cEEG) has become more widespread with awareness that non-convulsive seizures are common after brain injury.

Spreading cortical depolarizations (SDs) are pathological near-complete, sustained depolarization of neurons and astrocytes resulting in secondary injury due to mitochondrial damage, accumulation of intracellular calcium, and excitotoxicity. They occur in 50–60% of TBI patients, and have previously been detectable only via electrode strips placed directly onto the cortical surface. Recent data suggest that standard scalp cEEG may be able to detect SDs, offering the potential for routine monitoring of this important pathophysiological manifestation of acute brain injury.

Conclusions

Understanding of the mechanisms of secondary brain injury and awareness of its adverse outcome effects has resulted in significant advances in the early and intensive care management of TBI, which focuses on the avoidance of hypoxia and hypotension, control of ICP, and maintenance of CPP. Multimodality neuromonitoring, including continuous measurement of ICP and CPP, allows individualized interventions targeted to real-time changes in cerebral physiology with the aim of improving outcomes following TBI.

Surgical management of head injury

Hadie Adams, Angelos G. Kolias, Adel Helmy, Peter J.A. Hutchinson, and Randall M. Chesnut

Introduction

Traumatic brain injury (TBI) is a significant cause of preventable morbidity and mortality in the United Kingdom and across the world, leading to disability and loss of productivity (Maas et al., 2008). The estimated incidence of TBI in Europe is on average 235 per 100 000, ranging of 150–300/100 000 per year (Tagliaferri et al., 2006). The Glasgow Coma Scale (GCS) is often used to classify the severity of TBI, with patients scoring 8 or less being classified as severe, 9–12 as moderate, and scores of 13–15 as mild (CDC, 2015a). Mild TBI is the most common form of head injury, and the incidence of TBI is the highest in young adult males (Nguyen et al., 2016). In Western countries the major causes of TBI-related hospitalizations are falls, assaults, and motor vehicle traffic collisions (Lawrence et al., 2016). Indications for surgery following TBI include mass lesions (extradural, acute subdural and intracerebral haematomas and contusions), depressed skull fractures, and decompressive craniectomy for diffuse injury). North-American trauma registries demonstrated that craniotomies were performed in 3.6% of all TBI patients (Esposito et al., 2005). The European Brain Injury Consortium survey showed that 69% of TBI patients with a mass lesion (>25 ml) and/or radiological signs of raised intracranial pressure (ICP) underwent emergency cranial surgery (Compagnone et al., 2007). Acute subdural haematomas were the most frequent evacuated mass lesions, contributing to approximately two-third of all emergency cases, followed by extradural haematoma and contusions/intracerebral haematomas.

Intracranial pressure monitoring

Severe TBI patients in need of neurointensive care in the acute phase are often sedated and paralysed to facilitate endotracheal intubation and for control of intracranial pressure. This limits the utility of neurological examinations, and therefore computed tomography (CT) scanning and monitoring of intracranial pressure (ICP), remain the primary methods to guide treatment in a neuro-intensive care setting (Le Roux et al., 2014; Brain Trauma Foundation, 2016). Control of ICP remains the central tenet of management of moderate-severe TBI to maintain adequate perfusion and oxygenation of the brain and to avoid or mitigate secondary insults (Valadka and Robertson, 2007; Brain Trauma Foundation, 2016). The Brain Trauma Foundation (BTF) guidelines recommends management of severe TBI patients using ICP monitoring to reduce in-hospital and 2-week postinjury mortality (Brain Trauma Foundation, 2016). ICP monitoring is routinely used in the developed world, and observational studies have demonstrated repeatedly that ICP crises can lead to adverse outcomes (Forsyth et al., 2015). This is discussed further in Chapter 42 (Intensive Care Management of Head Injury). Ultimately, if left untreated, the pressure within the intracranial compartment can rise above a critical threshold, causing damage to neuronal structures, and eventually herniation, and brain death.

It important to be aware of intracranial pressure gradients within the brain parenchyma, especially in patients with space-occupying lesions. This group is prone to develop ICP gradients, since the supporting dural folds, namely the falx cerebri, and the tentorium cerebelli divide the intracranial cavity into compartments that normally protect against excessive movement. Pressure differences between the cerebral hemispheres have been described greater than 10 mmHg in the context of acute subdural haematoma (Chambers et al., 1998). This has underpinned the argument for intraventricular probes for measurement of ICP as, with a patent ventricular system, the pressure can equilibrate between the CSF spaces to a degree (Brain Trauma Foundation, 2016). In practice, the risks associated with prolonged ventricular drainage (both infectious and procedural) limit this approach in many units in favour of parenchymal probes.

Advanced cerebral monitoring combines ICP monitoring with other cerebral monitoring techniques, including cerebral autoregulation monitoring, microdialysis monitoring of brain chemistry, brain tissue oxygen ($PbrO_2$) monitoring, and jugular bulb monitoring of arteriovenous oxygen content difference (AVDO2) (Valadka and Robertson, 2007; Le Roux et al., 2014; Brain Trauma Foundation, 2016; Makarenko et al., 2016). These monitoring methods allow for individualized management of secondary cerebral insults by assessing brain metabolic needs and the response to therapeutic intervention. Some cranial access devices allow for multiple catheters and sensors to be transmitted into the brain parenchyma to facilitate continuous multimodality monitoring at the bedside (Hutchinson et al., 2000).

Ventriculostomy

The role of CSF drainage and the optimal draining techniques (continues vs. intermittent) in TBI patients has not been firmly established (Nwachuku et al., 2014; Brain Trauma Foundation, 2016). An external ventricular drain (EVD), or ventriculostomy, is a rapid method of controlling ICP by reducing the intracranial CSF volume, even in the absence of hydrocephalus (Kerr et al., 2001; Timofeev et al., 2009; Brain Trauma Foundation, 2016). Its use has been described as a secondary ICP-lowering manoeuvre as part of protocol-driven management of elevated ICP. Physiological improvements have been reported following CSF drainage, however in a significant proportion of patient's ICP fails to be controlled if not used alongside other ICP-lowering treatments (Timofeev et al., 2009). Ventriculostomies are also associated with complications, include the risk of EVD-related infections, haemorrhages during insertions, and subsequent shunt-dependency.

An EVD connected to a pressure transducer can measure ICP in a closed position (see section on ICP monitoring), and drain CSF when opened. There is no consensus on the optimal drainage technique in TBI patients (Nwachuku et al., 2014; Brain Trauma Foundation, 2016). Practice patterns seem to vary significantly, and shown to be influenced by physician and departmental preferences and resources. Management of CSF drainage in TBI patients also appears to be related to the patient's age (Shore et al., 2004; Nwachuku et al., 2014). Continuous CSF drainage has been more commonly described in the paediatric TBI population. It is important to note that while intermitted drainage can allow for real-time visualization of ICP, the patient can be exposed to detrimental elevations of ICP between drainage periods. Continuous drainage allows for more stable ICP control, however, this risks overdrainage with subsequent collapse of the ventricles. In this circumstance, the EVD can no longer be reliably employed as a method of gauging ICP as it relies on a continuous column of fluid between the site of the transducer and the intraventricular cavity.

Craniotomy for mass lesions

Surgical intervention is aimed at mitigating injuries to the brain caused by (expanding) haematomas and their sequelae (Bullock et al., 2006a; Bullock et al., 2006b; Bullock et al., 2006c). An initial assessment of neurologic deficits, pupil abnormalities, degree of midline shift, hematoma volume, and the presence/severity of associated trauma is required to determine the necessity for emergent cranial surgery. For neurosurgeons one of the most difficult decisions to make is whether or not moderate-sized mass lesions should be evacuated or observed. As surgical interventions might not always be necessary, there is a risk with conservative management of neurological deterioration with possible secondary insults to the brain that may negatively impact the patient's outcome. Current guidelines and recommendations are available, but are limited to expert consensus with limited quality of evidence (Bullock et al., 2006a; Bullock et al., 2006b; Bullock et al., 2006c). It is worth emphasizing that although guidelines necessarily incorporate specific metrics that guide surgery, the whole clinical picture incorporating the clinical state (GCS, pupillary function) of the patient, the trajectory of deterioration, other causes of neurological compromise (such as metabolic, drug induced, hypoxia or hypotension), associated injuries, and comorbidities all influence the speed and manner of intervention (Bullock et al., 2006a; Bullock et al., 2006b; Bullock et al., 2006c).

Extradural haematomas

Extra (or epi-) dural hematomas (EDH) usually develop in young adults following traffic-related accidents, falls, and assaults (Bullock et al., 2006b). In TBI patients the incidence of surgical and non-surgical EDH cases has been estimated to be between 2.7 to 4% (Bullock et al., 2006b) EDH are thought to result from a direct blow to head and are usually found on the same side impacted by the blow. Typically, the source of bleeding is arterial, following a fracture in the region of the pterion with subsequent tearing of the middle meningeal artery and hematoma formation in the middle cranial fossa. Extradural hematomas may occur in any anatomical location including in the frontal, occipital, and vertex regions and can be associated with the anterior ethmoidal artery, transverse or sigmoid sinuses, and superior sagittal sinus, respectively. EDHs originating from venous sources are thought to expand more slowly compared to their arterial counterparts (Nalbach et al., 2012). EDH specific mortality has been described to be around 10% in adult patients (Bullock et al., 2006b). The role of surgery is to prevent irreversible brain injury or death caused by hematoma expansion, raised ICP, and herniation of the brain. Patients presenting with (progressive) focal neurologic signs or symptoms and/or hematoma growth, have to be considered as an emergency case. Evidence and expert-based recommendations for evacuations of EDH recommend surgery for all adult patients with a hematoma volume more than 30 cm^3 (>30 ml) regardless of the GCS score, and comatose patients (GCS <9) with pupillary abnormalities (Bullock et al., 2006b). Evacuation should be performed through a craniotomy window fashioned according to the location of the haematoma, and providing adequate access to the hematoma margins. If the brain appears tight it is important to inspect the subdural space for additional clots. When the bone flap is replaced several tenting sutures should be placed to obliterate the epidural space both circumferentially and over the centre of the craniotomy. Bone flaps are not left out for isolated EDH with no parenchymal injuries as these are typically injuries with a fracture haematoma rather than a brain injury *per se* that is prone to swelling. Close observation and conservative management are appropriate for patients with no focal neurologic deficits, with a small hematoma (<30 cm^3), a clot thickness less than 15 mm, and midline shift less than 5 mm on imaging (Bullock et al., 2006b).

Acute subdural hematomas

Acute subdural hematomas (aSDH) usually develop following motor vehicle accidents (MVA), falls, or assaults (Bullock et al., 2006c). In younger patients (18–40 y) 56% of the ASDH were caused by MVA and only 12% were caused by falls. Unlike young patients, those aged 65 years and older had in 22% of the cases an MVA and 56% had a fall (Bullock et al., 2006c). The mechanism of bleeding varies depending on the age of the patient and the amount of force applied. Typically, in elderly patients with relative brain atrophy, the source of bleeding is usually venous caused by torn bridging veins with a modest degree of force. In younger patients or with a greater degree of violence, the brain surface itself is badly contused

and arterial bleeding sources reported for approximately 20% to 30% of aSDH cases (Gennarelli and Thibault, 1982; Zumkeller et al., 1996; Koc et al., 1997; Servadei et al., 1998; Maxeiner and Wolff, 2007; Ryan et al., 2012). Mortality for aSDH patient requiring surgery has been described to be between 15% and 60% (Haselsberger et al., 1988; Hatashita et al., 1993; Zumkeller et al., 1996; Kok et al., 1997; Servadei et al., 1998; Bullock et al., 2006c; Ryan et al., 2012). Evidence and expert-based recommendations for evacuations of aSDH recommend surgery for all adult patients with a haematoma thickness more than 10 mm, midline shift more than 5 mm, GCS score decreased by 2 points or further from injury to hospital admission, and/or patients presenting with pupillary abnormalities (Bullock et al., 2006c). As advanced age has been associated with increased rates of adverse outcome, age should be considered when deciding whether surgery will change the natural history of the disease. TBI patients presenting with an aSDH are frequently accompanied by significant parenchymal injury and swelling on imaging (Zumkeller et al., 1996; Bullock et al., 2006c; Li et al., 2012). Patients with aSDHs that require surgery to remove the clot are treated either with a craniotomy or a decompressive craniectomy (DC). However, there is often uncertainty as to whether the bone flap should be replaced or not (Kolias et al., 2012). The RESCUE-ASDH trial has recruited aSDH patients and aimed to compare craniotomy versus DC for adult patients undergoing evacuation of an aSDH (Protocol 14PRT/6944). The results of this trial will inform surgical decision making in the management of aSDH patients. Close observation and conservative management are appropriate for patients that are neurologically stable, hematoma thickness less than 10 mm, midline shift less than 5 mm, no pupillary abnormalities, and no intracranial hypertension on ICP monitoring (Bullock et al., 2006c). Conservatively managed aSDHs resolve gradually and are usually absorbed over weeks, although in a proportion of patients may form a chronic subdural hematoma.

Intracerebral haematomas/contusion

Traumatic intracerebral haemorrhage (ICH) is also referred to as traumatic intraparenchymal haemorrhage and (haemorrhagic) contusion. Post-traumatic contusions are usually multiple and are located in the basal surface of the frontal and temporal lobes (Bullock et al., 2006a). In the acute stages, the ICH consists of a (semi-)liquid mass of blood with surrounding oedema. These mass lesions evolve over days and change consistency while oedema begins to recede. Mortality secondary to traumatic ICH is related to the location and size of the lesion(s) (Bullock et al., 2006a). Surgical interventions are aimed at preventing secondary damage, brainstem compression, and herniation of the brain. Unfortunately, the only trial investigating the role of early surgery versus initial conservative treatment to anticipate and prevent secondary damage in traumatic ICH was halted early (Gregson et al., 2012; Mendelow et al., 2015). Although the evidence is limited due to the low sample size resulting from premature termination, it appears that the STITCH(Trauma) Trial observed reduced mortality with early surgery (Mendelow et al., 2015). However, it is important to note that patients in this trial were mostly recruited in resource-limited settings where ICP monitoring was not usually available. Current evidence and expert-based recommendations for evacuations of traumatic ICH involving the cerebral hemispheres recommend surgery for patients with focal lesions and the following indications; progressive neurological deterioration, medically refractory raised ICP, a hematoma volume more than 50 cm^3 (>50 ml), GCS score of 6 to 8 in a patient with a frontal or temporal haemorrhage more than 20 cm^3 (>20 ml) with either midline shift of more than 5 mm and/or cisternal compression on CT scan (Bullock et al., 2006a). Patients with diffuse injuries developing medically refractory post-traumatic cerebral oedema and intracranial hypertension may be considered for a bifrontal DC (Bullock et al., 2006a). DCs may also be considered for patients with refractory intracranial hypertension and diffuse injuries with clinical and radiographic evidence for transtentorial herniation. Evacuation of a traumatic ICH in the posterior fossa is recommended when there is evidence of neurologic dysfunction/deterioration and significant mass effect on the basal cisterns, fourth ventricle, or signs of obstructive hydrocephalus (Bullock et al., 2006d). Intensive monitoring and serial imaging are appropriate for patients with no focal neurologic deficits, and non-significant mass effect on imaging.

Decompressive craniectomy

Management of refractory raised ICP following severe TBI consist of medical and surgical treatments (Stocchetti et al., 2008; American College of Surgeons, 2015). DC is generally considered a surgical treatment for patients with diffuse brain swelling or expanding contusions/haematomas refractory to medical treatment and impending herniation (Bohman and Schuster, 2013; Kolias et al., 2013). In recent years, the role of DC has been discussed as a primary treatment in the acute phase, leaving out the bone flap after evacuation of a mass lesion, or as a second- or third-tier therapeutic measure for diffuse brain injury and oedema, commonly named secondary or protocol-driven DC. The expansion of a swollen brain outside the skull, can potentially lead to a reduction in ICP and risk of herniation. The physiological improvements described in severe TBI patients after DC, include improvement in brain tissue oxygenation, cerebral perfusion, and neurochemistry (Yamakami and Yamaura, 1993; Stiefel et al., 2004; Ho et al., 2008; Jaeger et al., 2010; Bor-Seng-Shu et al., 2012; Lazaridis and Czosnyka, 2012). The risk of complications should also be considered as early or delayed complications can occur after DC (Kolias et al., 2013). Expansion of (contralateral) mass lesions, wound infections, and healing problems, subdural or subgaleal collections, hydrocephalus, syndrome of the trephined, and complications related to the subsequent cranioplasty have been recognized as DC-related complications (Flint et al., 2008; Stiver, 2009; Nalbach et al., 2012). As the risk of severe disability and death in severe TBI remains relatively high, several trials have explored the use of DC to improve patient outcomes (Protocol 14PRT/6944; Hutchinson et al., 2006; Cooper et al., 2011). However, defining the indications, timing, techniques, and optimal outcome measures for DC has proven to be difficult, and good quality evidence linking efficacy to outcome is lacking (Kolias et al., 2013).

Decompressive craniectomy methods

Decompressive craniectomy is an umbrella term for a group of procedures in which part of the skull is removed. In severe TBI the most frequently described DC procedures in adults are bifrontal DC and unilateral frontotemporoparietal craniectomy, also termed hemi(spheric)-craniectomy or unilateral DC (Kjellberg and Prieto, 1971; Guerra et al., 1999; Kolias et al., 2013). For unilateral pathologies

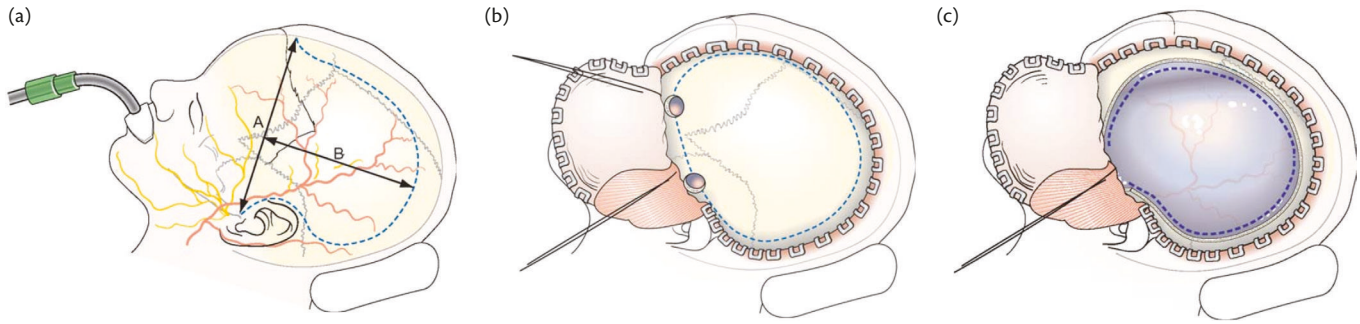

Fig. 43.1 Unilateral decompressive craniectomy. (A) The dotted line represents the usual skin incision made during unilateral decompressive craniectomy. To preserve adequate vascular supply, the length of the incision (distance B) should not exceed its width (distance A). (B) A myocutaneous flap is reflected. The dotted line represents the usual extent of the craniectomy. (C) The dotted line on the dura mater represents our preferred method for opening the dura. The dura is opened in a C-shaped fashion with its base along the sphenoid ridge. The dural incision is kept 5–10 mm away from the craniectomy edges to minimize the risk of injury to the protruding brain.

Reproduced with permission from I. Timofeev, T. Santarius, A.G. Kolias et al., Decompressive craniectomy—operative technique and perioperative care, *Advances and Technical Standards in Neurosurgery*, Volume 38, pp. 115–36, Copyright © 2012 Springer Nature.

with midline shift and (potential) swelling (e.g. aSDH with parenchymal injuries), a hemi-craniectomy can be useful (Fig. 43.1). Evidence and expert-based recommendations for adequate hemicraniectomies suggest that the bone flap should be large with a minimum anteroposterior diameter of 11–12 cm (Li et al., 2012; Tagliaferri et al., 2012) in order to achieve an adequate reduction of ICP and also reduce the risk of transcalvarial herniation that is associated with parenchymal injuries and cortical venous occlusion at the bone edge (von Holst et al., 2012; Li et al., 2013). Bifrontal DC is a treatment option for diffuse (bihemispheric) injuries with medically refractory intracranial hypertension (Fig. 43.2) (Kolias et al., 2013). A bifrontal DC extends from the floor of the anterior cranial fossa to the coronal suture posteriorly and to the temporal floor bilaterally. A widely opened dura mater is required to allow the brain to sufficiently expand. Different techniques have been described for the dura (left open with onlay of haemostatic material, pericranium, or temporalis fascia, or closure with dural expansion grafts) (Whitfield et al., 2001; Timofeev and Hutchinson, 2006; Guresir et al., 2011) and sagittal sinus sectioning or sparing (Bohman and Schuster, 2013). Studies have also described bilateral hemi-craniectomies as an approach for patients with diffuse injuries, although an improvement over the bifrontal DC approach has not been investigated (Guerra et al., 1999). For patients with temporal lesions or oedema causing brainstem compression, extension of the DC to the floor of the middle cranial fossa is essential.

Evidence base for DC in TBI

The DECRA trial failed to find an improvement in functional outcome by performing early bifrontal DC over medical management for patients with diffuse TBI (Cooper et al., 2011). The study showed that patients treated with DC had shorter duration of ventilation

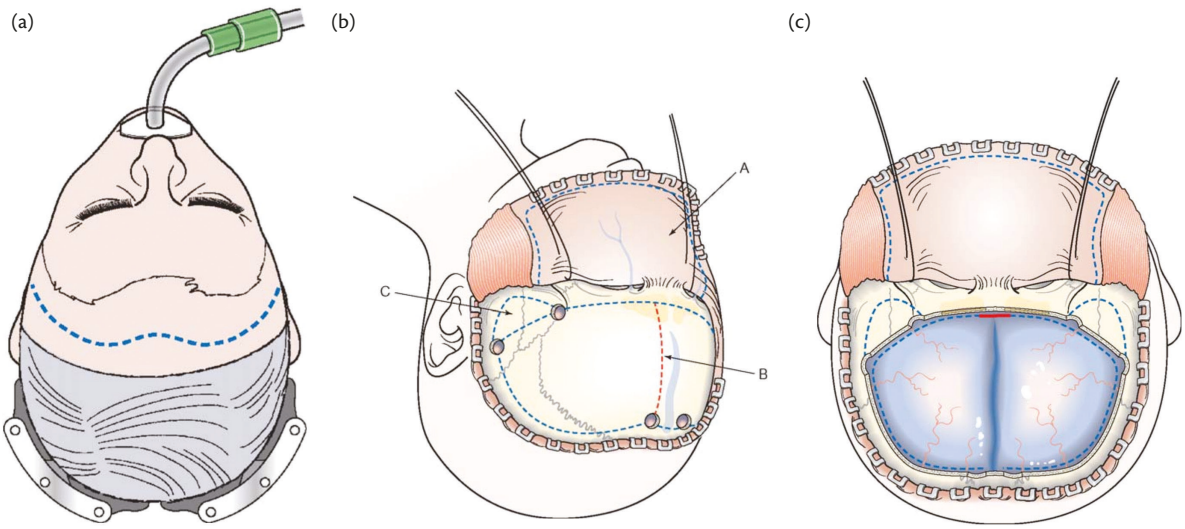

Fig. 43.2 Bifrontal decompressive craniectomy. (A) The dotted line represents the usual skin incision for bifrontal decompressive craniectomy, which should be kept behind the hairline. (B) A bicoronal myocutaneous flap is reflected anteriorly. The dotted line on the skull represents the usual extent of the craniectomy. Subtemporal decompression is optional. (C) The bone flap has been removed. The dotted line on the dura mater represents our preferred method for opening the dura. The dura is opened on either side of the midline in a C-shaped fashion with its base along the superior sagittal sinus. Division of the superior sagittal sinus anteriorly and of the falx (red line) is optional.

and length of stay in the intensive care unit. The RESCUEicp trial aimed to examine the clinical and cost effectiveness of secondary DC (unilateral or bifrontal DC) for severe TBI patients with refractory intracranial hypertension as a last-tier therapy. 408 patients with raised and refractory ICP (threshold 25 mmHg >1–12 hours despite standard medical therapy) were randomised to ongoing medical therapy (plus optional barbituartes) or secondary decompressive craniectomy (Hutchinson et al., 2006). The results showed that decompressive craniectomy resulted in a marked reduction in mortality, increase in vegetative state, increase in lower (dependent) and upper (independent at home) with similar rates of moderate disability and good recovery. Outcome improved between 6 and 12 months with a significant proportion of patients in the surgical arm being upper severe disability or better. In contrast to the aforementioned trials, the RESCUE-ASDH trial is a randomised trial comparing primary unilateral DC to craniotomy (bone flap out versus bone flap replaced) for patients with aSDH (Protocol 14PRT/6944). Information from these studies will define the role of secondary and primary DC in future TBI treatment guidelines. On the basis of the current available evidence, neurosurgeons and neurointensivists must weigh the potential risks and benefits faced by their individual patients when deciding to perform a DC.

Surgical management of depressed skull fractures

Skull fractures most frequently involve the parietal bone, followed by the temporal, occipital, and frontal bones (Cooper and Golfinos, 2000). TBI patients usually present with linear fractures, and less frequently with depressed and skull base fractures. The force of the trauma to the skull required to cause fractures is significant, therefore patients are at significant risk of underlying brain injury. Evidence and expert-based recommendations for skull fractures recommend elevation and washout for patients with open skull fractures depressed more than the thickness of the cranium or more than 5 mm below the adjacent inner table (Bullock et al., 2006e). The rationale is reducing the risk of infection for these cases with early surgery, especially in the presence of dural tears, pneumocephalus, frontal sinus involvement, or contaminated wounds. Emergent surgery is also indicated for fractures with an underlying (expanding) hematoma. Elevation of the fracture will also improve cosmesis for cases with significant displacement of the bone. Reconstruction can usually be achieved by using the bone fragments; if this is not feasible, implants can be used to cover the skull defect (Marbacher et al., 2008). Antibiotics are usually administered to patients with open skull fractures; currently routine prophylaxis for all skull fractures is not supported by the available evidence (Ali and Ghosh, 2002; Bullock et al., 2006e; Ratilal et al., 2015).

Management of skull base fractures

Skull base fractures can involve the anterior, middle, and posterior cranial fossae, or a combination thereof. This section will focus on fractures of the petrous temporal bone and frontal sinus fractures.

Petrous temporal bone fractures are traditionally classified according to the orientation of the fracture line in relation to the long axis of the petrous temporal bone (i.e. line from petrous base to apex). Longitudinal fractures are parallel to the long axis of the petrous bone and their most frequent complications are ossicular injury, tympanic membrane rupture, and conductive hearing loss. Transverse fractures are perpendicular to the long axis of the petrous bone and they are thought to carry a higher risk of sensorineural hearing loss and facial nerve injury compared to longitudinal ones (Zayas et al., 2011). In reality, many fractures are mixed and therefore, a new classification system based on whether the otic capsule is involved or not may be clinically more meaningful (Dahiya et al., 1999). The so-called otic capsule–violating fractures involve the labyrinth (i.e. cochlea, vestibule, or semicircular canals) and patients were found to be twice as likely to develop facial paralysis, four times more likely to have a CSF leak, and seven times more likely to develop profound hearing loss (Dahiya et al., 1999).

The onset of palsy (immediate versus delayed) and the degree of palsy are factors that are typically taken into account when managing patients with petrous fractures and facial nerve palsy. However, in reality, it is often difficult to ascertain the timing of onset and the severity of paresis, as many patients have impaired consciousness, are sedated and ventilated, or are undergoing treatment for life-threatening injuries (Nash et al., 2010). Steroids are often used for patients with facial nerve palsy but a recent systematic review identified only low-quality evidence with lack of controlled studies (Nash et al., 2010). Surgical decompression of the nerve in its canal is usually reserved for patients with immediate onset of serious facial nerve palsy that does not improve with steroids. The timing of surgery remains controversial (Nash et al., 2010). In terms of natural history, of 189 patients managed with observation, who were included in a recent systematic review, 66% had an outcome equivalent to House-Brackmann (HB) I, one-quarter had HB II-V, and only two patients had an HB VI score (Nash et al., 2010).

The frontal sinuses are involved in up to 15% of facial fractures (Echo et al., 2010). Overall, recent years have seen a shift towards conservative management, especially with the advent of endoscopic techniques. Fractures involving the anterior wall do not usually require intervention, unless they are open or depressed. Fractures involving the posterior wall carry a higher risk of CSF leak. The indications for intervention for posterior wall fractures are controversial but in general persistent CSF rhinorrhoea or significant displacement of the posterior wall are accepted indications for intervention (Echo et al., 2010). This typically requires a bicoronal incision, repair of any dural defects if present, and cranialization of the sinus. Cranialization of the sinus aims to reduce the risk of mucocoele formation and intracranial infection; it involves removal of its posterior wall, stripping of the mucosa, and packing the frontonasal ducts. A pericranial flap positioned across the anterior cranial fossa floor, reinforced with a dural sealant, can help prevent a CSF leak. The LeFort type of fractures are usually managed by the maxillofacial surgeons; LeFort I fractures involve the maxilla and pterygoid plates; LeFort II have a pyramidal shape and involve the orbital floor, medial orbital wall, and nasofrontal suture; LeFort III involves the zygomatic arches, frontozygomatic and nasofrontal sutures, and orbital floors, resulting in craniofacial dislocation.

Surgical management of penetrating head trauma

All traumatic brain injuries that are not caused by a blunt mechanism are defined as penetrating brain injury (PBI) (Esposito and Walker, 2009). The incidence of PBI is lower than closed TBI, but PBI has been associated with more adverse outcomes. Most PBIs are caused by gunshot wounds to the head (GSWH), which are the typically lethal, as more than 90% of GSWH have a fatal outcome (Maas et al., 2008). The incidence of PBI is increasing, especially in the United States, due to the use of firearms in violence-related injuries. In addition, worldwide, armed conflicts are causing more brain injuries (No authors, 2001; Maas et al., 2008).

Since the majority of PBIs are caused by missiles or projectiles, and understanding of ballistics is required. Primary injury from GSWH is determined by the ballistic properties (kinetic energy, mass, velocity, shape, and so on.) of the projectile and any secondary projectiles, such as bone or metallic fragments (Ordog et al., 1984). Projectile and possible secondary metal or bone fragments travel through brain parenchyma creating a permanent track of injury. Higher velocity projectiles will cause temporary cavitation, which is a kinetic energy and velocity-related phenomenon (Aarabi, et al., 2001). This results from the transmission of the kinetic energy of the projectile to the surrounding tissue as the projectile slows down. Subsequently, this temporary cavity collapses and expands in wave-like pattern causing further shearing forces to surrounding tissues resulting in haemorrhages and neuronal injuries (Ordog et al., 1984; No authors, 2001).

A non-contrast CT of the head is the recommended modality in the radiological evaluation of PBI cases, since it is quick and provides identification of bone and metallic fragments, characterization of the projectile trajectory, evaluation of the extent of brain injury, detection of intracranial haemorrhages, and possible mass effect (Aarabi, et al., 2001; Tsuei et al., 2005). A formal digital subtraction angiogram is recommended, in particular when the projectile trajectory is near the Sylvian fissure, the supraclinoid carotid artery, the vertebrobasilar vessels, the cavernous sinus region, the major dural venous sinuses, or if a delayed hematoma or SAH develops (No authors, 2001; Offiah and Twigg, 2009). The common vascular complications following PBI include traumatic intracranial aneurysms, arteriovenous fistulas (AVFs), SAH, and vasospasm (No authors, 2001).

Surgical management of PBI entails a superficial debridement and watertight dural closure as a standard of care, but in patients with small entry wounds, simple wound closure may be considered (Maas et al., 2008). In the case of significant mass effect, necrotic brain tissue and bone fragments should be removed, but routine bone or projectile removal in the eloquent areas is not recommended (No authors, 2001). Additionally, any significant intracerebral haemorrhages with significant mass effect should be evacuated. PBI patients are at high risk of CNS infection since contaminated foreign bodies are driven into the brain tissue along the projectile track, hence prophylactic broad-spectrum antibiotics are recommended, and should be started as soon as possible (No authors, 2001; Maas et al., 2008).

Surgical management of CSF leaks

In TBI patients it is estimated that CSF leaks occur in approximately 2% of patients (Mendizabal et al., 1992; Brodie and Thompson, 1997; Friedman et al., 2001). Fractures carrying a high risk of CSF leaks are those involving the frontal or ethmoidal sinuses, and the petrous temporal bone (Mendizabal et al., 1992; Ommaya, 1996). The majority of CSF leaks are self-limiting and resolve spontaneously within days (Chandler, 1983; McGuirt and Stool, 1995; Brodie and Thompson, 1997). Surgical interventions are aimed at reducing the symptoms and risk of infection in cases with persistent CSF leaks or fistulae. Studies have reported infection rates between 7% and 30% for TBI patients with CSF leaks, with each day of leakage increasing the risk of ascending intracranial infection (Leech and Paterson, 1973; Spetzler and Wilson, 1978; Brodie and Thompson, 1997; Savva et al., 2003; Nyquist et al., 2013; Mathias et al., 2016). Lumbar drainage has been recognized as a treatment option for TBI patient with CSF leaks, in order to relieve CSF pressure aiding spontaneous and surgical repairs, while also facilitating a route to administer intrathecal fluorescein for diagnostic purposes (Shapiro and Scully, 1992; Mathias et al., 2016). However, lumbar drainage in the presence of a patent CSF fistula risks entraining intracranial air with a consequent risk of intracranial infection. The relative importance of antibiotic prophylaxis as well as the selection of the high-risk candidates for surgical intervention remain to be defined (Rimmer et al., 2014). However, the Centre for Disease Control and Prevention recommends either the pneumococcal conjugate vaccine (PCV13) or the pneumococcal polysaccharide vaccine (PPSV23) for patients with CSF leaks (CDC, 2015b). In the United Kingdom, the National Institute of Clinical Excellence recommends pneumococcal vaccination for all skull base fractures.

Investigation and management of carotid or vertebral dissection

Post-traumatic dissection of the internal carotid (ICA) or vertebral artery (VA) is most prevalent in young TBI patients (Rubinstein et al., 2005). Mechanisms include motor vehicle accident, falls, hangings or sport accidents, and may lead to a stroke in an acute or delayed fashion from acute vessel occlusion or thromboembolism (Geddes et al., 2016). The mechanism of injury can be direct compression of the arteries against bony structures owing to flexion, extension and rotational head movements or acceleration/deceleration that results in shearing forces to the vessel endothelium. The VA is commonly dissected at the C1–C2 level by rotational forces or directly due to a fracture or dislocation of facet joints or transverse processes, whereas the ICA can be compressed between the spine and mandible (Blacker and Wijdicks, 2004). Clinically, dissections can present as TIA, stroke, or SAH. There is often a silent period between the injury and onset of neurological symptoms. Patients with polytrauma with impaired consciousness due to the head injury itself or the use of sedatives, can make the clinical diagnosis difficult (Blacker and Wijdicks, 2004). Prognosis is variable, as dissections can vary from being asymptomatic to causing profound neurological deficits and death (Mohan, 2014).

Dissections are initiated with a tear on the innermost intimal layer or the media layer of the blood vessel wall. Extravasation of arterial blood under pressure can extend the dissection between intima and tunica media creating luminal narrowing or occlusion. A subintimal dissection may result in an intramural hematoma with consequent luminal stenosis. Dissection within the intracranial cavity may also

lead to aneurysmal dilatation and haemorrhage into subarachnoid space. Rupture of an artery with subsequent encapsulation of the extravascular hematoma may or may not produce luminal narrowing (Yamaura, 1994). Distal embolization occurs due to platelet aggregation stimulated by exposed surfaces or dislodged thrombus. It may also cause reduced distal flow due to occlusion of lumen due to thrombosis or mural haematoma (Mohan, 2014).

Prompt recognition and diagnosis is paramount. Cerebral ischaemia related to ICA most commonly affects the middle cerebral artery territory, whereas VA dissections affect the brainstem, cerebellum, and occipital lobes. Infarctions or haemorrhages can be visualized with CT imaging, however CT angiogram (CTA) or catheter angiography alone can demonstrate luminal stenosis, fusiform dilatations, occlusions, intimal flaps, proximal beading, double lumen signs, or a kinked appearance of vessels (Kitanaka et al., 1994; Eastman et al., 2006; Geddes et al., 2016). Magnetic resonance imaging angiogram is generally not considered as accurate as CTA or catheter angiography.

Intracranial lesions with SAH can be treated endovascularly or microsurgically (Halbach et al., 1993; Pham et al., 2011), however, in modern practice surgical management is rarely warranted. Dissecting aneurysms may be fusiform and cover a long segment that precludes microsurgical clipping or endovascular stenting, and in this circumstance may be candidates for occlusion of the VA proximal to the basilar artery. Balloon test occlusion of the dominant VA is recommended since some patients might not tolerate total occlusion (Mohan, 2014). Other surgical techniques described include a combination of VA clipping with vascular bypass, resection accompanied with autogenous interposition vein graft, usage of fusiform-type clipping, and wrapping (Arimura and Iihara, 2016). Extracranial dissections are managed medically, and this includes antiplatelet therapy or anticoagulation for a total of 6 months (CADISS trial investigators, 2015).

Surgical management of post-traumatic hydrocephalus

Post-traumatic hydrocephalus (PTH) is a complication of TBI and studies have reported clinical improvement after permanent CSF diversion (Guyot and Michael, 2000). Patients who suffered TBI and under active follow-up are usually monitored for PTH, which can present as worsening neurological status or lack of improvement associated with pressure related headaches or the normal pressure hydrocephalus syndrome. Late CSF leak is also suspicious for PTH. It is important to recognize and treat PTH, since it could both impact morbidity and mortality if left untreated (Paoletti et al., 1983; Tribl and Oder, 2000; Low et al., 2013). The incidence of PTH has been reported to range between 0.7% and 51.4% (Bontke and Boake, 1991; Guyot and Michael, 2000; De Bonis et al., 2010). However, it is often difficult to determine whether ventriculomegaly observed post-TBI is related to atrophy or hydrocephalus; computerized CSF infusion studies have been reported to be useful in distinguishing between the two different processes (Marmarou et al., 1996; Czosnyka et al., 2005). Selection of patient benefiting from permanent CSF diversion is important, since shunting is also associated with significant complications. No clear guidelines exist for PTH treatment, however adjustable or flow-regulated ventriculo-peritoneal shunts are most commonly described as the preferred choice of shunting to reduce the risk of overdrainage. PTH has been reported as a relative contraindication to endoscopic third ventriculostomy (Singh et al., 2008), however this notion has been challenged by others (De Bonis et al., 2013). It is difficult to predict the response of CSF diversion in PTH, since these patients often have comorbidities and significant underlying brain injury. Studies have also suggested that DC is a risk factor for hydrocephalus (De Bonis et al., 2010; Kolias et al., 2013) whereas others do not support this hypothesis (Rahme et al., 2010). Hydrocephalus has been described in TBI patients undergoing DC, ranging in case series between 0% and 88.2% (Ding et al., 2014). It is thought that CSF malabsorption or obstructed flow are the cause of post-DC hydrocephalus. However, the current case series are limited by their design and heterogeneity of criteria used to diagnose hydrocephalus.

Cranioplasty

Cranioplasty is the surgical reconstruction of a bone defect after a previous operation, usually DC, or due to skull injury (**Fig. 43.3**). A cranioplasty is recommended for both protection of the underlying brain that is left vulnerable to damage with a skull defect and also for restoring the skull contour that might have psychological and social consequences for the patient (Kolias et al., 2013). The cranioplasty can also facilitate neurological rehabilitation and may also improve neurological function, as observed in patients with syndrome of the trephined (Segal et al., 1994; Di Stefano et al., 2012; Bender et al., 2013; Honeybul et al., 2013). However, this procedure is associated with challenging complications; the most common are wound-healing problems and implant related infections (Gooch et al., 2009; Honeybul and Ho, 2011; Wachter et al., 2013). The wide range of techniques, graft materials (autologous bone, metal or synthetic) and timing of reconstruction (1–12 months) discussed in the literature reflects the lack of consensus and good quality evidence (Liang et al., 2007; Beauchamp et al., 2010; Yadla et al., 2011; Glover et al., 2012; Schuss et al., 2012; Bender et al., 2013; Klinger et al., 2014). There main controversy in relation to timing revolves around whether performing the cranioplasty early increases the risk of infections or not and whether it can independently improve neurological outcome. A recent systematic review of available studies (all retrospective), including 528 patients, concluded that cranioplasty may improve neurological outcome, and earlier cranioplasty may enhance this effect (Liang et al., 2007; Beauchamp et al., 2010; Yadla et al., 2011; Glover et al., 2012; Schuss et al., 2012; Bender et al., 2013; Malcolm et al., 2018). In terms of materials, the patient's own bone is the most commonly used one, as it fulfils many of the requirements of an ideal material (i.e. it has a low cost and ideal contour and additionally is biocompatible, strong, and radiolucent). However, a few reports in recent years have shown a high failure rate due to resorption or infection; this was confirmed by a recent single-centre RCT of autologous cranioplasty versus titanium cranioplasty which found that of the 31 patients with an autologous cranioplasty, 7 patients (22%) had complete bone resorption (Honeybul et al., 2017). Acrylic cranioplasty, in the form of polymethylmethacrylate, is cheap, malleable, and lightweight. However, the fragility of the plates that can lead to fractures and the risks associated with exothermic reaction are concerns (Aydin et al., 2011). Hydroxyapatite has

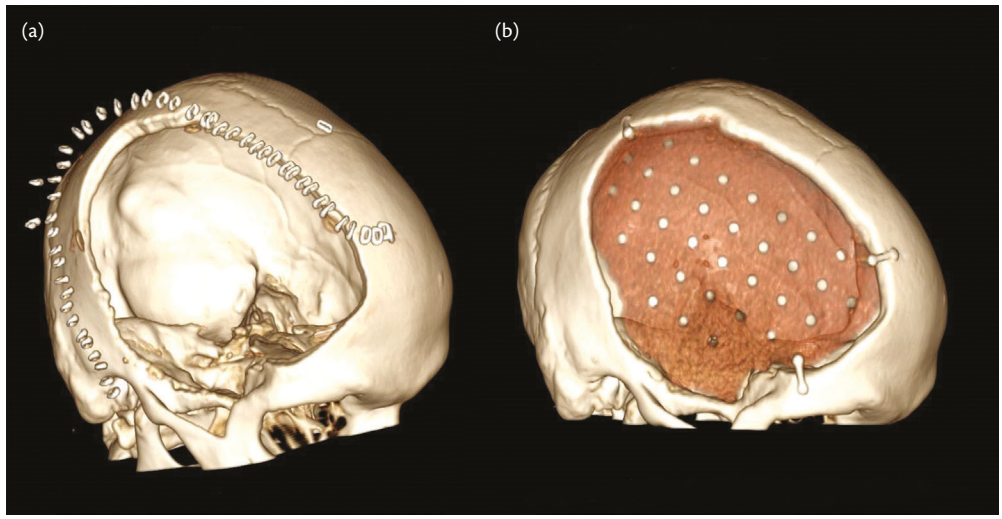

Fig. 43.3 Cranioplasty. (A) Postoperative computed tomography (CT) three-dimensional (3D) reconstructions of the head demonstrating a large calvarial defect following unilateral decompressive craniectomy for an evacuation of an acute subdural haematoma with significant intraoperative swelling. (B) Postcranioplasty CT 3D reconstructions following repair of the bony defect with customized PEEK prosthesis. Preoperative CTs were used for production of a tailored flap.

become popular in recent years, as it offers good osseointegration. Nevertheless, its cost remains high and there have been reports that the material can fracture following trauma. Titanium remains a widely used and relatively cheap option but leads to artefact on imaging. A recently published single-centre RCT of hydroxyapatite versus titanium found that the reoperation rate at 6-months (26.9% vs. 29.2% respectively) was similar, with a lower number of infections for hydroxyapatite (7.7% vs. 20.8%) but higher number of epidural haematomas (34.6% vs. 8.3%) (Lindner et al., 2017). Several other materials or combinations of materials for cranioplasty exist; detailed description of all options is beyond the scope of this chapter. Key steps of the surgical technique include careful dissection of the scalp from the dura, closure of any dural tears, exposure of bone margins circumferentially, and secure fixation of the autologous bone or artificial implant. In cases of an infection, the plate is usually removed and the wound debrided; it is important to wait until the underlying infection is clear, a process which can take up to 1 year, prior to re-inserting a plate in order to minimize the risk of further implant infection.

Complications of head injury

Fardad T. Afshari, Antonio Belli, and Peter C. Whitfield

Introduction

Complications following head injury can be classified according to the timing of the complication—early (within 1 week) or late (beyond 1 week). Complications can also be considered according to the underlying pathological process (e.g. cerebrospinal fluid (CSF) leak, vascular complications, epilepsy, CSF leak, and hydrocephalus). In addition, many rehabilitation needs are commonly identified following head injury. In the early phase, these focus around medical care (e.g. chest physiotherapy, avoidance of contractures, nutrition, and communication). In the later phases, patient-centred goal-directed therapy is of increasing importance. In this chapter we describe several early complications. Consideration is then given to delayed complications although it is recognized that classification by timing is an inexact science and there is considerable overlap between early and late complications.

Early complications of head injury

Vascular injuries

Traumatic brain injury may be associated with vascular injuries. Most of these occur as early sequalae directly related to the transmission of operant forces caused by the trauma. Rarely a vascular injury can occur as a result of penetrating injury (e.g. low velocity bullet) but is more commonly associated with bony injuries to the cervical spine and/or skull base.

Traumatic subarachnoid haemorrhage

Traumatic subarachnoid haemorrhage is the most common cause of subarachnoid blood on CT head. One-third of patients with moderate to severe head injury present with evidence of subarachnoid blood on CT head (Eisenberg et al., 1990; Servadei et al., 2002). The volume of traumatic subarachnoid haemorrhage on initial CT is associated with a worse outcome (Paiva et al., 2010).

Although vasospasm can occur following traumatic subarachnoid haemorrhage, this complication is not as common as vasospasm following aneurysmal subarachnoid haemorrhage. A systematic review found no evidence to suggest nimodipine improves outcomes in patients with traumatic subarachnoid haemorrhage (Vergouwen et al., 2006).

Carotid and vertebral artery dissection

Carotid dissection is the most frequent vascular injury and usually occurs in the extracranial or skull base segments at points of tethering or fracture (Fig. 44.1). Similarly, vertebral artery dissection occurs in the V2 and V3 segments where the artery enters and exits the foramen transversarium. Trauma to the carotid or vertebral arteries can cause an intimal tear resulting in a dissection with an associated false lumen. Expansion of this false tract can lead to occlusion of the parent vessel causing downstream infarction. Localized trauma to a vessel can lead to formation of mural thrombus and partial or total occlusion in the absence of dissection. A thrombus in a partially occluded vessel can cause distal emboli typically affecting watershed areas of the brain. Rarely a traumatic injury may cause a pseudoaneurysm that can cause a spontaneous post-traumatic intracranial haemorrhage. CT angiogram, MR angiogram and digital subtraction cerebral angiography are the most sensitive studies in the investigation of vascular injuries in traumatic brain injury. Antiplatelet therapy is the main mode of treatment for dissection injuries, although consideration must be given to concomitant intracranial or extracranial haemorrhagic injuries. Endovascular treatment is an option in some cases; however, most traumatic dissections tend to heal spontaneously in a matter of weeks. Wherever possible, the management of a traumatic dissection should involve neurosurgery, stroke medicine, and interventional radiology in a multidisciplinary fashion.

Arteriovenous fistulae

Although rare, arteriovenous fistulae can form following traumatic brain injury. These may present in the first week or may have a delayed appearance. The most common location for fistula formation is between the cavernous portion of carotid artery and the cavernous venous sinus. The incidence of carotico-cavernous fistulae (CCF) following head trauma is 0.2–0.3% (Fabian et al., 1999). These direct fistulae are true connections between a ruptured intracavernous carotid artery and the surrounding venous channels within the cavernous sinus and are therefore high flow and likely to be symptomatic (see Chapter 49). Clinically this condition can present with the triad of pulsatile proptosis, conjunctival injection, and bruit. The management of such fistulae is predominantly endovascular and aims to preserve ocular function and prevent cortical venous reflux and its haemorrhagic sequelae. Indirect CCF do not typically occur

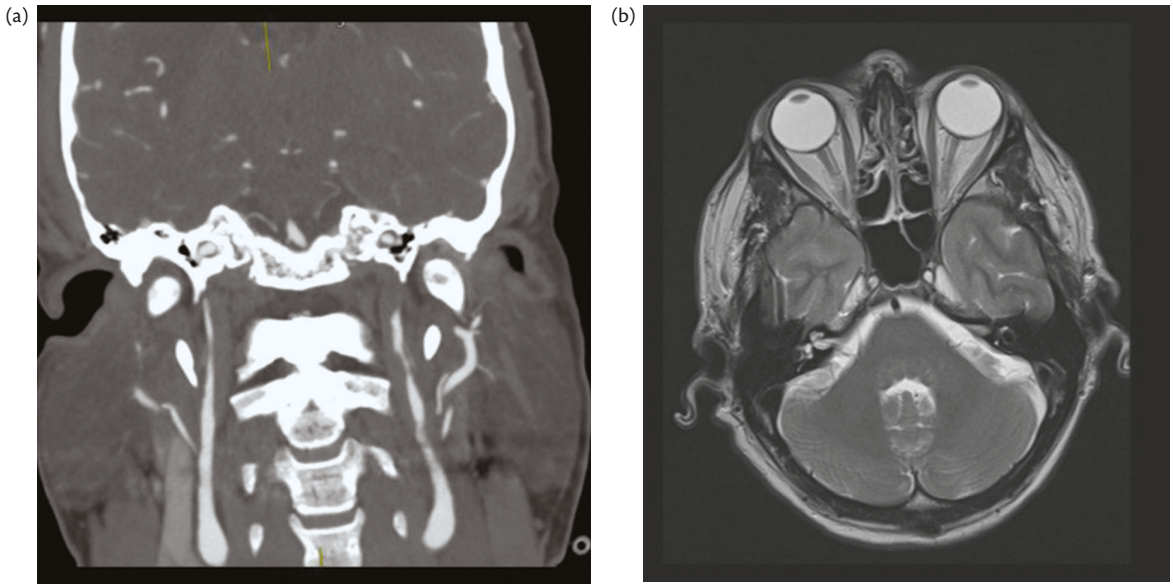

Fig. 44.1 Bilateral carotid dissection. (A) CT angiogram showing bilateral tapering of internal carotid indicative of dissection. (B) T2-weighted MRI demonstrating high signal within carotids. Normally the major vessels demonstrate flow voids (low signal such as in the basilar artery), however this is lost with carotid occlusion.

acutely following trauma, although, if identified in a patient with trauma, they can be managed less acutely and sometimes spontaneously regress.

Cranial nerve injuries

Cranial nerve injuries are common following head injury. Although they are almost always present as an early post-traumatic complication, it is not until the rehabilitation phase that the effects of a palsy become prominent. Cranial nerve palsies may result from traumatic disruption of cranial nerves, particularly at the interface with the exiting skull foraminae. They may also occur consequential to the effects of raised ICP (e.g. third nerve palsy, sixth nerve palsy, and seventh nerve palsy). Damage to the olfactory nerve is common, with or without anterior skull base fractures, as the delicate olfactory nerves are easily injured as they pass through the cribriform plate. The olfactory nerves can slowly recover in some cases, but the sensory loss is usually permanent; in addition, loss of smell can affect the sensation of taste due to overlapping perception of taste and olfaction.

Optic nerve transection or compression due to facial and orbital bone fractures typically presents with unilateral visual loss. A relative afferent pupillary defect is normally present. Visual impairment after trauma always warrants urgent radiological investigation and an ophthalmological consultation. Diplopia following head injury is common and can occur due to damage to oculomotor, trochlear, or abducent nerves and should be differentiated from non-neural, mechanical mechanisms of diplopia such as an orbital wall fracture or damage to the trochlear sling within the lateral orbit.

Temporal bone fractures can cause a range of deficits, particularly if they involve the otic capsule. Historically, these were divided into longitudinal fractures (along the long access of the petrous temporal bone) or transverse fractures. Transverse fractures being less common but more likely to cause sensorineural hearing loss and facial palsy. The involvement of the otic capsule is now recognized as the pre-eminent factor that influences cranial neuropathy. The deficits include facial nerve palsy, hearing loss, and CSF leak. Facial nerve palsies can recover over time, but the cornea must be protected if exposed. Evidence to justify the use of corticosteroids in the treatment of traumatic facial nerve palsy is weak. Early involvement of speech and language therapy and physiotherapy is recommended. Facial nerve reanimation techniques can be considered for permanent disabling deficits.

Hearing loss is a common presentation following head injury associated with temporal and petrous bone fractures. Hearing deficits may be conductive or sensory in nature. Conductive hearing loss is due to occlusion of the auditory meatus with blood, damage to tympanic membrane, or disruption of the ossicular chain. The latter may be amenable to surgical treatment and should be investigated with a high resolution fine-cut CT scan. Otological input is advised to guide further investigation and treatment. Sensorineural deafness can occur due to damage to the cochlear structures or the cochlear nerve itself. This can arise from fracture of the petrous temporal bone or secondary to nerve ischaemia caused by raised ICP.

Lower cranial nerve palsies can occur individually or in combination. These are usually secondary to occipital bone fractures extending to the jugular foramen. Different syndromes associated with lower cranial nerve palsies have been documented in the context of both tumour and trauma and are summarized in Table 44.1.

Depressed skull fractures

Traumatic brain injury is commonly associated with depressed skull fractures. Depressed fractures should be identified on the initial CT imaging and can be well visualized with volumetric reconstructions. Depressed skull fractures may be associated with underlying brain contusions, extradural, or subdural haematoma. In addition, they may be associated with a dural breach, increasing the risk of delayed infection, seizure, meningitis, or empyema. Absolute indications for elevation of a depressed skull fracture include treatment of an

Table 44.1 Jugular foramen syndromes

Syndrome	IX	X	XI	XII	Sympathetic
Villaret	Yes	Yes	Yes	Yes	Yes

Tapia	No	Yes	No	Yes	Yes/No
Jackson	No	Yes	Yes	Yes	No

open fracture that necessitates debridement of bone fragments and, in some cases, dural repair. Pericranium or temporalis fascia is the preferred material for dural repair. Relative indications for repair include significant fragment depression (+/- haematoma) causing mass effect, depression greater than the width of the bone and cosmetic defects. Any depressed fractures overlying the venous sinuses should be managed cautiously due to the risk of catastrophic haemorrhage following fracture elevation.

Early CSF leak

CSF rhinorrhoea and otorrhoea are common complications of skull base fractures and indicate breach of the dura. CSF rhinorrhoea can occur from complex ethmoidal fractures breaching the anterior fossa dura. CSF rhinorrhoea can also occur as a result of CSF egress via the aerated portion of the temporal bone, into the middle ear then through the Eustachian tube into the nasopharynx. CSF otorrhea can occur from a temporal bone fracture that is associated with a perforated ear drum. Up to 90% of these CSF leaks resolve spontaneously within 2 weeks. The remainder of the patients may continue to have persistent leak or develop delayed CSF leak. Antibiotic prophylaxis is not indicated, but antibiotic treatment should be instigated without delay if signs of meningitis develop. Antipneumococcal vaccination is also recommended in all skull base fractures or proven or suspected CSF leakage (Phang et al., 2016). For those patients with persistent CSF leak beyond 2 weeks, there is some contention as to the best subsequent treatment. CSF drainage by lumbar drain is very effective for minimizing the flow through the site of leak and therefore promoting healing. However, if the fistula is large, this may entrain air into the intracranial cavity, and caution must be used in any patient with presumed raised intracranial pressure to avoid tonsillar descent.

Although CSF rhinorrhoea or otorrhoea may be clinically evident, there are occasions that CSF leak post injury maybe difficult to distinguish from nasal discharge. In such cases, manoeuvres such as leaning the head forward may accentuate the CSF leak and further suggest CSF rhinorrhoea. Alternatively, if a CSF sample can be collected, it can be tested for beta-transferrin which is found at high levels in CSF. Glucose testing is unlikely to be helpful as nasal secretions may also contain glucose (Baker et al., 2005). **Figure 44.2** shows an algorithm for the management of a suspected CSF leak.

Pneumocephalus

Pneumocephalus (air within the cranial cavity) can occur following head trauma in association with calvarial or skull base fractures. The incidence of pneumocephalus secondary to head injury is between 0.5% and 1%. Air within the subarachnoid space indicates a breach of the dura. Patients with pneumocephalus are at high risk of CSF leak and should be closely monitored and managed as mentioned. Although small volumes of air within the cranium do not pose any danger, large amounts of air particularly when under pressure can act as a mass lesion causing midline shift. Pneumocephalus can cause a reduced level of consciousness, seizures, or focal neurological signs. The appearance of a large amount of air anterosuperior to both frontal lobes in the supine patient on axial CT scan is termed 'mount Fuji sign' owing to double peak appearance of the compressed frontal lobes (Michel, 2004). At times this can manifest as a tension pneumocephalus mandating emergency treatment. Pneumocephalus is normally managed with high-flow oxygen to reduce the partial pressure of nitrogen and encourage absorption of air from the intracranial space. Rarely, in cases of severe midline shift and tension pneumocephalus, urgent burr holes may be required to allow air egress from the subdural space.

Late complications of head injury

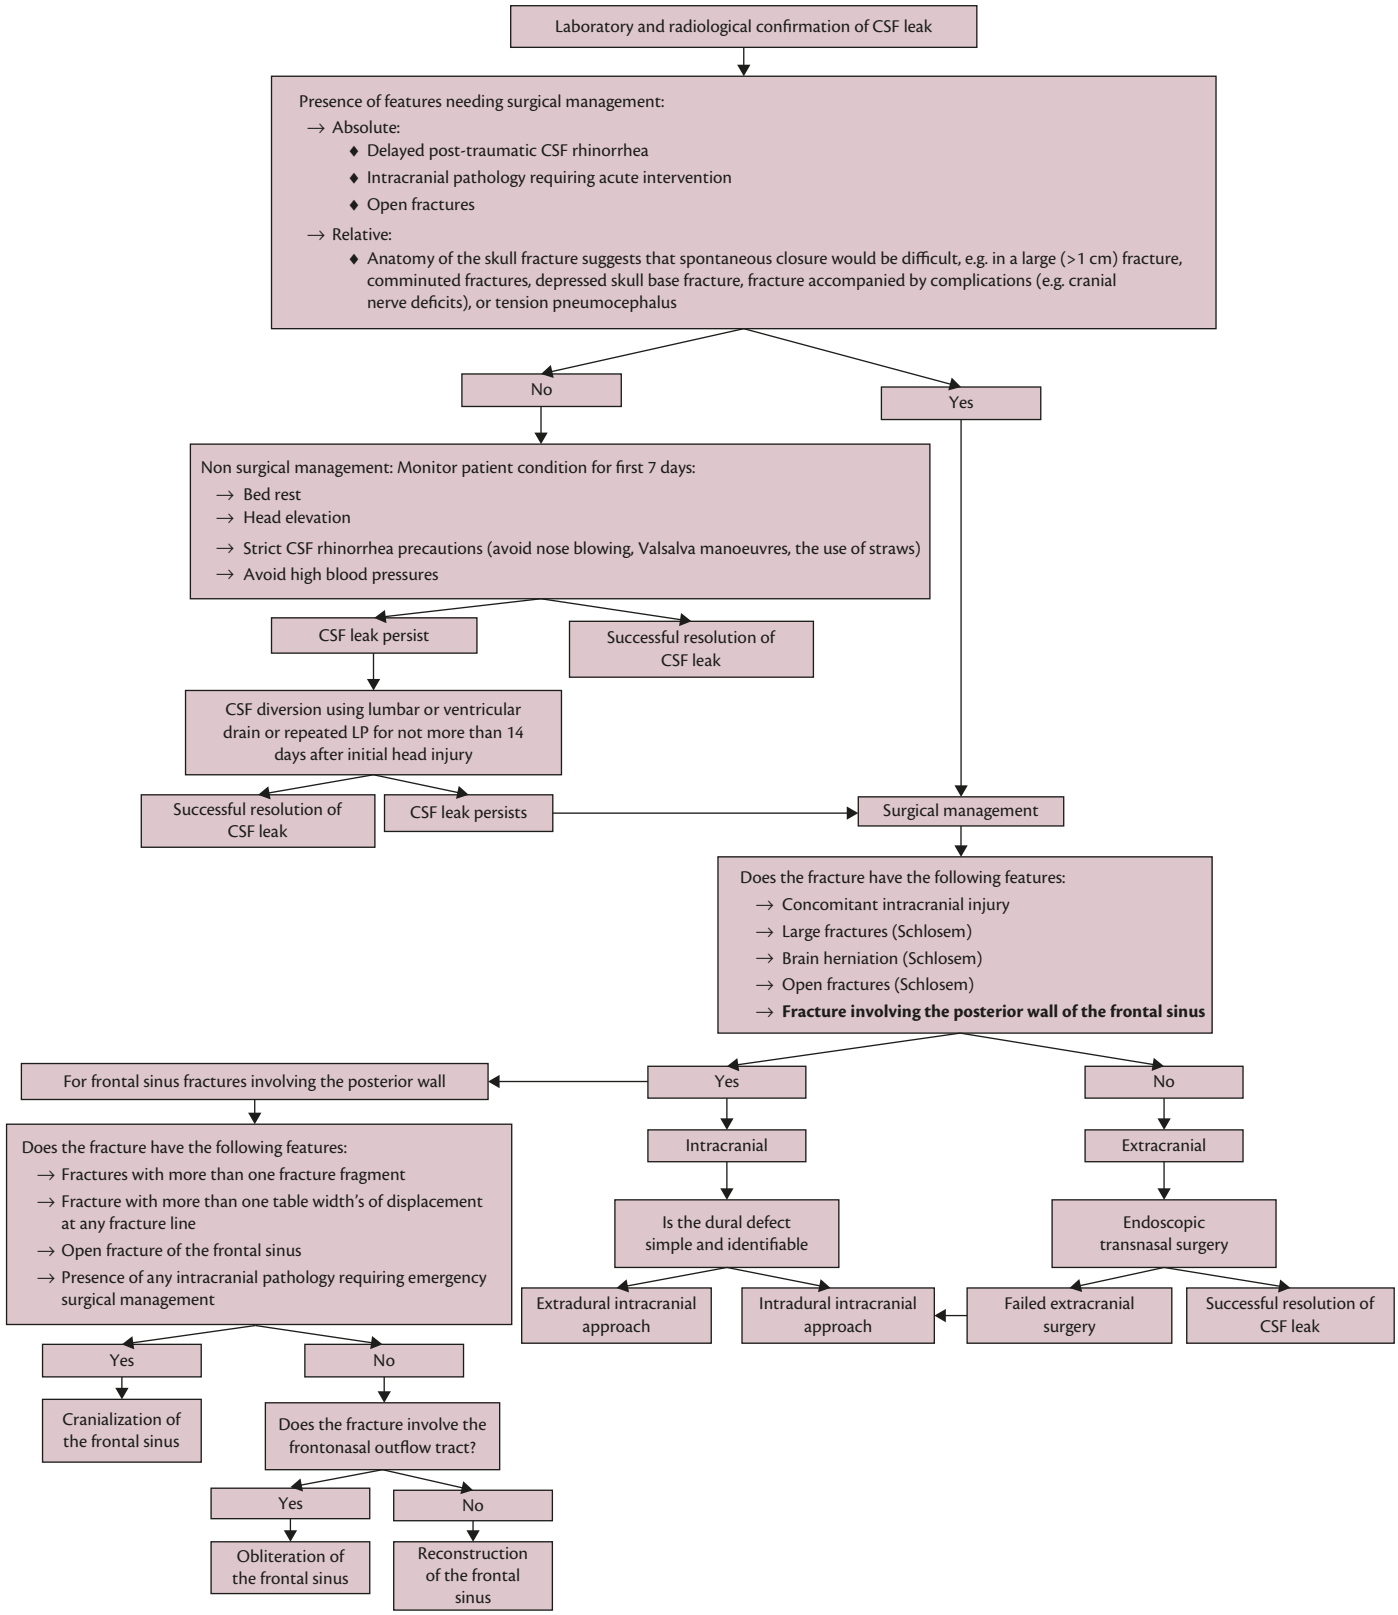
Seizures

Although seizures can present early after a traumatic brain injury, late seizures are of prime concern to recovering patients. Overall, seizures can occur in up to 30% of severe traumatic brain injury patients. In the early phase, seizures resulting in increased metabolic demand, excitotoxicity and raised intracranial pressure, and may cause severe secondary brain damage. Such issues also exist in the late phase although antiepileptics usually afford a degree of control over these processes.

The risk of seizure post head injury depends on several factors. The classical work of Bryan Jennett (pre-CT) defined the following: severity of injury, duration of PTA, presence of depressed skull fracture, and intracerebral haematoma/contusion. Patients who sustain a seizure within the first week are an increased risk of late epilepsy. Annegers et al. have defined the risk according to severity of injury, albeit also using data predominantly acquired pre-CT. Severe injury is characterized by brain contusion, intracranial haematoma, loss of consciousness, or post-traumatic amnesia for more than 24 hours. The 5-year cumulative probability of post-traumatic seizure is 10% and 30-year cumulative probability is 16.7%. Christensen's et al. study in children and young adults showed the risk of epilepsy was increased after a mild brain injury (RR 2.22, 95% CI 2.07–2.38), severe brain injury (7.40, 6.16–8.89), and skull fracture (2.17, 1.73–2.71). Overall, the risk of developing late epilepsy reduces with time, but nevertheless for patients at greatest risk, this remains above the baseline risk of the general population for 10–15 years (Jennett, 1973; Jennett, 1975; Annegers et al., 1998; Christensen et al., 2009).

There is currently class I evidence available that use of antiepileptics can lead to reduction in seizure frequency in early phase following head injury (first 7 days) but has no effect on the incidence of late onset seizures (Temkin et al., 1990). The use of prophylactic antiepileptics has no effect on mortality or neurological disability when used in the early or late phases post head injury (Schierhout and Roberts, 2001).

Traditionally phenytoin has been used as a first-line agent for seizure control in head injury patients. Recent prospective randomized studies have demonstrated that levetiracetam and phenytoin are



Laboratory and radiological confirmation of CSF leak
Presence of features needing surgical management:
→ Absolute:
♦ Delayed post-traumatic CSF rhinorrhea
♦ Intracranial pathology requiring acute intervention
♦ Open fractures
→ Relative:
♦ Anatomy of the skull fracture suggests that spontaneous closure would be difficult, e.g. in a large (>1 cm) fracture, comminuted fractures, depressed skull base fracture, fracture accompanied by complications (e.g. cranial nerve deficits), or tension pneumocephalus
No
Yes
Non surgical management: Monitor patient condition for first 7 days:
→ Bed rest
→ Head elevation
→ Strict CSF rhinorrhea precautions (avoid nose blowing, Valsalva manoeuvres, the use of straws)
→ Avoid high blood pressures
CSF leak persist
Successful resolution of CSF leak
CSF diversion using lumbar or ventricular drain or repeated LP for not more than 14 days after initial head injury
Successful resolution of CSF leak
CSF leak persists
Surgical management
Does the fracture have the following features:
→ Concomitant intracranial injury
→ Large fractures (Schlosem)
→ Brain herniation (Schlosem)
→ Open fractures (Schlosem)
→ Fracture involving the posterior wall of the frontal sinus
For frontal sinus fractures involving the posterior wall
Yes
No
Does the fracture have the following features:
→ Fractures with more than one fracture fragment
→ Fracture with more than one table width's of displacement at any fracture line
→ Open fracture of the frontal sinus
→ Presence of any intracranial pathology requiring emergency surgical management
Intracranial
Extracranial
Is the dural defect simple and identifiable
Endoscopic transnasal surgery
Extradural intracranial approach
Intradural intracranial approach
Failed extracranial surgery
Successful resolution of CSF leak
Yes
No
Cranialization of the frontal sinus
Does the fracture involve the frontonasal outflow tract?
Yes
No
Obliteration of the frontal sinus
Reconstruction of the frontal sinus

Reproduced with permission from See Yung Phang, Kathrin Whitehouse, Lucy Lee, et al., Management of CSF leak in base of skull fractures in adults, *British Journal of Neurosurgery*, Volume 30, Issue 6, pp. 596–604, Copyright © 2016 The Neurosurgical Foundation, reprinted by permission of Taylor & Francis Ltd, www.tandfonline.com on behalf of The Neurosurgical Foundation.

both effective as seizure prophylaxis agents in head injury with no significant difference in seizure control rates (Szaflarski et al., 2010). Levetiracetam has therefore become the favoured option given that treatment is effective, with a low risk of symptomatic side effects, no impact on cognition, and is relatively low cost (Eddy et al., 2011).

Patients with head injury and seizures should be informed about risks of swimming and working on open machinery. They should be advised to refrain from driving and to inform the appropriate driving regulatory agency.

The decision to stop antiepileptic medication in the longer term, once a patient has been seizure free for a period of time, is a difficult one. The risk of seizures is likely to decline as time progresses from the initial injury, however no specific guidelines exist. A decision on stopping antiepileptics needs to balance the complications and risks of prolonged therapy against the risk of a further seizure that can risk injury and lead to further limitations in driving and independence.

Hydrocephalus

Hydrocephalus can occur both in acute or late phase following head injury. Acute hydrocephalus is rare following head injury and tends to be associated with intraventricular haemorrhage. In some units, ventricular drainage is performed as an adjunct in the management of raised ICP. This is normally a temporary measure and is not usually indicative of hydrocephalus. Late phase hydrocephalus following head injury appears to be a separate pathophysiological entity. The incidence of post-traumatic brain injury hydrocephalus is variable depending on the criteria used in the studies. Kammersgaard et al. reported post-traumatic hydrocephalus in 14.2% of patients with majority of patients presenting during the rehabilitation (Kammersgaard et al., 2013). Many patients present with a plateau in their recovery, often in association with the triad of symptoms associated with idiopathic normal pressure hydrocephalus (gait disturbance, cognitive decline, and urinary urgency or incontinence). The exact mechanism underlying late phase hydrocephalus after head injury is not fully understood. Imaging normally demonstrates communicating hydrocephalus and lumbar puncture may demonstrate normal opening pressures. Patients with delayed hydrocephalus can however present with reduced level of consciousness and drowsiness even following a long period of recovery. Patients with hydrocephalus benefit from CSF diversion procedures such as a ventriculoperitoneal shunt. Uncertainty concerning the diagnosis is however a confounding issue: the differential diagnosis of ex-vacuo dilatation of the ventricles following post-traumatic cerebral atrophy should be considered, as, in this case, CSF diversion will not help and may risk overdrainage with the risk of subdural collections. ICP monitoring studies and CSF infusion studies may be helpful adjuncts in the investigation of these patients.

Pituitary dysfunction

In recent years pituitary dysfunction has been increasingly recognized as a previously overlooked delayed complication of traumatic brain injury. Traumatic brain injury may be associated with pituitary dysfunction, which may contribute to long-term physical, cognitive, and psychological disability. Pituitary dysfunction can be broadly divided into anterior or posterior pituitary dysfunction and can be detected either in early or delayed phase (>6 months) following head injury. In a study by Bondanelli, anterior pituitary dysfunction was reported to be 37.5%, 57.1%, and 59.3% in mild, moderate, and severe traumatic brain injury patients, respectively but in a small cohort of patients (Bondanelli et al., 2004). Other studies have reported rate of anterior pituitary dysfunction at 20–25% following traumatic brain injury (Agha et al., 2007; Alavi et al., 2016). The most common alterations in anterior pituitary hormones appear to be deficiency of gonadotrophins and growth hormone, followed by ACTH and thyrotropin. Symptoms of pituitary dysfunction, such as fatigue, depression, and sexual dysfunction, overlap with postconcussional symptoms; therefore, post-traumatic pituitary insufficiency can remain undiagnosed unless specifically investigated with specific endocrinology tests. Tests in the acute phase do not accurately predict long-term dysfunction and it is important to monitor symptomatic patients in the first year after injury. The notable exception is cortisol insufficiency, which can appear very early on and is potentially a life-threatening emergency: requiring immediate hydrocortisone replacement.

Posterior pituitary dysfunction can also lead to major complications following head injury. Abnormalities of this axis can occur in both the early and late phases. The syndrome of inappropriate antidiuretic hormone secretion (SIADH), diabetes insipidus, and cerebral salt wasting are three conditions that can lead to electrolyte imbalance following head injury. Clinical assessment of patient fluid status and measurement of plasma and urine sodium and osmolality are crucial in delineating the cause of electrolyte imbalance in these patients.

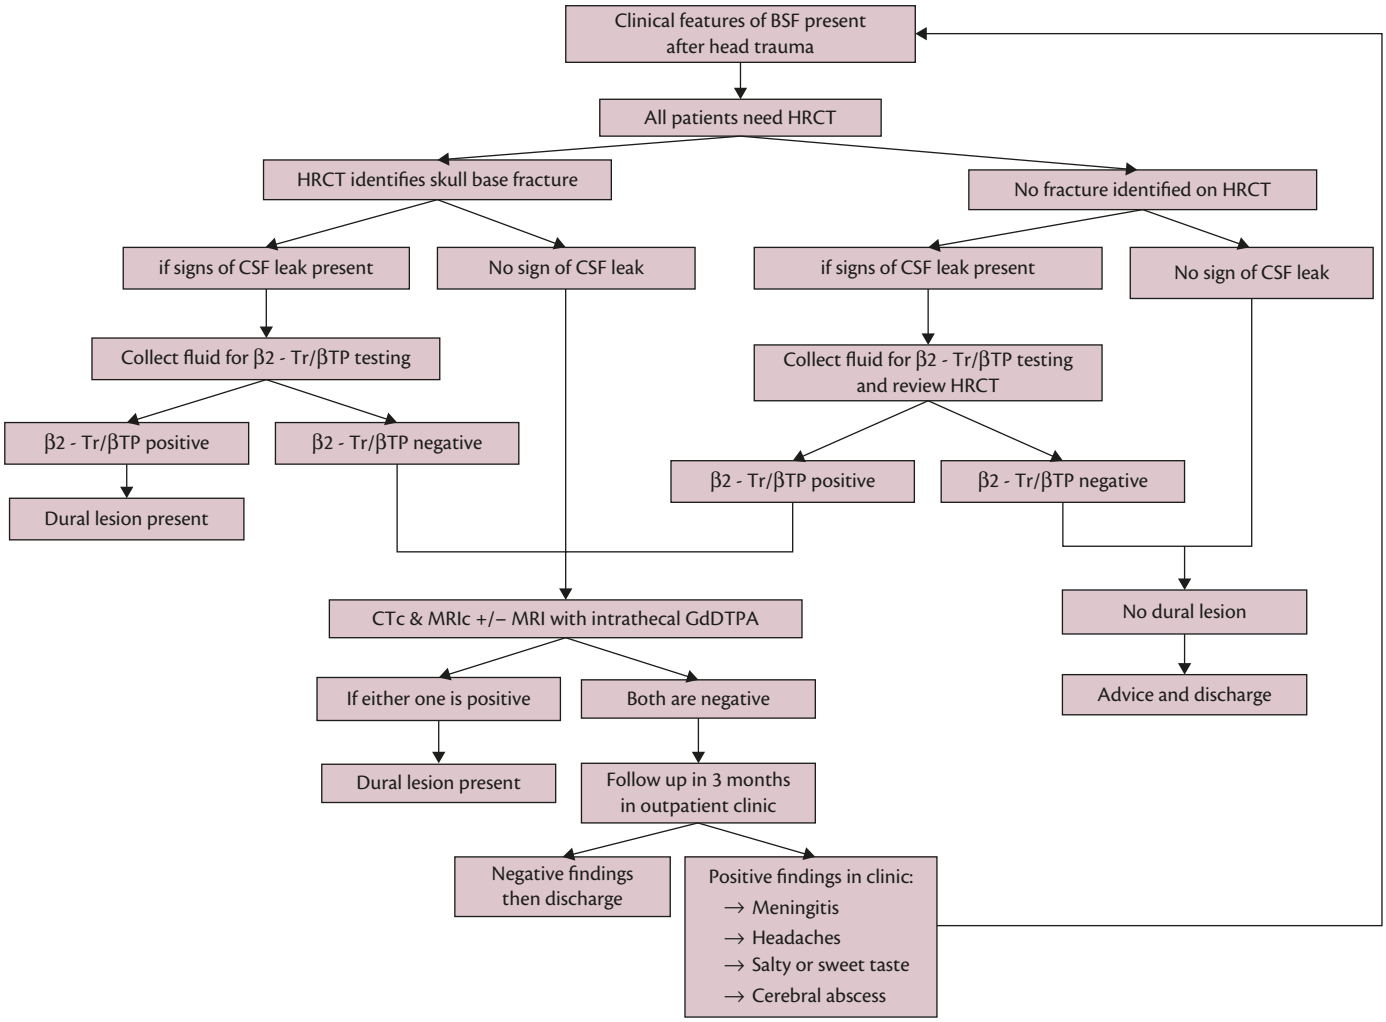
SIADH is the most common posterior pituitary/hypothalamic dysfunction syndrome and is reported to affect 33% of patients with head injury. Uncontrolled release of antidiuretic hormone (ADH) can lead to excessive fluid resorption resulting in serum hyponatraemia and reduced plasma osmolality. The patient is also in a state of relative fluid overload. This should be differentiated from hyponatraemia secondary to cerebral salt wasting: this is related to brain natriuretic peptide causing excessive sodium excretion in conjunction with a reduction in total body water.

Diabetes insipidus is associated with impaired release of ADH leading to excess diuresis and dehydration in association with hypernatraemia. Replacement therapy with DDAVP nasal spray may be required.

The British Neurotrauma Group has published guidance for the screening and management of pituitary dysfunction following traumatic brain injury in adults (Tan et al., 2017).

Delayed CSF leak

Although the majority of CSF leaks post head injury resolve within 2 weeks of injury, there are cases where persistent otorrhoea or rhinorrhoea continue and require surgical intervention (Phang et al., 2016). Fractures of the posterior wall of the frontal sinus are one of the most common injuries where persistent CSF leaks occur. In addition to persistent CSF leak since the time of injury, delayed CSF leakage sometimes occurs years following the injury, which may be due to re-opening of the fistula or coexistent hydrocephalus. Thin-slice cranial CT scan with 3D reconstruction provides the necessary anatomical detail to delineate the site of CSF leak. Due to the serious infective complications associated with CSF leaks, a systematic approach to the management of patients with skull base fractures is advisable. An algorithm for management is provided in **Figure 44.3**.



Clinical features of BSF present after head trauma
All patients need HRCT
HRCT identifies skull base fracture
No fracture identified on HRCT
if signs of CSF leak present
No sign of CSF leak
if signs of CSF leak present
No sign of CSF leak
Collect fluid for β2 - Tr/βTP testing
Collect fluid for β2 - Tr/βTP testing and review HRCT
β2 - Tr/βTP positive
β2 - Tr/βTP negative
β2 - Tr/βTP positive
β2 - Tr/βTP negative
Dural lesion present
CTc & MRIc +/– MRI with intrathecal GdDTPA
No dural lesion
If either one is positive
Both are negative
Advice and discharge
Dural lesion present
Follow up in 3 months in outpatient clinic
Negative findings then discharge
Positive findings in clinic:
→ Meningitis
→ Headaches
→ Salty or sweet taste
→ Cerebral abscess

Fig. 44.3 Algorithm for the investigation and treatment of a skull base fracture (HRCT, high resolution CT).

Formal skull base repair of troublesome CSF leaks is challenging. At the anterior skull base, a bicoronal flap can be raised and the pericranium delivered through an anterior 'letterbox' at the inferior extent of the craniotomy in order to provide a vascularized flap to cover the site of leak either extradurally or intradurally. This is a significant surgical undertaking and risks anosmia. Alternatively, endonasal endoscopic repair with a nasoseptal flap provides a much less invasive approach providing there is accurate localization of the leak. This approach may be augmented with the use of soft tissue (such as fascia lata graft or a vascularized nasoseptal flap), tissue glues, and lumbar CSF drainage with good effect. The leak can be identified using fine-cut bone kernel CT scan, contrast-enhanced CSF studies on CT/MRI (iodinated contrast or gadolinium delivered via the lumbar cistern), or fluorescein instillation into the lumbar cistern to allow intraoperative localization. Lateral skull base leaks can be more challenging and may require surgical approaches such as middle cranial fossa craniotomy, transmastoid or combined procedures (Phang et al., 2016). Ultimately, blind sac closure (obliteration of the Eustachian tube) can address the final common pathway for these leaks but at the cost of hearing.

Infections post CSF leak and skull fracture

Skull fractures or persistent CSF leaks following head injury can increase the risk of subsequent meningitis or delayed subdural empyema. Patients with penetrating trauma or gunshot wounds are at highest risk due to contamination and breach of the dura. Management of patients with contaminated wounds requires debridement, washout, and dural repair. Intravenous antibiotics are indicated for such contaminated or infected open fractures.

Skull base fractures associated with CSF leak pose a high risk of meningitis and delayed infection, and require specific attention. The incidence of meningitis post severe head injury ranges from 0.2 to 17.8% (Helling et al., 1988). The use of prophylactic antibiotics in patients with CSF leak is not supported by current literature. A Cochrane review of randomized controlled trials concluded that there is no evidence for prophylactic antibiotic use in patients with skull base fractures, whether there is evidence of CSF leakage or not (Ratilal et al., 2015). Pneumococcal vaccination is recommended for all skull base fractures given that *Streptococcus pneumoniae* is a common pathogen, although the evidence based for this treatment

is poor. In persistent cases of CSF rhinorrhoea or otorrhoea, repairing the defect is advocated to prevent delayed risk of infection.

Growing skull fractures

Skull fractures in paediatric population (particularly below age 3), when associated with dural tear, can progress to enlarging skull defect over time and are termed growing skull fractures. Interposition of a fold of arachnoid between the edges of the fracture transmits CSF pulsation into this space and can lead to progressive expansion of the defect with subsequent herniation of the neural elements. The herniated brain and the formation of cystic arachnoidal elements is called a leptomeningeal cyst. The incidence of growing skull fracture is reported to be between 0.05% to 1.6% (Muhonen et al., 1995). This normally occurs in the weeks to months following a fracture. Therefore, monitoring skull fractures in the paediatric population, particularly below age 3, is recommended. Treatment of leptomeningeal cysts involves craniotomy and exposure of the dural tear. Following repair of the dural tear, the bone flap is replaced to cover any bony defect. In advanced cases, extensive reconstructive surgery or ventriculoperitoneal shunting is required to allow correction of brain herniation and the bony defect.

Chronic subdural haematoma

Chronic subdural haematomas are generally considered to develop as a delayed complication of a minor traumatic brain injury. In clinical practice many patients have no recollection of trauma so other mechanisms of pathogenesis may exist. The incidence of chronic subdural is 5 per 100 000 in general population with increasing incidence linked to an ageing population (Santarius and Hutchinson, 2004; Whitehouse et al., 2016). Chronic subdural haematomas classically occur following a long delay after head injury. This delay can range from weeks to months. An initial minor head injury, which may go unnoticed by the patient, can lead to tears in bridging veins leading to low flow bleeding and acute subdural haematoma. Liquefaction of the haematoma over time leads to progressive compression of the underlying brain. Patients may present with headaches, reduced level of consciousness, seizures, or focal neurological deficits. Symptomatic chronic subdural haematomas can be managed surgically using burr hole evacuation. Cases complicated by recurrence or significant membranes may be managed with mini-craniotomy to allow better access to vascularized membranes that may occur over the clot. The role of steroids in management of chronic subdural haematoma remains controversial with no reported randomized trials reported in the literature. Randomized trials assessing the efficacy of steroids in chronic subdural haematoma are currently underway

Postcraniectomy complications

Following craniectomy, several specific problems can occur that require special consideration. Focal neurological deficits related to the area of brain below the craniectomy defect are termed the 'syndrome of the trephine'. This may relate to venous congestion due to kinking of the draining veins at the edge of the craniectomy or due to deranged cerebral blood regulation. These deficits may reverse following reconstitution of the integrity of the skull cavity.

Hydrocephalus in the context of a craniectomy can be difficult to assess as with an open craniectomy defect, the pressure that normally accumulates within a closed skull to drive the passive resorption of CSF, is absent. Ventriculoperitoneal shunting in the presence of a craniectomy defect is susceptible to overdrainage and sinking of the craniectomy flap. In this case, if the skull integrity can be reconstituted with cranioplasty this can sometimes aid CSF resorption, and if there are further concerns about hydrocephalus, this is a better juncture to consider CSF diversion.

Post-traumatic encephalopathy and dementia pugilistica

Post-traumatic encephalopathy can develop many years after a traumatic brain injury (TBI). Evidence from contact sports such as boxing and rugby suggests that repeated head trauma can lead to neuropathological changes including accumulation of beta-amyloid, neurofibrillary tangles, cerebellar degeneration, gliosis, and cortical atrophy. Patients may present with a wide range of symptoms including affective disorders, gait disturbance, cognitive decline, and parkinsonism. This chronic traumatic encephalopathy is sometimes referred to as punch drunk syndrome, or dementia pugilistica (McKee et al., 2009). This syndrome has been reported in association with a single severe injury or repeated concussion over a long period of time, such as sustained by contact sport players, and combat personnel. The pathophysiology is complex as it does not occur in every instance, and may reflect a genetic predisposition towards tau deposition in vulnerable individuals. There are currently no therapies available for this condition.

Neurorehabilitation following head injury

Rehabilitation is the process of facilitating the recovery of the patient postinjury and aims at maximizing quality of life and the patient's ability to participate in activities of daily living, work, and leisure.

Traumatic brain injury is a heterogeneous condition and the consequences of head injury are wide depending on the location of the injury and severity of head injury.

The neurorehabilitation service should be delivered by a multidisciplinary team involving medical, nursing, occupational therapy, speech and language therapy, neuropsychology, physiotherapy, social work, and psychiatry.

The process of rehabilitation starts with assessment of the patient to determine the nature of cognitive, emotional, and behavioural impairment, and to identify the functional consequences. A patient-centred goal setting process is then undertaken identifying short-term and long-term goals. This is a dynamic process depending on patient's changing needs (Holliday et al., 2007).

Neuro-rehabilitation has both acute and postacute and community components. Acute phase rehabilitation places a significant focus on the medical condition of the patient. Physiotherapy in the acute setting aims at optimizing chest function and oxygenation. This involves attention to positioning of the patient, chest physiotherapy, manual chest techniques of sputum expectoration, regular suctioning with pre- and post-treatment hyperoxygenation.

Speech and language therapy, in the acute phase is normally focussed upon difficulties with swallowing. The incidence of swallowing disorders following TBI is unknown. Post-traumatic impairment in the level of consciousness and tracheostomy can lead

to dysphagia. Many of these patients are at increased risk of aspiration, particularly if there is any coexistent gastroparesis. Early assessment of swallowing allows an appropriate route of feeding to be established, preventing unnecessary weight loss and malnutrition. Once swallowing reflexes resume an appropriately textured diet can commence.

Occupational therapy in the acute phase focuses on reduction of impairment and the prevention of complications to maximize long-term function. This involves evaluation of cognitive, motor, sensory skills of the patient allowing appropriate and meaningful goals to be established. Cognitive assessment establishes the level of awareness in this group of patients and facilitates their interaction with the environment. Motor and sensory assessment allows appropriate management and provision of equipment such as splints, seating, wheelchairs and various specialized positioning aids and orthoses to allow maximal function and prevention of long-term complications of muscle disuse (Whitfield, 2009).

Acute neuropsychological input aims at dealing with large array of behavioural and psychological issues caused by TBI. Neuropsychologists develop individualized behavioural management programmes and make recommendations to health professionals and staff about modifying approaches to provide the patient with the optimum environment for rehabilitation (Wilson and Zangwill, 2003). In addition, neuropsychological input can provide education to patients' families allowing a better understanding of the patient's behaviour and therefore enabling better coping and adaptation strategies to maximize the function of the patient.

Following acute rehabilitation of the patient, the long-term and community phases of rehabilitation ensue. This phase aims at maximizing the function of the patient on the path of recovery and is composed of similar components seen in acute phase albeit with a greater focus on promoting recovery of function, adaptation to dysfunction, and insight into psychological components with development of long-term compensatory strategies. The interaction of the patient with their environment and others is a crucial consideration in development of rehabilitation goals during this phase of care.

Physiotherapy at this stage aims at optimizing and maximizing limb function. Spasticity following head trauma is common and can have detrimental effects on patient's limb function. A long period of immobility may also have led to fixed deformities which further limit the functional recovery of the patient. Active and passive stretching of muscles aims to prevent contracture formation. Prolonged stretching of muscles is achieved by casting to reduce spasticity (Conine et al., 1990). Further control of spasticity can be achieved by use antispasmodics such as baclofen or use of botulinum toxin. In addition, physiotherapy aims to enhance proprioceptive input by moving the patient in different positions to allow better efferent control of muscles (Allum et al., 1998).

Speech and language therapy plays an important role at this stage of rehabilitation as it aims to maximize communication and interaction of the patient with others. Both verbal and non-verbal communication is impaired frequently post head injury. Although in many cases this is due to linguistic processes of language generation, in others difficulty is due to cognitive communication disorders. Patients with cognitive deficits such as impaired concentration and attention exhibit poor communication and language skills. The speech and language therapist in conjunction can identify the communication aspects that are most disabling and employ techniques aiming at resolving issues. In refractory cases, compensatory and adaptive techniques are used to assist the patient and their communication skills: technological aids may be helpful in these cases (Evans et al., 2009).

Occupational therapy during this phase focuses on functional performance and improving independence to allow patient independence in as many daily activities as possible. This is achieved by relearning basic skills such as activities of daily living including personal hygiene, dressing, meal preparation, and shopping. In addition, occupational therapy provides aids and adaptive equipment, such as specialized seating and wheelchairs to support independent living. Restorative or adaptation techniques developed by occupational therapists involve tailoring individual treatment programmes to introduce activities that the patient normally enjoys performing and to optimize their functional capacity in living independently and in regaining their role in society. Occupational therapy therefore plays an extremely important role in transition of care from hospital to community to allow ongoing holistic recovery of the patient (Evans et al., 2009).

Cognitive and neuropsychological rehabilitation is pivotal to this stage of recovery. Patients with TBI may suffer from impairments of memory, attention, executive functioning/planning, language, or perception. Various training models for improving memory, attention, executive functioning, and visuospatial function are currently under investigation and being applied that have the potential to improve our approach to cognitive rehabilitation of patients post head injury (Whyte et al., 2009).

Concussion and sports-related head injury

Mark Wilson

Introduction

Interest in concussion and sports-related injury has intensified in recent years for three main reasons: (1) it is a preventable form of brain injury; (2) there is increasing evidence that repeated injury can result in long-term neurocognitive loss; and (3) as a result there are potential medicolegal costs to organizations that, possibly inadvertently, allow this form of brain injury to occur within their sport. The long-term effects of boxing resulting in dementia pugilistica have been appreciated for some time, however the results of repeated mild head injury in other sports is now under focus.

The definition of concussion has changed over time. Traditionally sports concussion occurred if there was immediate and full loss of consciousness (LOC) of variable duration accompanied by post-traumatic amnesia at least for the event. The requirements of LOC were dropped and the Congress of Neurological Surgeons defined concussion (and it has subsequently been applied to sports concussion) as:

> *A clinical syndrome characterized by immediate and transient impairment of neural function, such as alteration of consciousness, disturbance of vision, equilibrium etc due to mechanical forces.* (Gurdjian and Volis, 1966)

Others have defined concussion as:

> *A biomechanically induced brain injury characterized by the absence of gross anatomic lesions.* (Signoretti et al., 2011)
>
> *Concussion is recognized as a clinical syndrome of biomechanically induced alteration of brain function typically affecting memory and orientation, which may involve loss of consciousness (LOC).* (The American Association of Neurology)

Concussion can have short, medium, and long-term sequelae. In the immediate period an assessment and decision on return to play is required. In the medium term, managing postconcussion syndrome and the risk of second impact syndrome should be recognized, with the longer-term risks managed at an organizational or union level.

Recently there has been a call to 'retire' the term concussion, which, as can be seen from the evolving and different definitions, is confusing. Replacing it with a term that reflects it as being on the traumatic brain injury spectrum (e.g. mild traumatic brain injury), a term that is commonly used interchangeably with concussion anyway, is probably most appropriate (Sharp and Jenkins, 2015). However, for the purposes of this chapter, the term concussion will continue to be used.

Postconcussion syndrome

Common symptoms that occur after mild traumatic brain injury (TBI) include headache, dizziness, fatigue, irritability, reduced concentration, sleep disturbance, memory impairment, anxiety, heightened sensitivity to noise and light, blurred vision, and depression. The majority of these symptoms resolve within 3 months, although in approximately one-third of patients they persist beyond 6 months.

Impact brain apnoea

Although rarely considered, early descriptions of concussion specifically mention respiratory changes and apnoea occurring (Koch and Filehne, 1874). John Hughling Jackson (1835–1911) knew that concussion if severe enough could be fatal through cardiovascular and respiratory failure and at autopsy, the brain in such cases could be normal/near normal. The animal literature reports that apnoea after relatively mild brain injury is common, and the greater the impact the longer the apnoea (Atkinson et al., 1998). These phenomena occur with very little or no visible structural defect on imaging or at post-mortem. Although not the focus of this chapter, this phenomenon should receive greater focus as it may account for a significant proportion of TBI-related death.

History and sport-related injury

The Persian physician Razes (854–925 AD) used the term concussion to describe an abnormal physiological state of the brain, separate from severe traumatic brain injury. In the thirteenth century Lanfrancus subsequently separated commotio cerebri (transient disruption due to brain shaking) from *contusio cerebri* (brain injury with bruising). In the early twentieth century, many accepted the theory that explained cerebral concussion and contusions were caused by deformation of the shape of the skull causing an anaemia of the brain.

In more modern times, concussion has become commonly associated with sport. In 1893 a shoemaker fabricated a leather helmet for an American football player who had had repeated head injuries. In 1905 the American College Football season suffered 18 deaths and 159 serious injuries which came to the attention of President Roosevelt. He ushered in rules to make the game safer. The use of leather helmets increased and in 1935 these became mandatory at the high school level and in 1939, mandatory at the college level. Between 1931 and 1940 the number of football fatalities dropped from 33 to 11. In 1950s the outer plastic rigid shell of the helmet was invented, however this enabled the head to be used as a battering ram—the protective equipment becoming a weapon. With this, fatalities increased (244 between 1961 and 1970) 75% of which were from cerebral haemorrhages. Alteration of rules and increased awareness of this between 1987 and 2008 has resulted in direct football fatalities for all levels of play in the single digits per year (Mueller and Cantu, 2011). Following a high-profile brain injury, Washington and many other states now have the Zackery Lystedt Law (named after the individual who had the TBI). In this the key provisions are: (1) education for parents, athletes, and coaches; (2) immediate removal from play during game or practice after a suspected concussion with no return to play until (3); (3) written clearance by a concussion expert for return to play; and (4) uniformity of rules for all schools who use public land (Ellenbogen, 2014).

Sport-related brain injury was historically the domain of neurosurgeons. For example, in 1941 Walter Dandy patented the first protective baseball cap insert liner (Fox, 1984). However, recent decades have seen intense interest from emergency medicine, sports physicians, and other health professionals, each bringing important aspects of diagnosis and management to this field. Despite this, the regular management of all forms of TBI by neurosurgeons provides a unique experience into the patterns of parenchymal injury and their likely sequelae. Neurosurgeons have a role to lead and be accountable in this field.

The association of concussion with sport has resulted in a definition specific to sport-related concussion. The International Symposia on Concussion in Sport define sports concussion as: *A complex pathophysiological process affecting the brain, induced by traumatic forces.* Several common features include:

1. Can be caused by direct blow to head, face, neck, or elsewhere with impulsive force transmitted.
2. Usually results in rapid onset of short-lived functional neurological impairment.
3. While neuropathological changes can occur, acute symptoms are neurological functional impairment rather than structural.
4. Can be graded and may or may not involve LOC.
5. Grossly normal neuroimaging studies.
6. Occasionally symptoms are prolonged.

There is nothing specific that separates sport-related concussion from concussion due to other mechanisms (e.g. falling off a bike) hence again this separate definition and classification only adds more confusion.

Of course, some sports can result in considerably more injury than mild TBI or concussion. For example, the forces involved in motorsport are more likely to result in immediately life-threatening injuries.

The pathophysiology of concussion

Aetiology of head injury in sport

The results of brain injury in sport have to reflect a combination of laws of physics with the specifics of neuroanatomy (and the function of the areas affected). The head can undergo sudden acceleration/deceleration events causing shearing between intracranial structures. This occurs at high velocity such as in motor-racing and horse riding in which there is external force applied to the individual. Slower velocities result where the head hits the floor or other players during tackles in contact sports such as rugby, American football and soccer, and similarly causes shearing forces. While these may often be milder, they are more likely to recur resulting in cumulative injuries.

In contrast to acceleration/deceleration of the head, other sports have a propensity to cause focal injuries where objects strike a (relatively) stationary head. This can occur with hard balls for example in golf and cricket. The type of injury can be quite different.

Concussion causes a temporary disturbance of proper functioning of the brain. If allowed to return to play, he/she may appear to play normally (especially if a regular player) with relative preservation of cerebellar and motor reflex actions. However, questioning may reveal confusion or disorders of memory.

John Hughling Jackson described an intermediate or 'middle' centre which would correlate with a midbrain-diencephalic region including the upward projections of the reticular activating system and thalamocortical projections that maintain arousal and alertness. It is likely that LOC occurs with transverse shearing forces (produced by angular accelerating rather than linear forces) specifically disrupting this area.

British Neurologists Derek Denny-Brown (1901–1981) and W. Ritchie Russell (1903–1980) demonstrated that acceleration/deceleration induced concussions in cats and monkeys caused stunning without macroscopic or microscopic lesions. Holding the head rigid when the blow was delivered reduced concussion (Denny-Brown and Ritchie Russell, 1940). Shortly after this, it was demonstrated that nerve cell loss and chromatolysis within the brainstem reticular activating system occurred in primate concussion (Gurdjian, 1975).

Sabina Strich (a British neurologist) characterized extensive white matter axonal injury in those severely concussed (Strich lesions). These patients survived because of improved immediate critical care. It became apparent that neuronal disruption not previously appreciated was occurring. Bryan Jennet (1926–2008) understood that this diffuse concussional injuries could have cumulative effects such as those that occur in boxing.

Ayub Ommaya tested Holbourn's hypothesis that annular (rotational) acceleration was more damaging through shearing forces than linear acceleration and impact forces which caused less harmful compressive and tensile (pulling) forces. Non-impact isolated translational linear acceleration had a much greater threshold to produce concussion and resulted in predominantly focal lesions (Ommaya and Gennarelli, 1974).

In the 1950s and 1960s, Richard Schneider's group extensively investigated concussion and patterns of injury in monkeys visualizing the brain through a transparent clear lexan calvarium surgically replacing skull. He suggested that instantaneous respiratory or cardiac arrest may be secondary to compression of the vertebral arteries

between the occipital condyles and C1; or direct transaxial transmission of force to the skull, cervicomedullary junction and high cord, or shear force damage caused by the tethering of the upper cervical cord by the dentate ligaments (Schneider et al., 1970).

Functional vs. structural injury

Traditionally concussion has been thought of as a 'functional' injury because of the lack of macroscopic pathology demonstrated on imaging such as CT scanning. However, there is increasing evidence that there is microstructural injury underlying the functional impairment. While not detectable on CT, injury can often be seen using advanced MRI techniques such as susceptibility weighting and diffusion tensor imaging. Advanced MRI techniques taken before and after a single season of college hockey suggest the presence of scattered cerebral microhaemorrhages and white matter injury in those who experienced concussion (Helmer et al., 2014; Pasternak et al., 2014; Sasaki et al., 2014).

At a cellular level, biomechanical injury results in potassium efflux, sodium and calcium influx, depolarization (and hence indiscriminate glutamate release), and a diffuse 'spreading depression-like' state that may account for acute postconcussive symptoms (Katayama et al., 1992). To correct this cellular ionic imbalance, adenosine triphosphate (ATP)-requiring membrane ion pumps work excessively causing hyperglycolysis, depleting ATP, and increasing ADP. In the setting of reduced cerebral blood flow this leads to metabolic insufficiency. The energy crisis results in free radical generation and more damage or possibly underlie susceptibility to further injury. It has been suggested that following the hyperglycolysis period, a state of impaired metabolism occurs lasting 7 to 10 days and is associated with some postconcussive memory symptoms (Giza and Hovda, 2014).

At a cytoskeletal level, microstructures such as dendritic arbours and astrocytic processes can be disrupted and calcium influx can result in neurofilament side arm phosphorylation and collapse breaking down axons. Axonal stretch disrupts microtublues that alters bidirectional axonal transport altering synaptic neurotransmitter release.

Diffuse axonal injury has axonal disconnection and microhaemorrhages resulting in 'moderate' and 'severe' TBI. Stretching and bending of axons as may occur in mild TBI or concussion can disrupt axonal microstructure. Axolemmal permeability increases after experimental TBI (Pettus et al., 1994). Fluid percussion models injuring the white matter tracts of the corpus callosum demonstrate unmyelinated axons are more vulnerable to injury (Reeves et al., 2005). This, in addition to anatomical factors altered shearing forces may explain greater susceptibility of some brain areas to injury. There is evidence that TBI results in altered glutamate (N-Methyl-D-aspartate) receptor subunit composition altering neurotransmission, calcium influx and both intra and extracellular cell signalling (Atkins et al., 2009). This could have functional (e.g. memory) consequences. There is a dropout of hilar GABAergic interneurons following lateral fluid percussion injury in rats (Zanier et al., 2003). All of these micropathologies could explain slowed cognition.

Inflammatory changes also occur in mild TBI with up-regulation of cytokines and inflammatory genes as well as microglial infiltration. The latter is associated with damage to the substantia nigra with implications specifically for TBI-related parkinsonism (Hutson et al., 2011). The location of these injuries clearly influences functional symptomatology (hippocampus → memory; amygdala → fear/anxiety).

Markers of concussion

The chronic sequelae of repeated concussions are classically seen in boxers, but they are becoming attributed to other contact sports as well. Aggregated tau protein is considered the pathological hallmark of 'chronic traumatic encephalopathy'. While human studies indicating a dose–response correlation are lacking, there is little doubt that boxers develop hippocampal atrophy and ventriculomegaly, strongly implying that cell death has occurred. This appears to be accelerated in elderly TBI.

N-acetylaspartate (NAA), a brain-specific compound may be surrogate marker of post-traumatic biochemical damage, and monitor concussion recovery being detectable through proton magnetic resonance spectroscopy. NAA levels are reduced in the frontal lobes of concussed adults, returning to normal over 30 days except where second injury occurs delaying return for 45 days (Vagnozzi et al., 2008).

Genetic vulnerability

Channelopathies, such as the CACNA1A mutation which is associated with familial hemiplegic migraine is also associated with an exaggerated response to mild TBI (Kors et al., 2001) and may underlie different postconcussive response to injury, or even susceptibility to second impact syndrome.

In animal studies, transgenic animals (3×TG-ApoE4) show increased tau protein accumulation after TBI (Tran et al., 2011). The role of ApoE4 in TBI and Alzheimer's is gradually becoming apparent (Wilson and Montgomery, 2007).

Imaging concussion

Standard MRI techniques can falsely reassure that there is no structural injury. Gradient Echo and susceptibility weighted imaging can demonstrate small microbleeds (**Fig. 45.1**). Diffusion tensor imaging can demonstrate specific white matter tract disruption. While these have previously been mainly research techniques, they should now be considered clinically for those with persisting concussion symptoms. Positron emission tomography imaging can be used to demonstrate B-amyloid and tau pathology which may be of clinical use in the future.

Symptoms of concussion

The classification of concussion has evolved since the first mild, moderate and severe grades proposed by Thorndike in 1948 (Thorndike, 1948). Many others including Schneider (Schneider and Kriss, 1969) and Kelly (Kelly et al., 1991) have proposed other systems with the most recent being a revised version by Cantu (**Table 45.1**) (Cantu, 2001).

Grading concussion on the duration of LOC and amnesia, does not truly reflect the nature or severity of the underlying injury, though on average on a population basis, longer unconsciousness probably reflects greater injury.

Management of concussion

Figures vary, but concussion usually resolves for most patients within a few weeks of injury.

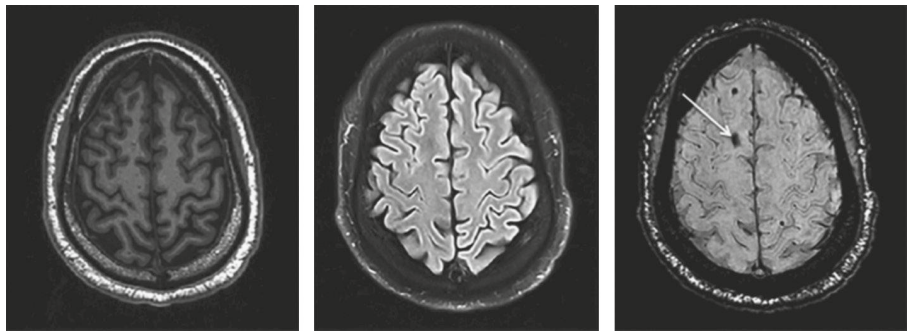

Fig. 45.1 A microbleed is clearly identified on susceptibility weighted MRI, but not seen on standard T1 of fluid attenuated inversion recovery.

Immediate management

Removal from play

Prior to removal from play, a sports club should undertake preseason planning (specific to sport and venue), assessment and education such that removal (or not removal) from play decisions are not made without forethought. Planning comprises immediate and long-term plans incorporating emergency management of immediately life-threatening head injuries. Assessment of individuals requires a comprehensive history of previous concussions and preexisting conditions that can modify concussion (e.g. migraine, depression, and anxiety).

Sideline assessment

The most universal assessment tool is the Sport Concussion Assessment Tool, or SCAT (3rd edition) (http://bjsm.bmj.com/content/47/5/259.full.pdf). This is the accepted tool for many organizations such as FIFA and the Olympic committee. It is suitable for those over 13 (there is a Child SCAT for those under). Within the initial assessment, if the player lost consciousness, has balance or incoordination issues, is disorientated or confused, has memory loss, or looks blank or vacant, then they should be withdrawn from play and not return for the day. There is a Glasgow Coma Scale (GCS) and Maddocks score component. Beyond this is a symptom evaluation including cognitive assessment (orientation, memory, and concentration), neck, balance, and coordination examinations.

Return to play

At the 4th International Conference on Concussion in Sport (2012), it was unanimously agreed that no return to play on the day of concussive injury should occur (McCrory et al., 2013). This is in agreement with American Academy of Neurology guidelines (Giza et al., 2013). Current guidelines suggest a stepwise supervised programme increasing from no activity (day one), to light aerobic exercise, sport specific exercise, non-contact training, full contact practice before return to normal play with at least 24 hours between each of these stages.

Table 45.1 Revised classification of concussion by Cantu

Grade I	No loss of consciousness, posttraumatic amnesia/ postconcussion signs or symptoms <30 mins
Grade II	Loss of consciousness <1 minute or posttraumatic amnesia >30 min but <24 hours, or postconcussion signs or symptoms >30 min but <7 days
Grade III	Loss of consciousness ≥1 minute or post-traumatic amnesia ≥24 hours, postconcussion signs or symptoms >7 days

Reproduced from Cantu, R. C., Guidelines for Return to Contact Sports After a Cerebral Concussion. *The Physician and Sportsmedicine*, 1986, Vol. 14 No. 10, p. 75–83 with permission from Taylor and Francis.

Second impact syndrome

Second impact syndrome, thought to represent malignant brain swelling following an injury without recovery from previous concussion, was put forward as a concept by Schneider in 1973. If real, it appears that the risk of second impact syndrome seems greatest in first 10 days postinjury. This may relate to the energy crisis and cellular vulnerability described. It may be that some second impact injuries are just coincidental severe injuries in people who, because of their sport, regularly suffer brain injury.

Management in the following weeks

Evaluating some of the cognitive aspects over the following few weeks after injury can be performed with tests such as the mini-mental state examination or Addenbrooke's Cognitive Examination.

The commonest issue for families of patients with mild TBI is their loved one's agitation and short-tempered nature with lack of insight into the issue. Indeed, many patients are insistent that they are fine. The best management comprises spending time with the patient and their family, explaining that this is real and common and normally resolves over a few weeks to months. There are pharmacological treatments for some symptoms. For cognitive dysfunction, lack of concentration, anger, and aggression, methylphenidate or amantadine can be useful. Donepezil (used in Alzheimer's) may also have a role. For depression, selective serotonin reuptake inhibitors are preferred (sertraline, citalopram). For headache, non-steroidal anti-inflammatory drugs, triptans, propranolol, and amitriptyline can be used, the latter being good if insomnia is also an issue.

Dizziness occurs in approximately 80% and can persist. Benign paroxysmal positional vertigo is the most common type. It can be diagnosed with a Hallpike test and often treated with repositioning manoeuvres. Referral to a specialist is recommended if prolonged symptoms do not respond.

Summary

Concussion is a common condition following relatively mild TBI, and mild TBI may be a better term to describe it as we begin to understand that it is associated with structural injury (even if microscopic). Mild TBI can have very significant consequences both for the patient and their family and labelling the condition as concussion that usually gets better on its own, may do a disservice those affected. It is important to recognize postconcussive symptoms and investigate and manage further those in whom they persist.

Vascular anatomy

Embryology and the circle of Willis

The cerebrum receives blood from two sets of paired arteries, the carotid and vertebral arteries, representing anterior and posterior circulatory systems. The circle of Willis, described by Sir Thomas Willis in 1664, refers to the branches of the internal carotid and basilar arteries of these systems which anastomose, forming a stellate appearance within the suprasellar cistern. Functionally, with occlusion of one supplying vessel, the circle affords a degree of collateral circulation. Typically, during initial embryological development, the internal carotid artery supplies the anterior, middle, and posterior cerebral arteries. Later, the posterior communicating artery (PComA) atrophies, with the basilar artery supplying the posterior cerebral artery (PCA). However, if the PComA remains larger than the ipsilateral P1, this is termed a fetal PComA (approximately 25% individuals). In the majority of individuals, a completely intact circle of Willis is not present, with other common variants including PComA hypoplasia or absence, A1 hypoplasia, and anterior communicating artery (AComA) absence. Embryonic connections between the carotid and basilar arteries exist and can persist into adulthood. Most common is a persistent primitive trigeminal artery, arising from the precavernous internal carotid lateral to the dorsum sellae, to join the basilar artery. A persistent primitive hypoglossal artery can also connect the internal carotid to the basilar, thereby representing a single artery supplying the brainstem and cerebellum. Both variants are associated with an increased incidence of cerebral aneurysms.

Structure of cerebral vessels

Cerebral arterial vessels progressively divide into smaller arteries, arterioles, penetrating arterioles, and ultimately parenchymal arterioles and capillaries. Pial vessels, surrounded by cerebrospinal fluid, form penetrating arterioles. As these arterioles become intracerebral, a small extension of the subarachnoid space exists surrounding them, termed the Virchow-Robin space. These parenchymal vessels become encased by astrocytic end-feet.

The walls of cerebral arterial vessels are comprised of three concentric layers termed, from out to in, the tunica adventitia, tunica media, and tunica intima. The tunica adventitia is predominantly made up of collagen and fibroblasts. In the small parenchymal arterioles and capillaries, the associated astrocytic end-feet connect them to astroglia. The tunica media contains mostly smooth muscle, the larger arteries having a generally greater number of layers. The tunica intima is composed of one layer of endothelium and a layer of elastic tissue, the internal elastic lamina, separating it from the tunica media. Structural differences exist between cerebral and other arteries. Cerebral arteries have a thinner adventitia which contains no external elastic lamina and the tunica intima correspondingly has a more developed internal elastic lamina.

The cerebral veins have thin walls and unlike systemic veins do not contain valves, have minimal smooth muscle, and less closely follow the course of the arterial system.

The internal carotid artery (ICA) and its branches

The origin of the ICA is variable, but is typically between C3 and C5. The carotid sinus (or bulb) is a fusiform dilatation at its origin that functions as a major baroreceptor. Alongside is the carotid body, a chemoreceptor influencing respiratory regulation.

Multiple classifications of the ICA segments exist. The simplest divides it into four segments—cervical, petrous, cavernous and supraclinoid (cerebral) (Gibo et al., 1981). An alternative classification describes seven segments (Bouthillier et al., 1996):

1. Cervical
2. Petrous (horizontal)
3. Lacerum
4. Cavernous
5. Clinoid
6. Ophthalmic (supraclinoid)
7. Communicating (terminal)

The extradural ICA

The cervical segment usually has no branches. Angiographically if tortuous, a 'tonsillar loop' may be visualized. It enters the skull base through the carotid canal in the petrous portion of the temporal bone, runs near horizontally and medially before it turns upward on the foramen lacerum and then passes under the petrolingual

ligament to enter the cavernous sinus. The petrous portion has several small branches, not visible angiographically:carotico-tympanic (to the inner ear) and mandibulovidian. The lacerum segment, considered by some a redundant classification, has no branches.

The cavernous segment begins as the artery enters the posterior part of the sinus, where it runs forwards. It is surrounded by sinus endothelium and supported by trabeculae and typically contains two important branches. The first, the meningohypophyseal trunk, has three branches; the inferior hypophyseal artery supplying the posterior pituitary lobe, the dorsal meningeal artery, and the tentorial artery (artery of Bernasconi and Cassinari) supplying the tentorium. The second branch of the cavernous segment is the inferolateral trunk, which supplies the cavernous sinus cranial nerves. Angiographically, the U-shaped section of the ICA, formed from mostly the cavernous portion, is termed the carotid siphon.

The ICA exits through the dural covering of the sinus termed the proximal dural ring, which forms the roof of the sinus and is in continuity with the dura covering the adjacent anterior clinoid process. The clinoid segment is a transitional segment between the cavernous sinus before the ICA exits through the distal ring and enters the subarachnoid space (Rhoton, 2002). Clinically this region is important as the distal dural ring differentiates aneurysms that cause subarachnoid haemorrhage versus those that cause carotico-cavernous fistulae. It is therefore unfortunate that the distal ring is not visible radiologically and its location can only be estimated. Surgically understanding of this region is important as access to proximal aneurysms at or near the origin of the ophthalmic artery will require an anterior clinoidectomy. The distal dural ring sits inclined posterior-medially and is continuous medially with the falciform ligament and with the dura overlying the superior-medial aspect of the anterior clinoid process. While the two rings are fused posteriorly, they are variably separated anteriorly, giving rise to two regions medially and laterally. The lateral region may be considered to be extradural and extracavernous. On the medial side, the space between a redundant portion of distal dural ring and ICA is termed the carotid cave. Although usually extradural, rupture of carotid cave aneurysm extending superiorly out of the cave may result in subarachnoid haemorrhage.

The ophthalmic segment—ophthalmic and superior hypophyseal arteries

The ophthalmic segment gives rise to the ophthalmic artery, with its origin just beyond the distal dural ring, inferior to the optic nerve and anterior clinoid process. It enters the orbit through the optic foramen. Ophthalmic artery aneurysms arise at the origin of the artery and project dorsally or dorsomedially. The small and variable superior hypophyseal arteries arise distal to the ophthalmic artery from the medial ICA to surround the pituitary stalk. Of note, aneurysms within the clinoid, ophthalmic and hypophyseal region are frequently termed 'paraopthalmic' aneurysms, reflecting the difficulty in their angiographic localization.

Two important variants of the ophthalmic artery origin exist. It can arise from the extradural clinoid complicating surgical access. It may also rarely arise from the external carotid artery risking blindness from inadvertent sectioning (Geibprasert et al., 2009). A meningo-ophthalmic artery arising from the middle meningeal artery and entering the orbit through the superior orbital fissure may replace the ophthalmic artery and poses a risk if sacrificed at surgery or during endovascular procedures.

The communicating segment—posterior communicating and anterior choroidal arteries

The communicating segment extends from the posterior communicating artery (PComA) origin to the ICA bifurcation. The PComA arises from the dorsolateral aspect of the ICA, and connects after approximately 1 cm, to the posterior cerebral artery, thereby connecting the anterior to the posterior circulation. Its course is in close proximity to the oculomotor nerve explaining why typical posterolaterally projecting aneurysms can cause a surgical (involving the pupil) third nerve palsy. Small branches commonly arise from the PComA supplying the genu of the internal capsule and thalamus, the largest branch termed the premamillary artery. The anterior choroidal artery (1–3 mm distant to the PComA origin) usually arises from the posterior aspect of the ICA, prior to its termination at the circle of Willis and can arise as several (1–5) separate trunks. This must be recognized in surgery for ICA origin aneurysms. It is of surgical importance as inadvertent injury can lead to significant neurological deficits and is well documented from early studies of ligation of the artery for Parkinson's disease where a significant proportion of patients developed hemiparesis, hemianaesthesia, and hemianopia. It can be divided into cisternal and intraventricular segments. The cisternal segment crosses the optic tract running along its lateral aspect towards the medial temporal lobe, passes the cerebral peduncles to reach the lateral geniculate body before entering the choroidal fissure and becoming the intraventricular segment. Its supply includes the optic pathways, posterior limb of the internal capsule, basal ganglia, and choroid plexus of the temporal horn of the lateral ventricle. At the ICA bifurcation the middle cerebral artery (MCA) typically projects posterolaterally, with the bifurcation therefore best viewed angiographically with an oblique projection which separates it from the anterior cerebral circulation (Figs. 46.1A–C). Of note blister aneurysms typically arise from the dorsomedial wall of non-branching parts of the ICA, although more rarely they may arise at other anterior and posterior circulation sites.

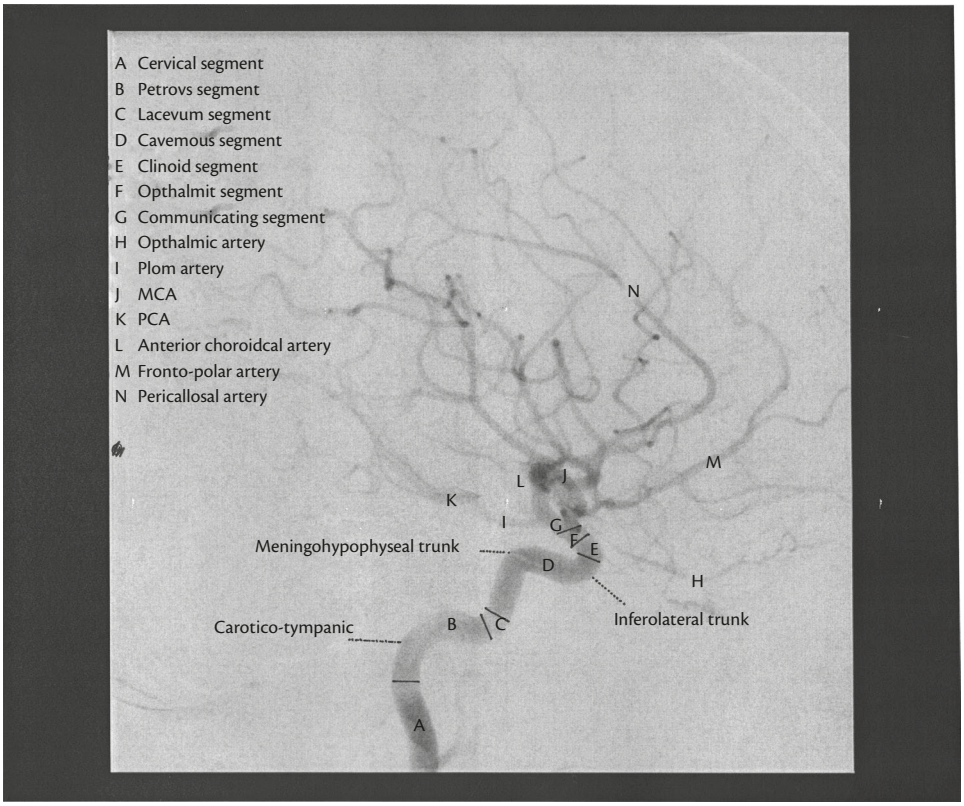
The anterior cerebral artery (ACA)

Although wide anatomical variability exists, the typical description of the ACA is of two arteries, each with A1 and A2 segments, divided by the anterior communicating artery (AComA) (MacDonald, 2009). The A1 segment arises at the ICA bifurcation, crosses over the optic tract anteromedially, and sits in close proximity with its counterpart A1 segment, linked by the AComA. The A1 segment is sometimes referred to as the precommunicating or horizontal segment. The relationship of the A1 to the ICA, optic nerve, and MCA, having performed a classical pterional approach with splitting of the Sylvian fissure, is shown schematically in **Figure 46.2A** and in part intraoperatively in **Figure 46.2B–C**.

There are many variants of this region. The A1 segment may be hypoplastic, with supply from the contralateral A1 via the AComA and can be duplicated. An unpaired or azygous ACA, where a single A2 segment continues distal to the A1 confluence, may be recognized as well as duplicated or fenestrated AComA segments (Yasargil, 1987).

Medial (lenticulo)striate branches typically arise from the inferoposterior aspect of the A1 segment and supply the globus pallidus and medial putamen (**Fig. 46.3**) through the anterior perforated substance. The A2 segment extends from distal to the AComA

(a)



(b)

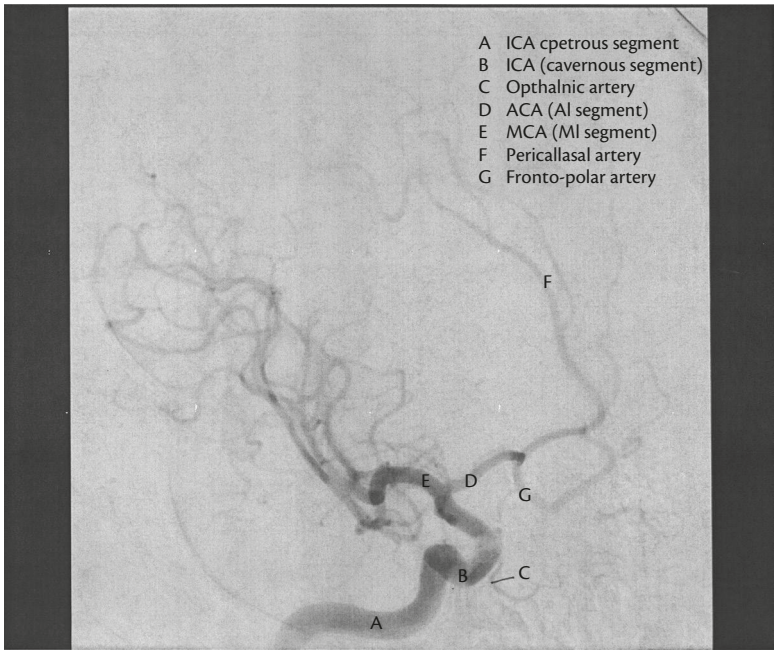


Fig. 46.1 (A) Lateral projection digital subtraction angiogram following internal carotid artery injection. Note the absent callosal marginal artery and corresponding unusually prominent frontopolar artery. The dotted lines mark the approximate origins of the angiographically invisible branches of petrous and cavernous ICA segments. At the MCA bifurcation at the base of the insula, the pattern of branching varies considerably, but typically contains an anterior (superior) and posterior (inferior) trunk which lie deep within the fissure. The angiographic appearance is termed the middle cerebral candelabra. The anterior trunk branches, including the precentral, central (Rolandic) and operculofrontal arteries, generally supply frontal and parietal regions, including the middle and inferior frontal gyri, precentral and postcentral cortex. The posterior trunk typically has three branches. The posterior parietal and posterior temporal arteries supply a significant portion of the temporal and occipital convexities. Finally, the angular artery, which courses the entire length of the insula, supplies the superior temporal gyri and parts of the parietal and occipital lobes. (B) Oblique projection digital subtraction angiogram following internal carotid artery injection. (C) Anteroposterior projection digital subtraction angiogram following internal carotid artery injection. Note cortical branches (M4) will anastomose with ACA branches over the medial convexity. (D) Lateral projection digital subtraction angiogram following external carotid artery injection. The main branches, in ascending order, are the superior thyroid artery, ascending pharyngeal artery, lingual artery, facial artery, occipital artery, posterior auricular artery, maxillary artery, and superficial temporal artery. Note in particular the occipital artery is not opacified in this image.

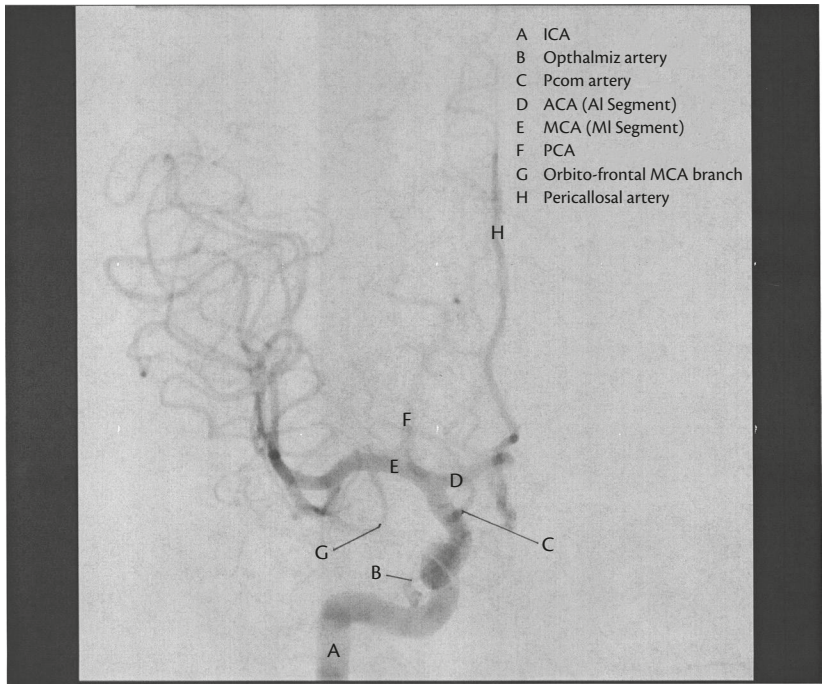
(c)



(d)

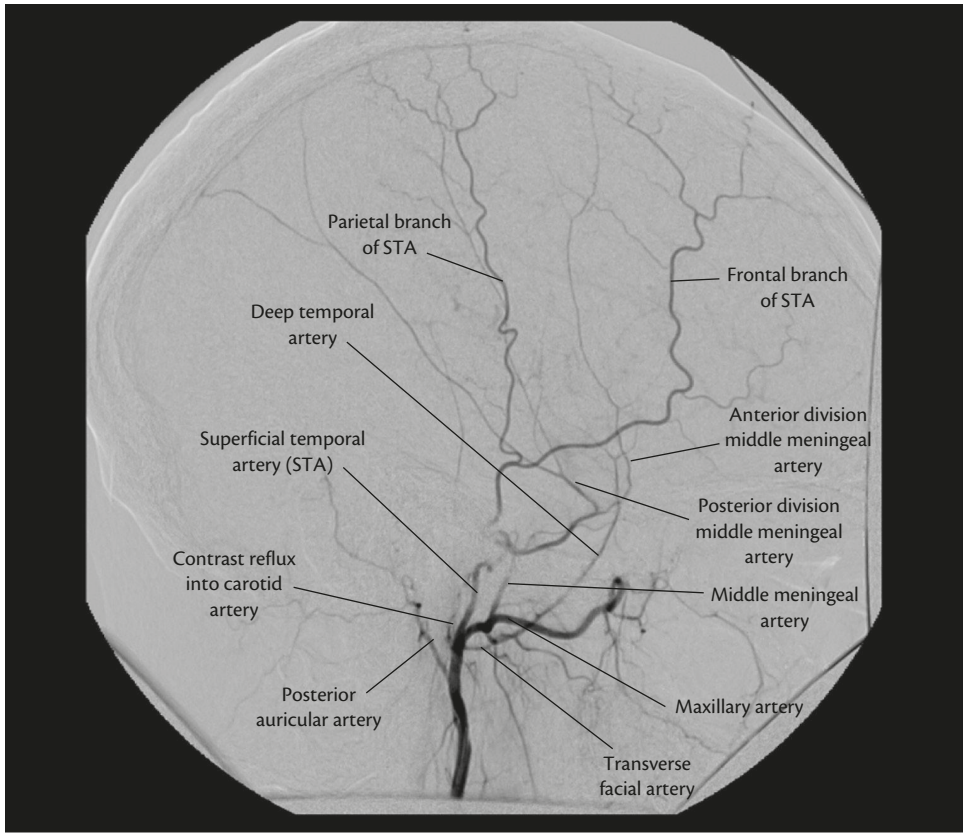


Fig. 46.1 Continued

and ends with the formation of the callosomarginal and pericallosal arteries, at the genu of the corpus callosum. Branches of the A2 include the orbitofrontal artery (typically the first cortical branch) supplying the inferior part of the frontal lobe, and the frontopolar artery supplying the anterior part of the superior frontal gyrus.

The anterior communicating artery (AComA)

This artery lies within the cistern of the lamina terminalis and is important due to its high incidence of aneurysm formation. It is short, measuring up to 3 mm in length. Its perforating branches vary in number but can be classified as subcallosal,

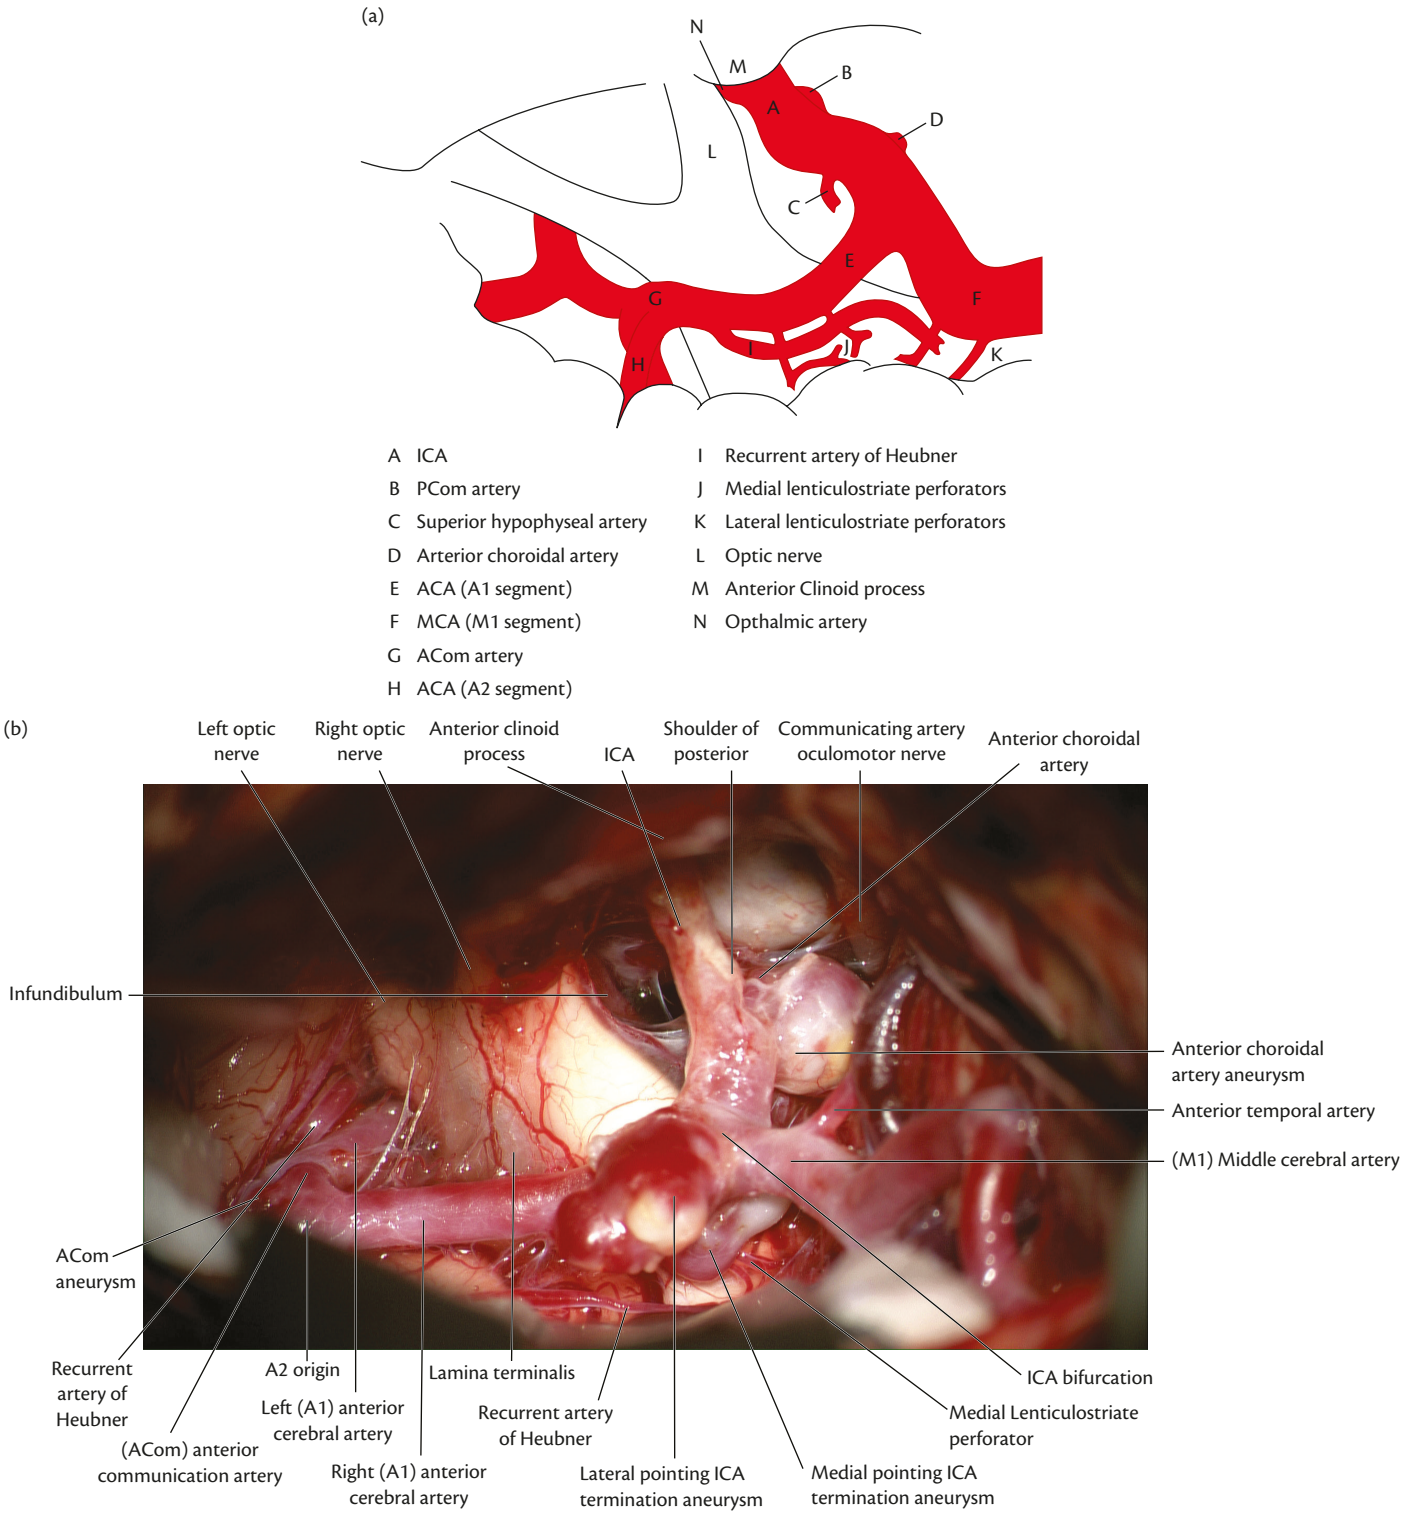

Fig. 46.2 (A) Schematic Sylvian fissure split following pterional craniotomy showing major arterial vessels at base of brain. (B and C) Intraoperative photographs following Sylvian fissure split demonstrating exposure of the ICA, optic nerve, ACA, MCA, and multiple aneurysms (a) and in the same patient with the anterior choroidal artery aneurysm gently retracted exposing the basilar termination and its branches (b). Note the direction of the PCom is deep to the ICA and therefore not seen in these views. The anterior choroidal artery is difficult to visualize as it is closely adherent to the aneurysm dome. The right recurrent artery of Heubner origin at the A1/A2 junction is obscured and the infundibulum is poorly visualized.

hypothalamic, or chiasmatic according to their regions of blood supply.

The recurrent artery of Heubner

This artery is the largest of the perforating branches of the ACA, typically it arises from the proximal A2 segment near the A1/A2 junction, but can also arise from the A1. Its course generally follows the A1 laterally and supplies the anterior limb of the internal capsule and parts of the caudate nucleus and globus pallidus.

The callosomarginal and pericallosal arteries

The pericallosal (trunk) artery is considered a continuation of the ACA and closely follows the corpus callosum. Its branches supply the corpus callosum and its splenium, the septum pellucidum, fornix, and precuneus cortex. The cortical branches anastomose with the branches of the MCA and posterior cerebral artery. A callosomarginal artery is present in approximately 50% of cases (Butler et al., 2012). It supplies the superior frontal gyrus through various branches, taking a course through the cingulate sulcus. It terminates as the paracentral artery supplying the paracentral lobule.

The middle cerebral artery (MCA)

The MCA is the largest branch of the ICA. Its proximal segment (M1) ends at the MCA bifurcation as the distal (M2) segment. The M1 runs laterally in the anterior (or sphenoidal) compartment of the deep component of the Sylvian fissure, between the frontal and temporal lobes. A variable number of lateral striate (or lenticulostriate) arteries arise from the posteroinferior part of the M1, travel backwards along its course and penetrate the lateral portion of the anterior perforated substance. They supply the basal ganglia, internal capsule, and caudate nucleus. Clinically, these arteries are the frequent source of hypertensive intracerebral haemorrhage. The M1 bifurcates at its genu, turning upwards at a right-angle, at the anteroinferior aspect of the insula. The only large branches of the M1 are usually the anterior temporal artery and temporopolar branch.

The vertebrobasilar (posterior) system and its branches

The vertebral arteries arise as the first branch from the subclavian artery and enter the cranial vault through the foramen magnum, traversing anterolateral to the medulla before joining at the pontomedullary junction to form the basilar artery (Figs. 46.4A–B). Significant branches arise prior to their unification. Each vertebral artery gives off a posterior spinal artery that descends along the posterior aspect of the spinal cord. The second, and usually largest branch, is the posterior inferior cerebellar artery (PICA). It can sometimes arise below the foramen magnum (~15% individuals). If hypoplastic, there is characteristically a corresponding increase in the calibre of the anterior inferior cerebellar artery (AICA). A further variation is that one vertebral artery may form a PICA directly. The PICA courses around the medulla from its origin where it is closely related to the hypoglossal nerve passing around the inferior aspect of the medullary olive—termed the anterior medullary segment (Table 46.1). Next the lateral medullary segment curves beside the medulla and the tonsillomedullary segment courses around the caudal half of the cerebellar tonsil, forming the caudal loop visible on lateral angiography. The telovelotonsillar segment passes in a cleft between the tela choroidea and medulla, travelling superiorly to form a cranial loop at its apex. A cortical segment overlays the cerebellar surface (Lister et al., 1982). Branches of the PICA supply the medulla, fourth ventricle choroid plexus, and inferior and posterior cerebellum. Finally, prior to the vertebral arteries forming the basilar artery, two very short branches unite to form the descending anterior spinal artery.

The pattern of arterial supply to the midbrain, pons, and medulla from the superior cerebellar arteries (SCA), AICA and PICA is via short and long circumflex perforators to the anterior and posterolateral parts with the long circumflex branches travelling over the lateral surface. In addition, there are more direct anterior branches from the proximal segments of these vessels and the basilar trunk.

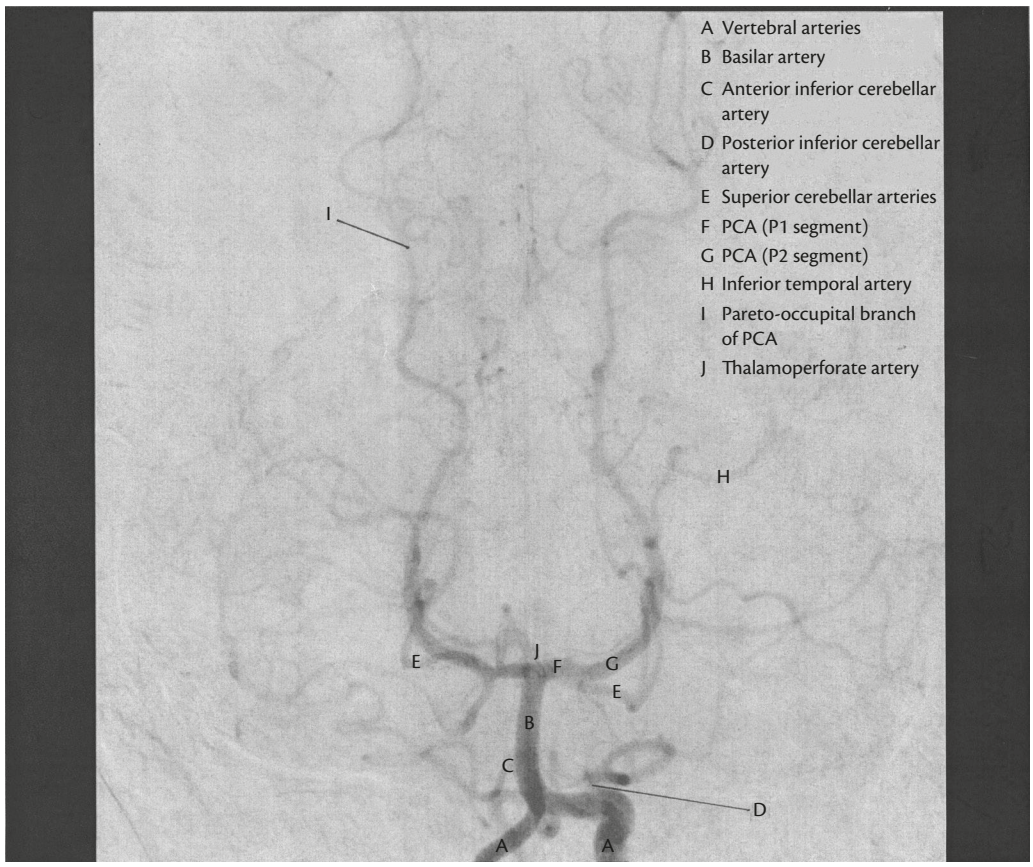
The basilar artery

The basilar arises at the pontomedullary junction and travels along the anterior surface of the pons in the pontine cistern and terminates, at the midbrain, into the two posterior cerebral arteries. Typically, small perforators supply the pons throughout its length. The paired anterior inferior cerebellar arteries arise from the basilar in close proximity to the abducens nerve. Each AICA traverses the cerebellopontine angle, closely related to the facial and vestibulocochlear nerves, to supply the anterior and inferior cerebellum (Table 46.1). The AICA usually gives rise to the labyrinthine artery, although it can also arise direct from the basilar or elsewhere. It accompanies the vestibulocochlear nerve and traverses the internal acoustic meatus to supply the cochlea and vestibular apparatus. Prior to the basilar bifurcation, the two paired SCA arise, running laterally around the midbrain in the ambient cistern. They pass below the oculomotor nerve, which separates them from the posterior cerebral arteries. The SCA approaches the midline in the quadrigeminal cistern, to supply the superior cerebellar hemispheres, peduncles, and vermis. The SCA is anatomically subdivided from proximal to distal (Table 46.1) but may also be described radiographically, as prepontine, ambient, and quadrigeminal segments. The SCA may be duplicated in approximately one-third of cases. Overall, the three neurovascular complexes of the posterior fossa are summarized in Table 46.2 (Rhoton, 1994).

The posterior cerebral artery (PCA)

From its origin, the first segment of the PCA, the P1 (or horizontal segment), sits within the interpeduncular fossa before anastomosing with the PComA. Varyingly with the PComA, perforating vessels arise from the posterior-superior surfaces of the P1 and supply the internal capsule and thalamus. A single large thalamoperforate branch is occasionally seen angiographically, often referred to as the artery of Percheron and can supply both thalami and the midbrain. Occlusion can result in a paramedian thalamic syndrome with a triad of altered conscious state, vertical gaze palsy, and impaired memory. The P2 segment formed distal to the PComA, then traverses around the oculomotor nerve, in the ambient cistern, to sit above the tentorium, before the P3 segment starts at the quadrigeminal cistern. The P2 is divided into P2A (anterior) and P2P (posterior) segments, with their junction at the most lateral aspect of the cerebral peduncle. The P2 segment has multiple perforating branches including the thalamogeniculate and lateral posterior choroidal arteries. The lateral posterior choroidal artery enters the ventricle adjacent to the lateral geniculate nucleus through the choroid fissure. The medial posterior choroidal artery arises from the proximal P2 or from the P1 segments in the ambient cistern and passes beneath the splenium of the corpus callosum to enter the roof of the third ventricle in the velum interpositum. Branches of the P2 also contribute to cerebral

(a)



(b)

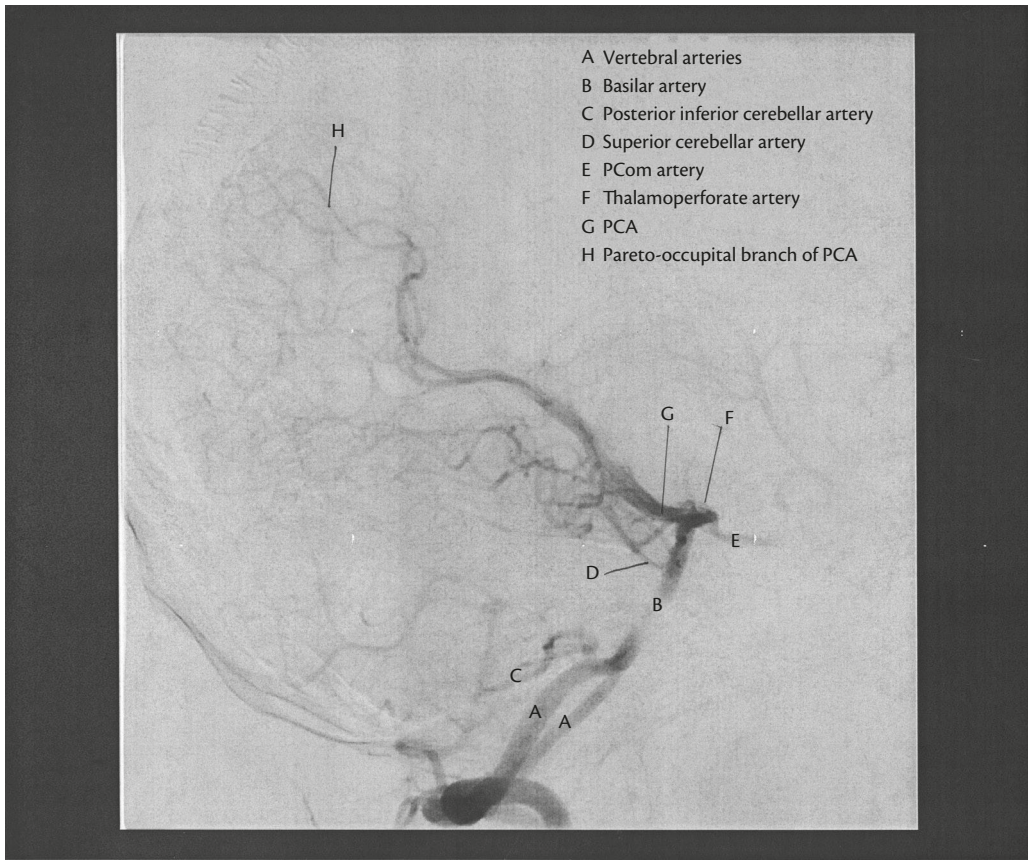


Fig. 46.4 Anteroposterior (A) and lateral (B) digital subtraction angiograms following vertebral artery injection. Note the asymmetry in the level of origin of the left and right PICA.

Table 46.1 Vascular segments of posterior fossa arteries

AICA	Anterior pontine	Lateral pontomedullary	Flocculonodular		Cortical (petrosal surface)
PICA	Anterior medullary	Lateral medullary	Tonsillomedullary	Telovelotonsillar	Cortical (suboccipital surface)

peduncle and quadrigeminal plate supply. Additional P2 branches to the temporal and parietal lobes have relevance to arteriovenous malformations (AVM) surgery. The temporal-occipital area receives blood inferiorly from the posterior inferior temporal artery and anteriorly from branches of the MCA. Notably, the P2, in the presence of high intracranial pressure, can be compressed against the tentorium resulting in occipital lobe infarcts. The P3 segment traverses along the inferomedial aspect of the temporal lobe, with associated cortical perforating branches, before bifurcating into the parieto-occipital and calcarine arteries. The calcarine artery principally supplies the visual cortex in the medial occipital lobe. Cortical PCA branches anastomose with MCA branches over the lateral surfaces of the occipital and temporal lobes. In approximately, 20% of cases the P1 segment is absent, with the PCA supplied via the PComA by the ICA (Harnsberger and Macdonald, 2006).

The external carotid artery (ECA)

The ECA typically arises at the level of C4 and initially lies anteromedial to the ICA. Classically eight branches are described (Fig. 46.1D)—although in practice this can vary considerably. Several anastomoses exist between ECA branches and both ICA and vertebral artery branches. Ascending pharyngeal artery branches anastomose with cavernous ICA branches and meningeal vertebral artery branches; the facial artery with branches of the ophthalmic artery and the occipital artery with vertebral artery branches (and also superficial temporal artery branches). Dural supply from ECA branches have relevance to dural fistula diagnosis and management, for example, ascending pharyngeal artery and occipital artery supply to the posterior fossa dura or middle meningeal and accessory meningeal branches of the maxillary artery supplying supratentorial dura.

Vascular territories in the brain

An overview of the arterial supply to the brainstem, cerebellum, and cerebrum is shown in Figure 46.5. The cerebral vascular territories supplied, despite traditional textbook reports, can vary considerably. This can be due to arterial anatomical variation and also individual variation in the area of cortex supplied by a given arterial branch (van der Zwan et al., 1992). Recent MRI flow studies have confirmed this variability but also showed that it can be related to anatomical variability of the circle of Willis (van Laar et al., 2006). It may also vary between hemispheres within the same patient.

Venous anatomy

The cerebral venous system is comprised of both superficial and deep cerebral veins and the dural venous sinuses.

The superficial system

The superficial venous system is made up of numerous and variable superficial cortical veins, which typically accompany arteries travelling within the cerebral sulci. These drain into a number of larger named veins, which subsequently drain into the venous sinuses:

- Superficial middle cerebral vein—drains into the cavernous (or sphenoparietal) sinus
- Great anastomotic vein (of Trolard)—drains the superficial middle cerebral vein into the superior sagittal sinus
- Posterior anastomotic vein (of Labbé)—drains superficial middle cerebral vein into the transverse sinus. There is often a reciprocal arrangement between the two anastomotic veins with Labbé larger in the dominant hemisphere and Trolard in the non-dominant.

The deep system

The deep venous system drains the deep white and grey matter surrounding the lateral and third ventricle and basal cisterns. The great cerebral vein (of Galen) is found below the splenium of the corpus callosum and is a short, single midline vessel. It is formed by joining of the two internal cerebral veins, and also receives the two basal veins (of Rosenthal) as well as the occipital veins draining the medial and inferior occipital lobes. It runs to the venous confluence where it is joined by the inferior sagittal sinus to form the straight sinus. The basal veins (of Rosenthal) arise at the anterior perforated substance on the medial aspect of the temporal lobe and run posteriorly and medially. They travel laterally around the midbrain through the ambient cistern and drain the hypothalamus, midbrain, and medial and inferior portions of the frontal and temporal lobes, including the insula and operculum. The internal cerebral veins, situated in the velum interpositum (roof of the third ventricle), are formed by the union of the choroidal and thalamostriate veins. The choroidal vein drains the choroid plexus of

the lateral ventricle. Tributaries draining into the thalamostriate vein include the transverse caudate veins, anterior terminal vein (draining the ventricular surface of the caudate nucleus) and septal vein (draining the corpus callosum and deep frontal white matter).

Dural venous sinuses

Dural sinuses are valveless, venous channels formed from dural folds. The principal dural sinuses are the superior sagittal, transverse, sigmoid, straight, superior, and inferior petrosal, cavernous, and sphenoparietal sinus. The superior sagittal sinus typically arises at the crista galli and ends at the torcular Herophili. It can also divide prior to the torcula, where it usually meets the transverse sinuses, leading clinically to misdiagnosis of superior sagittal sinus thrombosis. The smaller inferior sagittal sinus lies in the free margin of the falx cerebri, drains tributaries from the corpus callosum and cingulate gyrus, and itself drains into the straight sinus at the venous confluence. It is typically not visible radiologically. The transverse sinuses are commonly asymmetric, usually with a dominant right side which receives the majority of the blood from the superior sagittal sinus at the torcula. They become the sigmoid sinuses at the posterior petrous edge, which then continue to the jugular bulb. The sigmoid sinus can vary in size compared to the transverse sinus, particularly when receiving large flow from the posterior anastomotic vein (of Labbé) into its proximal part.

Fig. 46.5 Continued

The cavernous sinus typically receives flow from the superficial middle cerebral (Sylvian) veins, ophthalmic veins, and sphenoparietal sinus (itself sometimes draining the Sylvian veins). Outflow from the cavernous sinus is through the superior and inferior petrosal sinuses (connecting to the sigmoid sinus and jugular foramen respectively) and also the contralateral cavernous sinus and the pterygoid and clival venous plexuses. Varyingly present, and more common in children, an occipital sinus may run from the torcula in the midline to the foramen magnum and can be the source of significant bleeding in an otherwise straightforward midline posterior fossa approach. The dural venous sinuses also communicate with the extracranial venous system through valveless emissary veins, which can serve as a route for the introduction of intracranial infection (Fig. 46.6).

The cerebellum and brainstem

There is considerable variation in the venous system draining the cerebellum and brain stem. The superficial cerebellar hemispheres drain into the nearest of the sigmoid or transverse sinuses. The (superior and inferior) vermian veins are the exception, which run along the vermis in the midline. The anterior cerebellum drains into the superior or inferior petrosal sinuses. In the brain stem, the veins are small and networks widespread. The lateral mesencephalic vein, which is contiguous with the petrosal vein, is commonly present and runs along the lateral aspect, connecting superiorly the basal vein (of Rosenthal) with the superior petrosal sinus. The superior petrosal vein or Dandy's Vein, represents the large vein, extending from the lateral surface of the pons that drains into the superior petrosal sinus. It drains a large area, including the anterior cerebellum, lateral and posterior medulla, and anterior pons. The vein running longitudinally on the anterior aspect is termed the anterior mesencephalic, pontomedullary, or spinal vein depending on its most adjacent structure. The precentral (or cerebellar) vein is an unpaired vein running posterior to the brainstem, draining into the superior vermian vein or great vein (of Galen) and is of note as its inferior aspect marks the upper border of the fourth ventricle. It predominantly drains the cerebellum.

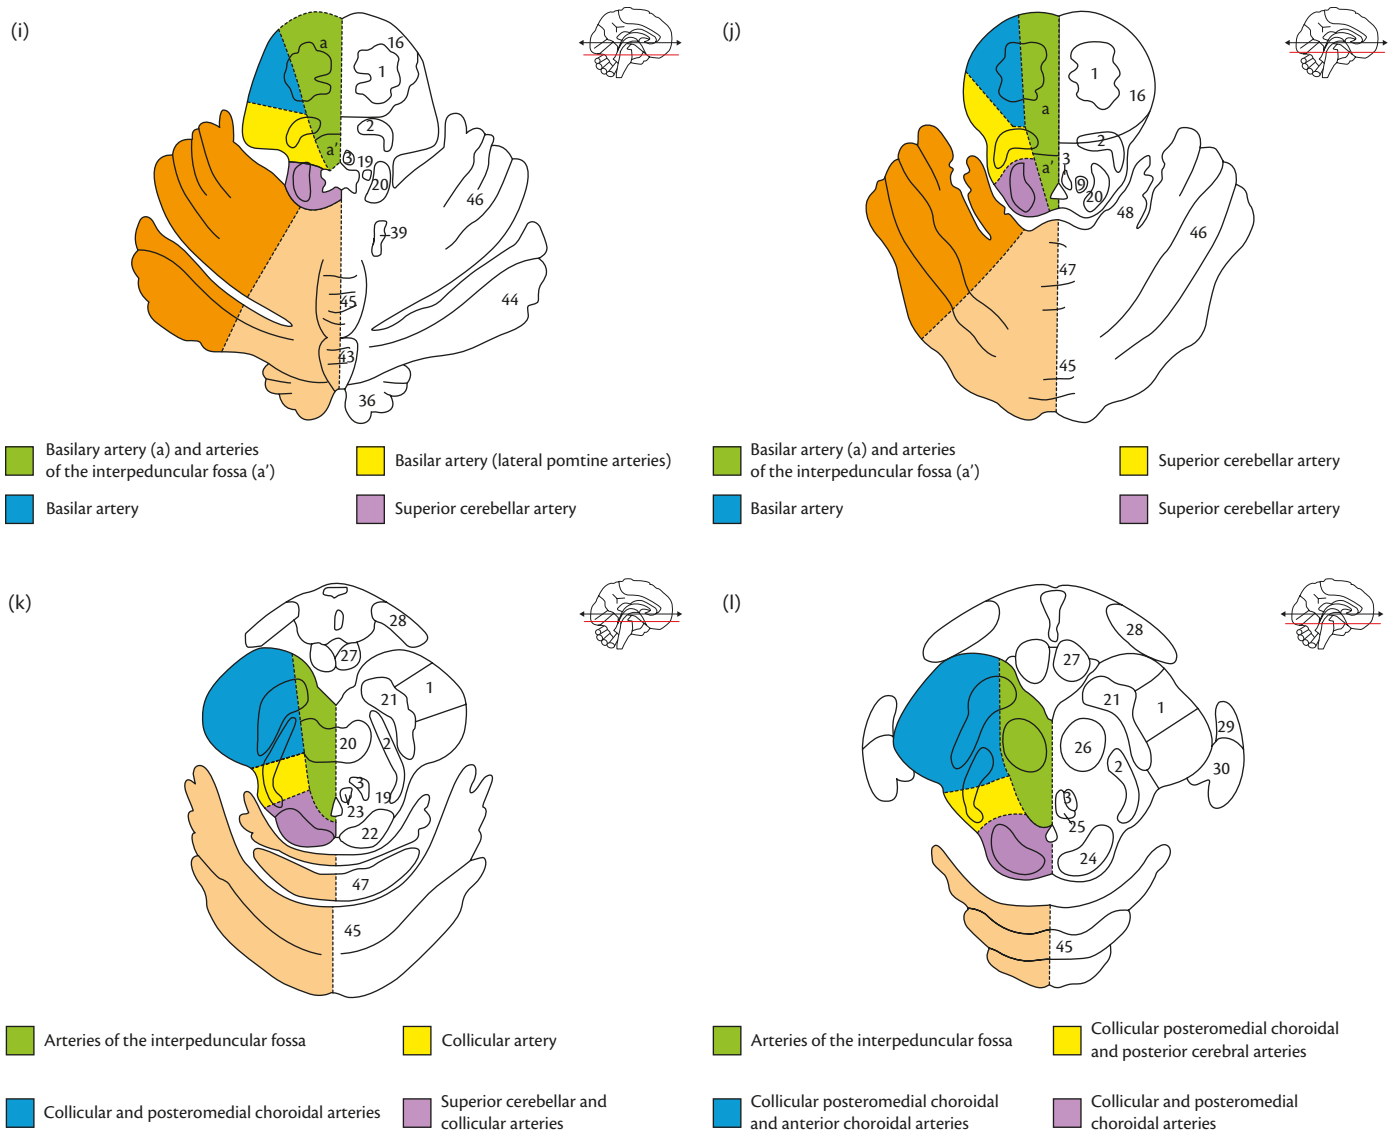

Fig. 46.5 Continued

Anatomical considerations for AVM surgery

As arterial feeders to the AVM nidus arise from normal cortical and deep arterial branches, understanding the anatomical location of these vessels based on angiographic studies is imperative for safe planning of AVM treatment. These are somewhat predicted by the lobar location of the AVM as regards the cortical arterial supply and by their deep location or extension regarding recruitment of deep perforator branches. Large AVMs straddling more than one lobe would naturally be supplied by feeders from the adjacent vascular territory as well: 'watershed' regions. This is of importance when studying angiograms (DSA) as awareness of the existence of further feeders from another vascular territory will avoid underestimation of the extent of the lesion.

Lateral hemisphere AVMs

On the lateral hemisphere AVMs are divided into frontal, temporal, parietal, occipital, and peri-Sylvian locations. Extension towards the superior frontal lobe or to the frontal pole attracts supply from distal ACA branches such as the frontopolar artery anteriorly, the fronto-orbital artery basally, and the callosomarginal artery superiorly. Extension of the surgical exposure to the medial or basal aspects of the frontal lobe is necessary to access these vessels for proximal control. M4 branches from the superior M2 trunk of the MCA extend to the cortical/subcortical surface of most of the frontal and central (the pre- and postcentral gyri) lobes with probable *en passant* vessel supply to the motor and speech areas. Corresponding vessels from the inferior M2 trunk feed AVMs located in the temporal and parietal lobes and extend to the lateral surface of the occipital lobe as well. Peri-Sylvian AVMs predominantly involve the frontal or temporal operculum with feeders arising from the opercular (M3), the M2, or the distal M1 segments. Deep extension, including to the insula, involves feeders from the lenticulostriate perforators. The short perforators supply the insular cortex while the long perforators supply the internal capsule and corona radiata. Proximal access to MCA feeders is through splitting of the Sylvian fissure. Frequently temporal AVMs

extend inferiorly and onto the basal tentorial surface. In this case a proportion, if not the predominant feeders, are from the anterior, middle, or posterior temporal branches of the P2 segment of the PCA and these are encountered as they arise proximally at the ambient cistern and over the tentorial edge and a subtemporal approach provides access to these.

Provided there are no significant deep extensions, the majority of AVMs on the lateral hemisphere drain via superficial veins to the superior sagittal or transverse sinus and those in a central location may involve the veins of Trollard or Labbé. Temporal AVMs extending on the tentorial surface may partially drain via tributaries of the vein of Rosenthal to the deep system.

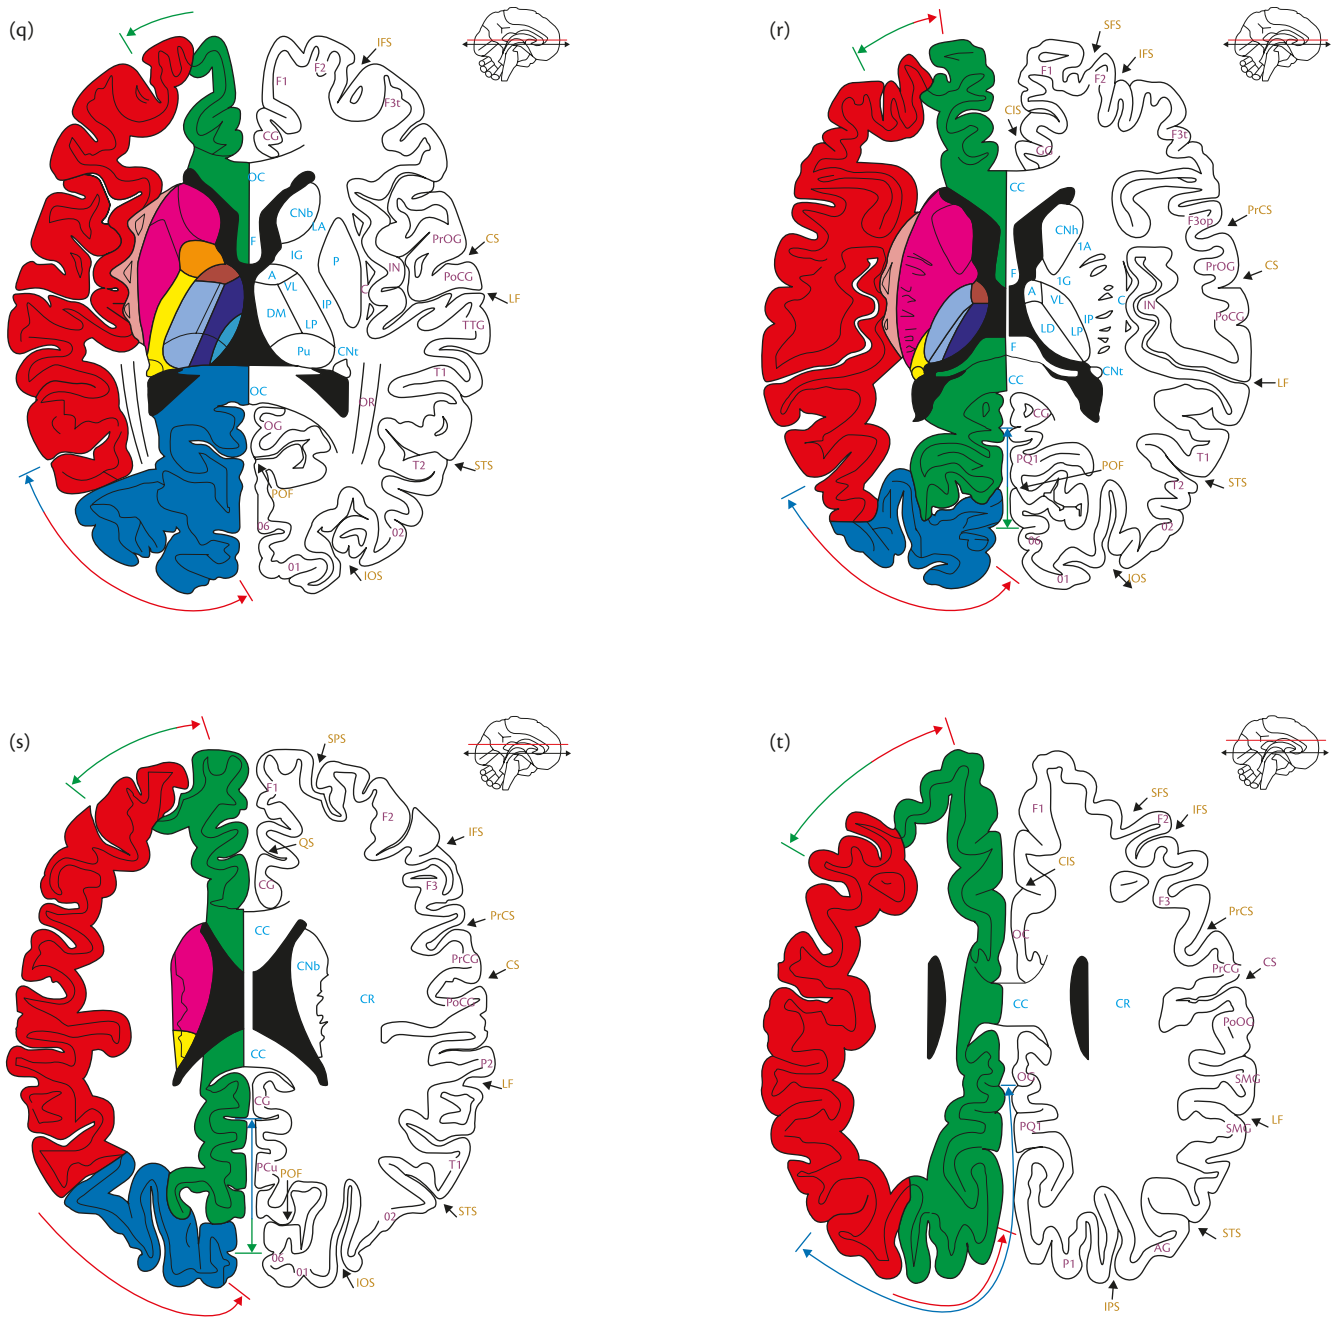

Fig. 46.5 Continued

Medial hemisphere AVMs

Anteriorly these AVMs are fed by branches arising from the callosomarginal anteriorly superiorly and the pericallosal arteries inferiorly adjacent to the corpus callosum and the frontopolar artery at the frontal pole. Cortical disruption or ischaemia in this region may result in a transient superior mesenteric artery (SMA) syndrome. The distal pericallosal (A3 and A4) arteries supply to the paracentral lobule should be maintained. AVMs on the medial parietal lobe and those adjacent to the splenium are fed by distal ACA or PCA as one of the terminal branches of the PCA is located in the medial parieto-occipital sulcus. The other terminal branch of the PCA is located in the calcarine fissure and medial occipital AVMs adjacent to the visual cortex in the cuneus and lingual gyrus are fed by its branches. These AVMs drain to the superior sagittal sinus and those involving the ventricle, splenial, or medial occipital lobe may drain to the vein of Galen via ependymal, splenial, and calcarine tributaries. Access to these feeders are through interhemispheric approaches.

Deep supratentorial AVMs

Subcortical deep extensions of some AVMs recruit deep perforator feeders such as the lenticulostriate from the MCA, A1 perforators, and Heubner's artery from the ACA. Access to these and

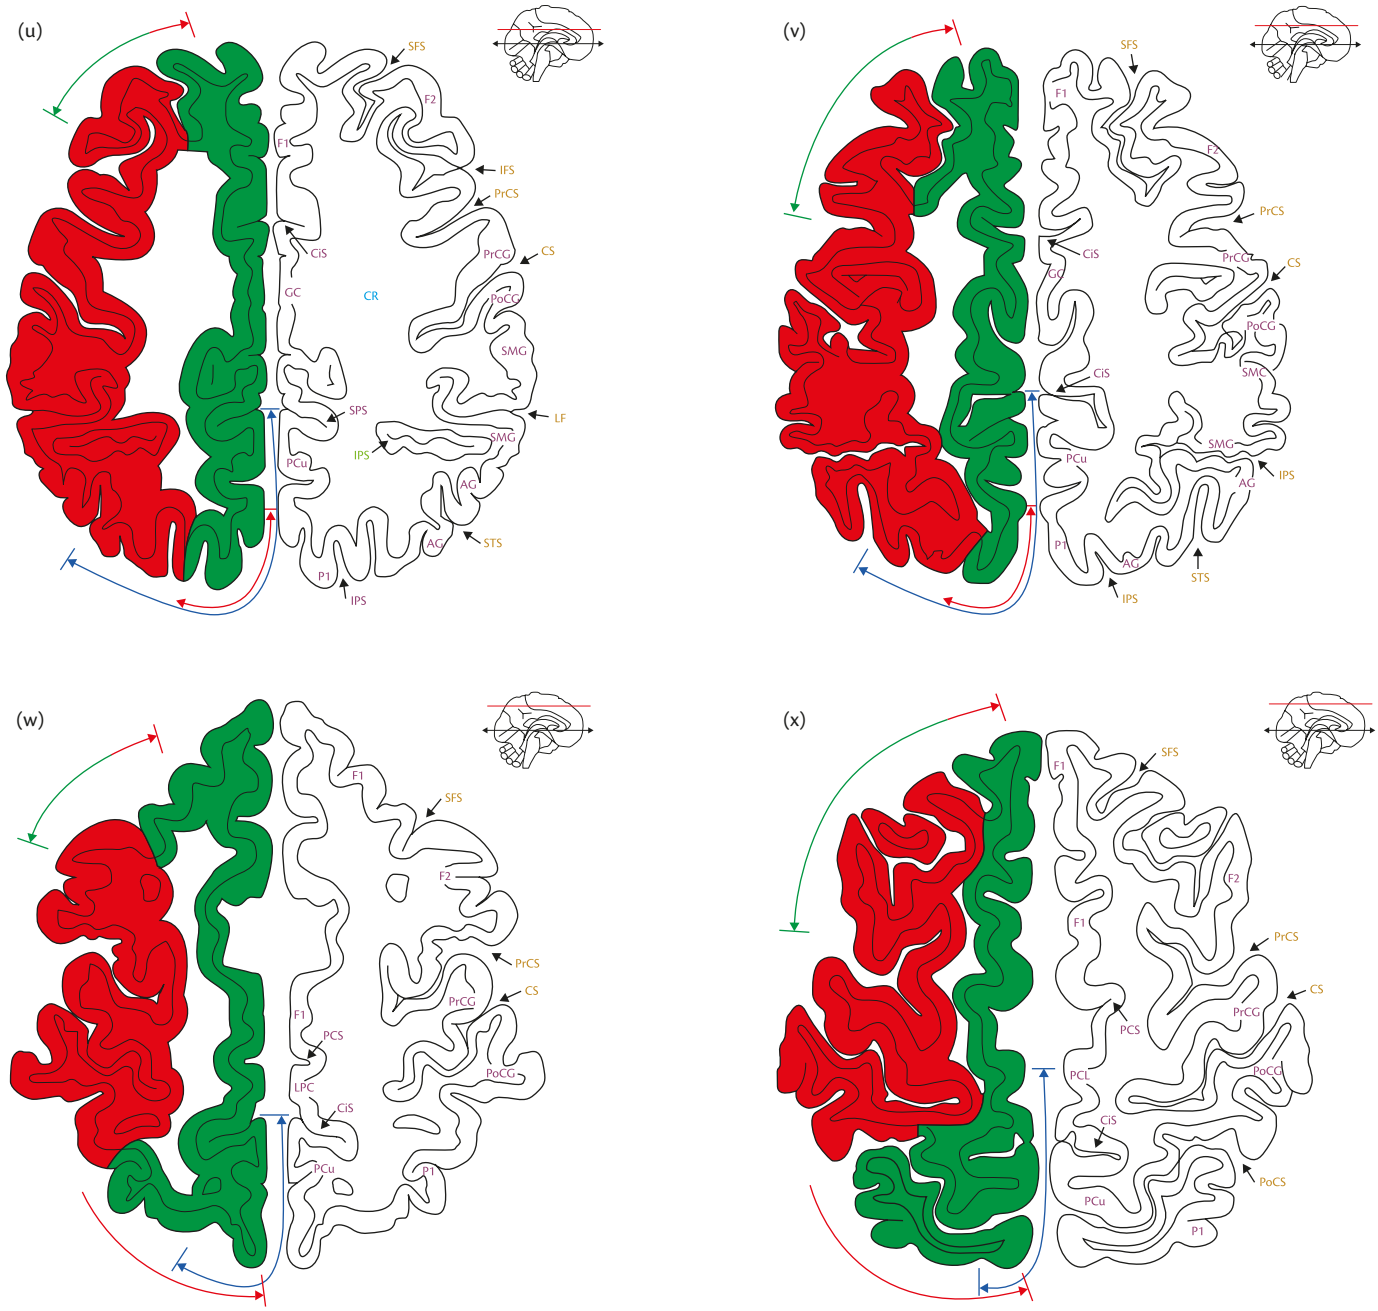

Fig. 46.5 Continued

deep dissection of the nidus can potentially disrupt the white matter tracts such as the superior longitudinal, arcuate, uncinate fasiculi, IFOF, corona radiata, and optic radiation with a resulting neurological deficit, which in contrast with cortical lesions which demonstrate plasticity, are likely to be permanent. Deep perforators also indicate that the nidus involves the basal ganglia. Frequently AVMs extend in a cone-like fashion towards the ventricles and are expected to have deep ependymal feeders even though these are not identified on the preoperative angiogram. Extensive intraventricular extension can be anticipated by demonstrating supply from choroidal arteries on angiography. Those in the temporal horn are fed by distal anterior choroidal artery or the lateral posterior choroidal artery. This extends to the choroid plexus protruding from the foramen of Monro and involved in supplying AVMs in these regions. Thalamic involvement by the AVM can be predicted by identifying the 'flame-like' appearance of the perforators adjacent to the superior basilar artery and proximal P1/P2 on angiography. Anteriorly these perforators are thalamoperforators from P1 and more posteriorly are thalamogeniculate branches from P2. Venous drainage is to the deep system.

Cerebellar AVMs

Depending on their location cerebellar AVMs are supplied by cortical branches of one or more of the three branches namely SCA, AICA, and PICA. Those on the suboccipital surface and paravermian location are fed by PICA branches beyond the 'tonsillar' loop and with the fourth ventricular extension, also its choroidal branches. Proximal control at the tonsil or through a telovelar approach is straightforward. Frequently flow-related aneurysms are seen on the feeding branches proximal to the nidus. Superiorly on the suboccipital and tentorial surfaces the AVMs are fed by distal SCA branches which in fact are the predominant supply to the cerebellum. Proximal control of these is through a supracerebellar infratentorial approach and the more proximal segment can be identified at the tentorial hiatus and adjacent to the fourth nerve. Superiorly and near the midline a deep branch through the cerebellum supply the dentate nucleus which lies in a deep paravermian location. AVMs located at the petrosal cerebellar surface near the CPA may have feeders from the cortical branches of the AICA and are in relationship to the VII—XII cranial nerves. It is important to recognize that not only the premeatal but also the postmeatal segment of the AICA gives perforating blood supply to the pons and brainstem and hence only the feeders and not the main artery should be obliterated. The apex of the loop is related to the internal auditory meatus. The venous drainage is to the transverse, straight (which contrary to supratentorially located AVMs this does not constitute deep drainage for posterior fossa AVMs in the Spetzler-Martin classification) and sigmoid sinuses. Near the deep surface, venous drainage is to the Galenic deep system.

Vascular physiology

Autoregulation and the control of cerebral perfusion

Despite its small relative size, the brain requires around 14% of cardiac output and is critically dependent on adequate cerebral blood

flow. Impairment can trigger unconsciousness within one minute and irreversible neuronal tissue damage can occur if ischaemia is prolonged over four minutes (although surgically much longer vascular occlusion times may be tolerated due to collateral pathways). Autoregulation of cerebral blood flow is the ability of the brain to regulate its blood flow despite changes in systemic blood pressure (Cross and Plunkett, 2008). Cerebral perfusion pressure (CPP) is classically defined as:

CPP = MAP—(ICP + CVP)
MAP mean arterial pressure
ICP intracranial pressure
CVP central venous pressure

Early studies with baboons demonstrated that ICP represented the effective cerebral venous outflow pressure and importantly the sagittal sinus pressure did not change within a range of ICP, reflecting the rigid nature of dural sinuses compared to parenchymal veins (Johnston and Rowan, 1974). CVP is normally low, approximately 2–5 mmHg. Clinically, CVP is therefore often omitted from the equation, giving:

$$CPP = MAP - ICP.$$

As per the Monro-Kellie hypothesis, when the intracranial volume rises, compensatory mechanisms can initially maintain ICP at normal or near normal levels (ICP <20 mmHg) (**Fig. 46.7**). The volume of cerebrospinal fluid (CSF) is reduced through movement of CSF into the spinal canal and increased absorption into the venous circulation. In addition, there may be partial compression of venous sinuses. At a critical level, compensatory mechanisms are overwhelmed and a small change in intracranial volume results in a significant rise in ICP. Pathophysiologically, this rise in ICP is associated with a reduction in CPP and cerebral blood flow.

Cerebral blood flow

Cerebral blood flow (CBF) is approximately 700 ml per minute (50 ml per 100 g per minute). Grey matter has considerably greater requirements than white matter, receiving 70 ml per 100 g per min compared to 20 ml per 100 g per min. Overall, the level of CBF is critical to prevent ischaemia. Electroencephalographic changes are noted when blood flow falls below 20 ml per 100 g per minute and irreversible cerebral infarction below 10 ml per 100 g per minute (Yentis et al., 2013). An autoregulatory range exists within which a relatively constant CBF is maintained over a range of mean arterial pressure, between approximately 50 and 150 mmHg (Phillips and Whisnant, 1992) (**Fig. 46.8A**). The autoregulatory range is increased in hypertensive individuals. At low or high mean arterial pressures outside this range, CBF increases passively with rising arterial pressure.

Mechanisms of cerebral blood flow regulation

The mechanisms responsible for the autoregulation of CBF are not fully understood. Certain methodologies exist for the measurement and study of CBF. To measure total blood flow, the Fick principle can be applied following the inhalation of an inert gas (e.g. N_20), while the detection of radioactive 133-xenon, positron emission tomography, functional magnetic resonance imaging, and Doppler probes have all been utilized to measure regional blood flow. Three principle theories have been proposed to describe the mechanism of autoregulation; myogenic, metabolic, and neurogenic regulation. The calibre of vessels that mediate autoregulation may span the range of 40–300 μm but typically less than 100 μm.

Myogenic regulation

The maintenance of a relatively constant CBF across a range of CPP is thought to involve the myogenic response of cerebral smooth muscle in vessel walls, particularly at higher pressures within the autoregulatory part of the curve. Classical studies have shown that isolated vessels constrict in response to raised pressure and dilate to reduced pressure.

Neurogenic control of CBF—extrinsic and intrinsic control

The cerebral vasculature receives sympathetic innervation from the superior cervical ganglion. Extraparenchymal vessels are thought to be regulated by the autonomic nervous system. However, it is not thought to play a major role in the physiological regulation of intraparenchymal vessel tone, largely due to evidence from denervation studies. However, it may play a role when blood pressure rises above the normal limits of autoregulation through resetting or modulation of the normal autoregulatory curve. This represents an important physiological mechanism that prevents significant rises in CBF and any associated breakdown in the blood-brain barrier that would otherwise be expected from acute surges in blood pressure. The cerebrovascular system also receives parasympathetic supply, but it is thought to have little role under normal physiological conditions. Some evidence from chronic denervation studies suggests a potential role in maintaining CBF during periods of low perfusion pressure and thereby reducing ischaemia and infarction. Intrinsic or central neural regulatory pathways have also been investigated to establish their autoregulatory role, with neuronal nitric oxide implicated and so-called neurovascular units, comprised of neurons separated from microvessels by perivascular ganglia and basement membrane (Talman and Nitschke Dragon, 2007). Their exact contribution remains unclear.

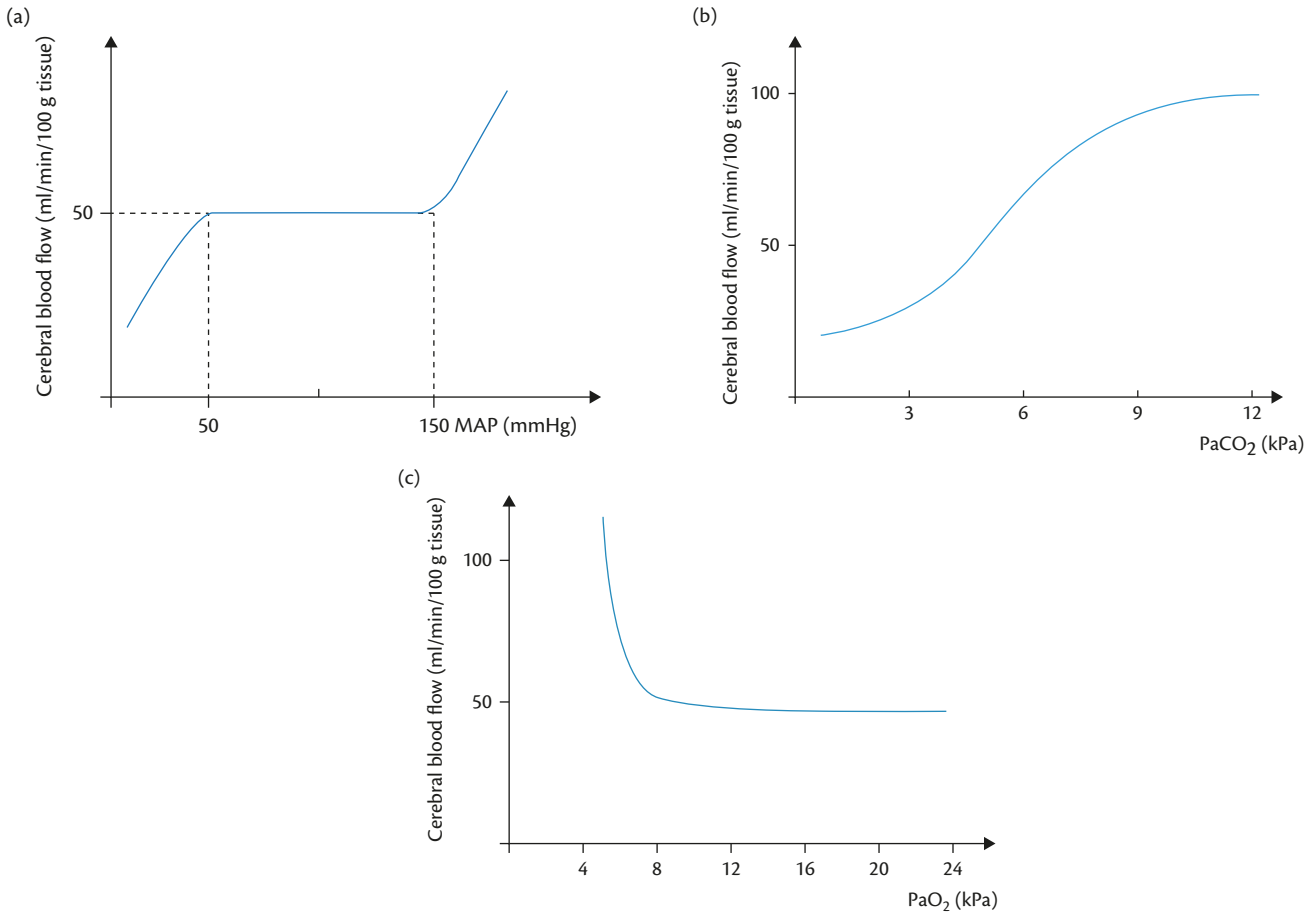

Fig. 46.8 (A) Relationship between CBF and MAP. (B) Relationship between CBF and PCO_2. (C) Relationship between CBF and PO_2.

Metabolic regulation and the control of blood vessel diameter

Metabolic regulation is thought to be most influential at low perfusion pressures. When CBF falls to levels outside the autoregulatory range, there is a compensatory rise in oxygen extraction from blood. Regional increases in neuronal activity are associated with corresponding regional increases in cerebral metabolic rate. Mechanisms are likely to involve hypoxia, intrinsic neural pathways, and associated release of metabolic factors.

Arterial PCO_2 and PO_2 can affect CBF (Figs. 46.8B and 46.8C), through changes in cerebral vessel diameter. CO_2 has a marked and reversible effect on CBF. Hypercapnia causes significant dilation of cerebral arteries and arterioles, with a resulting increase in CBF, while hypocapnia causes the reverse. Following hypocapnia, detectable changes in pial artery diameter and CBF occur after 30 seconds. Due to the curvilinear relationship, outside the physiological range of PCO_2, reductions cause a marked reduction in CBF. After a period of 24–48 h, due to physiological buffering, hypocapnic reduction in CBF may not be maintained. At values beyond 10 kPa, near maximal vasodilation is achieved therefore increases in PCO_2 have a modest effect on CBF. The mechanism of hypercapnic vasodilation is not fully understood but is thought to involve the direct effect of H^+ on cerebral vascular muscle (Kontos et al., 1977). Finally, hypocapnia is known to improve cerebral pressure regulation while hypercapnia impairs it.

Hypoxia is also a profound vasodilator to ensure adequate oxygenation of brain tissue. At levels above 8k Pa, changes in PO_2 have a very minimal effect on CBF, with CBF near constant. Below 6.7 kPa, CBF increases rapidly with increasing hypoxia. Again, the mechanism of hypoxic related cerebral vasodilation is not fully understood. Mechanisms are thought to include reduction in adenosine triphosphate (ATP) levels opening potassium channels on cerebral smooth muscle and local changes in nitric oxide and adenosine production.

Controversy: Mannitol and cerebral blood flow

The blood haemocrit level and therefore viscosity of blood can affect CBF. Increases in CBF due to reduced haematocrit and viscosity may be counterbalanced by reduced and suboptimal oxygen delivery. At haematocrit levels below 30%, increases in CBF can be attributed to low arterial PO_2 and may result in cerebral ischaemia. Mannitol is known to reduce ICP, but its mechanism of action is disputed. Traditionally mannitol has been suggested to reduce ICP through a direct osmotic action and subsequent reductions in cerebral oedema (Nath and Galbraith, 1986; Donato et al., 1994). However, evidence including its speed of action, is more consistent

with an autoregulatory cerebral vasoconstriction and reduction in intravascular volume in response to a rapid increase in peripheral intravascular volume and hence cerebral perfusion (Rosner and Coley, 1987). It is also postulated the perfusion and autoregulatory cerebral vasoconstriction occurs due to a reduction in blood viscosity (due to changing red blood cell rheology) (Burke et al., 1981; Muizelaar et al., 1983). However, more recent studies in head-injured subjects have not demonstrated a fall in cerebral blood flow following mannitol administration (Diringer et al., 2012) and others have suggested it has a direct effect not on pressure but as a neuroprotectant. For example, it is thought to act as a free radicle scavenger. Studies have also suggested that prolonged usage may be detrimental through subsequent increases in ICP and recent studies have focused on hypertonic saline which may similarly lower ICP but without such rebound rises (Castillo et al., 2009; Rickard et al., 2014). In summary, although mannitol acutely reduces cerebral volume and ICP, its exact mechanism of action remains unclear (Sakowitz et al., 2007).

The pathophysiology of aneurysms

Federico Cagnazzo, Giuseppe Lanzino, and Neal F. Kassell

Introduction

Cerebral aneurysms are pathological acquired dilatations of the arterial wall (Sforza et al., 2009). Approximately 80–90% of intracranial aneurysms (IAs) are saccular or berry aneurysms (Wiebers et al., 2004) and in this chapter, unless otherwise specified, we will refer to this specific aneurysm type. Intracranial aneurysms are found in 1–2% of people undergoing imaging studies while autopsy studies indicate a prevalence in the adult population between 1% and 5%. Intracranial aneurysms are responsible for about 80–85% of all cases of non-traumatic subarachnoid haemorrhage (SAH). The commonest age of presentation of aneurysms is in the fifth decade of life, with a slight female preponderance of 3:2.

Theories regarding aneurysm formation and development

The pathophysiology of IAs is controversial, most likely multifactorial and related to interactions between haemodynamic forces, biology of the vessel wall, genetic predisposition, and external modifiable factors (Sforza et al., 2009).

Vessel wall biology

Intracranial aneurysms are often located at bifurcation points where there are more collagen than elastin fibres, and where the muscular layer is less developed. Smooth muscle–cell (SMC) apoptosis and elastin/collagen fibre–reconstitution mechanisms which occur as part of vascular wall remodelling may be implicated in the weakening of the vessel wall, with subsequent aneurysm formation (Hara et al., 1998). Kondo et al. (Kondo et al., 1998) examined the role of medial layer smooth muscle cell (SMCs) apoptosis during development and growth of IAs. In this experimental study, IAs were induced through ligation of the left common carotid artery combined with renal hypertension. Progressive apoptotic changes in the SMCs appeared in the medial layer as the experimental aneurysms formed. In the late stages, most medial SMCs had disappeared and the aneurysm wall consisted mostly of connective tissue. Electron microscopic studies confirmed progressive SMCs apoptotic changes such as chromatin condensation and fragmentation of the cytoplasm and nucleus. Moreover, the aneurysmal dome showed late characteristics of apoptosis (advanced nuclear and cytoplasmic condensation, and formation of apoptotic bodies). This study supports the theory that aneurysm formation can result from complex remodelling of the wall which induces apoptosis of the media layer.

Vascular extracellular matrix enzymes such as gelatinase, elastase (Chyatte and Lewis, 1997), or matrix metalloproteinase (Bruno et al., 1998) may also be implicated in this process.

Genetic factors

Genetic factors are implicated in the genesis of intracranial aneurysms. Intracranial aneurysms are more prevalent in siblings of patients with a history of IAs in another first-degree relative. Many studies have focused on the isolation of genetic loci correlated with IAs and several potential candidate genes have been identified (Table 47.1).

Haemodynamic factors

The role of haemodynamic factors in the genesis of IAs is suggested by the observation of an increased risk of aneurysm formation in situations of increased haemodynamic stress such as an 'unbalanced' anterior communicating artery (Acom) complex (dominant A1 segment of the anterior cerebral artery on one side with hypoplasia of the contralateral one), in patients with low-pressure shunts such as high-flow arteriovenous malformations, and along the collateral pathway after spontaneous or iatrogenic carotid occlusion (Matsuda et al., 1983; Kayembe et al., 1984; Redekop et al., 1998).

More recently, sophisticated computer-generated flow modelling has suggested a potential role of wall shear stress and other local haemodynamic factors in the genesis, growth, and possibly rupture of IAs. However, most of these models are flawed by the fact that such calculations are based on comparisons between ruptured and unruptured IAs which are two fundamentally different pathological processes.

Environmental (modifiable) factors

Several longitudinal and case-control epidemiological studies have been conducted to identify a possible correlation between various modifiable (external) factors and development or rupture of IAs. Convincing evidence exists only for cigarette smoking and hypertension. The HUNT study, prospectively conducted in Norway (Koskinen and Blomstedt, 2006) between 1983 and 1986, showed that current smokers (hazard ratio (HR) 6.1) and, to less extent former smokers (HR 2.7), have a higher incidence of aneurysmal SAH than

Table 47.1 Most common heritable disorders associated with intracranial aneurysms

Disorder	Inheritance pattern	Gene	Gene product	Prevalence
ADPKD	AD	PKD1	Polycystin 1	>1/1000
EDS	AD	COL3A1	Collagen type III	1–9/100 000
MfS	AD	FBN1	Fibrillin 1	1–5/10 000
NF 1	AD	NF1	Neurofibromin	1–5/10 000
PXE	AD and AR	ABCC6	ATP binding cassette	1–9/100 000

ADPKD, autosomal dominant polycystic kidney; disease; EDS, Ehlers-Danlos syndrome; Marfan's syndrome; NF1, neurofibromatosis type 1; PXE, pseudoxanthoma elasticum.

those that have never smoked. The reason for this association is not completely understood. It is possible that smoking triggers an inflammatory response through various mechanisms resulting in aneurysm formation and/or rupture (Chalouhi et al., 2012).

Systolic blood pressure is another modifiable risk factor associated with IAs. In the HUNT study, the risk of aneurysmal SAH was significantly higher in people with systolic blood pressure between 130 and 139 mmHg than in the reference population (<130 mmHg systolic). Furthermore, a HR of 3.3 was present in people with systolic blood pressure more than 170 mmHg (Koskinen and Blomstedt, 2006). It is interesting how hypertension and smoking combined have an additive interaction: in a prospective study, the hazard ratio for aSAH was 13.3 times higher for smokers with hypertension than subjects without any of these two factors (Lindekleiv et al., 2012). The association between other modifiable factors (including alcohol consumption, hormonal factors, and so on) with aneurysm formation and rupture is more controversial.

Location

Saccular aneurysms arise typically at branching points of arteries forming the circle of Willis. Rhoton introduced (Rhoton et al., 1979) three basic rules about the location of saccular aneurysms: (1) aneurysms arise at branching sites of the parent artery (e.g. PComA, middle cerebral artery (MCA) bifurcation, basilar bifurcation); (2) aneurysms arise from a turn or curve of the artery; and (3) the dome lays in the direction of the maximal haemodynamic flow. Non-branching aneurysms (located at non-branching sites of the artery) are less common and often are not berry aneurysms.

About 90% of saccular aneurysms are located in the anterior cerebral circulation and their relative distribution in relation to various specific locations varies across different populations and is different between ruptured and unruptured aneurysms. Among ruptured aneurysms, anterior communicating complex aneurysms are the most frequent (30–35%) followed by internal carotid aneurysms (including PComA, 30%) and MCA aneurysms (20%). In the posterior circulation, the basilar bifurcation is the most common site.

Size and morphology

Size of an aneurysm is very important because it correlates with the risk of aneurysm rupture and with the risk of treatment. Conventionally IA are classified in three groups based on the maximum diameter of the dome: Small (up to 10 mm in diameter); Large (between 11 and 25 mm), and Giant (larger than 25 mm).

A saccular aneurysm is composed of a neck (the portion of the aneurysm connected to the parent artery) and a fundus or sac. With the development of endovascular techniques, determination of the size of the neck has become especially important. Aneurysms with a neck larger than 4 mm are considered wide-neck aneurysms. The neck/dome ratio is another important morphological feature affecting endovascular treatment.

With computational fluid dynamic studies, several other morphological aspects of IAs have been analysed particularly as they relate to the risk of rupture. These morphological features include the aspect ratio (aneurysm cranio-caudal dimension divided by transverse diameter) and the aneurysm angle (Fig. 47.1).

The presence of irregularities and secondary outpouching (also known as blebs, 'daughter sacs', or lobulations) is not uncommon. In ruptured aneurysms, these daughter sacs often identify the point of rupture (Fig. 47.2). These daughter sacs are commonly located on the dome opposite to the point of maximal inflow. In unruptured aneurysms, such irregularities may be associated with an increased risk of rupture (Cebral et al., 2010) and their presence or absence is one of the important factors in deciding whether or not to treat.

Familial IA and associated conditions

Familial aneurysms

The risk of harbouring an IA is increased in relatives of patients with IAs with or without history of aneurysmal SAH (Thompson et al., 2015). The risk is increased in first-degree relatives, in the presence of hypertension and/or smoking, and in people with two or more relatives affected the risk is increased 15-fold. Screening of family members of patients with aneurysmal SAH without additional affected relatives is controversial. Screening of family members older than 30 is recommended if two or more relatives are affected in a given family (Thompson et al., 2015). Before screening, counselling

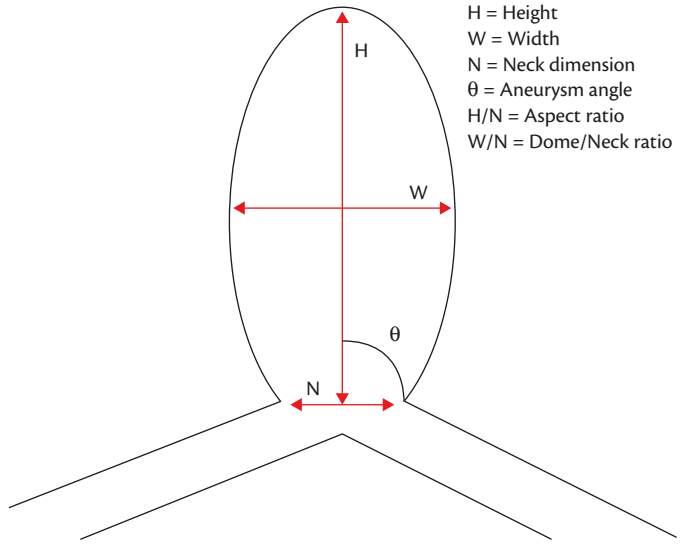

Fig. 47.1 Schematic illustration of a cerebral aneurysm and morphological parameters.

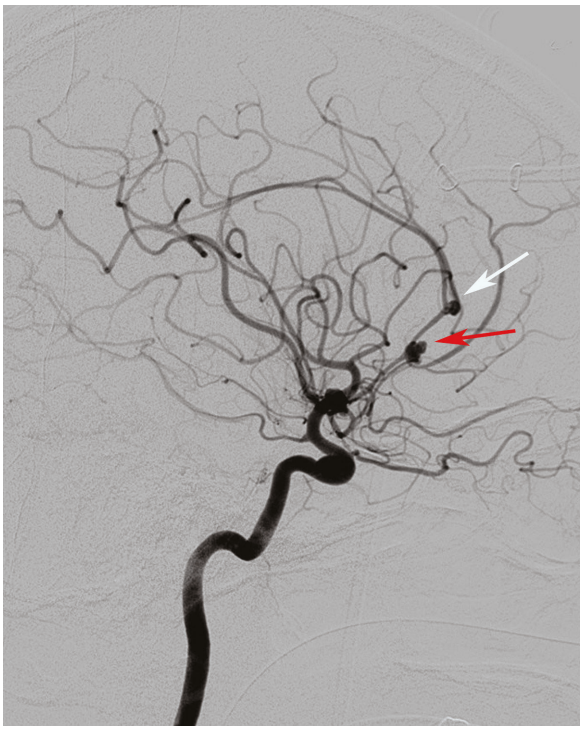

Fig. 47.2 Patient with acute subarachnoid haemorrhage (SAH). Arterial phase lateral angiogram of the left internal carotid artery (ICA) shows two distal anterior cerebral artery aneurysms (red and white arrows). The daughter sac (red arrow) identifies the point of rupture.

regarding the implications of a diagnosis of IAs is indicated since not all unruptured aneurysms warrant treatment.

There is a large spectrum of hereditable and non-hereditable pathological conditions which have been associated with IAs (Table 47.1). Some of these conditions include:

- *Autosomal dominant polycystic kidney disease (ADPKD)*: monogenetic pathology present with renal and visceral cysts associated with a spectrum of vascular abnormalities including cerebral aneurysms (often multiple). Cerebral aneurysms are found in 25% of patients with this condition and screening is recommended in patients with polycystic kidney disorder and a family history of IAs. ADPKD increases the risk of IA by 10–20-fold depending on whether there is also a family history of IAs. In ADPKD coexistent hypertension may further facilitate the formation of IAs. A recent study showed that ADPKD patients with IAs had higher blood pressure parameters (especially those older than 45 years of age), compared with ADPKD patients without IAs. Patients with ADPKD and hypertension should therefore be screened for IAs (Niemczyk et al., 2014).
- *Collagenopathies (such as Ehlers-Danlos, Type IV)*: anomalies in type III collagen with fragile skin and hypermobile joints, vascular fragility, disposition of supra-aortic vessel dissections, carotid–cavernous fistulas, and intracranial aneurysms. Although rare, it is important to recognize this condition since these patients are at very high risk of complications from intravascular diagnostic and therapeutic catheterizations because of their vascular fragility.
- *Marfan's syndrome*: abnormalities of the cardiovascular system caused by a disorder of fibrillin (the major glycoproteic component of elastic tissues). Patients are often tall with arachnodactyly and hypermobile joints, and present a higher risk of intra- and extracranial aneurysms development.
- *Aortic coarctation*: narrowing or constriction of the lumen of the aorta most commonly located distal to the origin of the left subclavian artery, near the insertion of the ligamentum arteriosum. IAs are found more often in patients with aortic coarctation (10.3% in an MR angiography series of 117 patients with aortic coarctation) (Curtis et al., 2012).
- *Fibromuscular dysplasia*: idiopathic, segmental, non-atherosclerotic, non-inflammatory vascular disease that mainly affects renal, extracranial carotid, and vertebral arteries. Intracranial fibromuscular dysplasia is rare. The most common clinical manifestations of fibromuscular dysplasia are related to steno-occlusive disease of major arteries. The incidence of IAs is higher in patients with fibromuscular dysplasia compared with the general population (7.3% in a meta-analysis performed by Cloft et al.) (Cloft et al., 1998).

Intracranial aneurysm progression and risk of rupture

Aneurysm growth is reflected in radiological (macroscopic) change and structural wall variations (microscopic) at the molecular levels. Aneurysms progression depends on a balance between wall repair and wall destruction which can be accelerated in patients who smoke or have arterial hypertension (Etminan and Rinkel, 2016). In a recent meta-analysis of nearly 13 000 IAs, Brinjikji et al. found that the overall proportion of growing aneurysms was 3% per aneurysm-year. The most important risk factors for growth included age older than 50 years, female sex, smoking history, and non-saccular shape. Aneurysm growth appears to be associated with a high risk of rupture (rupture rate of 3.1% per year compared with 0.1% per year for stable IAs) (Brinjikji et al., 2016). Similarly, Villablanca et al. found that the annual rupture rate was 12 times higher in growing compared with non-growing IAs (Villablanca et al., 2013), whereas Mehan et al. found that IAs growth was associated with an OR 55.9 for rupture on a multivariate analysis (Mehan et al., 2014).

Special situations

Traumatic aneurysms

Traumatic aneurysms (TAs) account for less than 1% of all intracranial aneurysms, although their true incidence is unknown and many may go undetected. Traumatic aneurysms are the second most common type of aneurysm encountered in children and adolescents (5–15% of all aneurysms in children) and are more prevalent in men. Traumatic aneurysms can be subdivided into 'true' TAs composed of all of the three layers of the vessel wall. Usually, they are caused by direct blunt trauma or by indirect forces and represent a 'bulge' in the vessel. 'False' TAs are the result of a direct interruption of the continuity of a vessel with formation of a perivascular haematoma. The wall of false TAs is composed only of fibrin tissue surrounding a partially organized haematoma.

All major intracranial arteries can be involved, and the vessels affected are a function of the mechanism of injury. The most common locations are the internal carotid artery (ICA) (46%), the MCA (25%), and the anterior cerebral artery (ACA) (22%).

The natural history of untreated TAs is not well understood. The risk of rupture can be high especially if progressive enlargement is documented on serial imaging studies. A low index of suspicion is important for adequate diagnosis and in high-risk cases, repeating another vascular imaging study after a negative first one may be indicated, since TAs may become visible a few days after the trauma. Iatrogenic pseudoaneurysms are a special subcategory of traumatic aneurysms and have been reported after a variety of surgical procedures including trans-sphenoidal surgery, craniotomy for tumours and vascular lesions, third ventriculostomy, and even after external ventricular catheter placement.

Dissecting aneurysms

Dissecting intracranial aneurysms are becoming increasingly recognized and are a potential, albeit less common, source of SAH. They originate from a dissection, which corresponds to a tear through the intima and internal elastic lamina in which blood accumulates between the different layers of the vessel wall. Often called pseudoaneurysms or false aneurysms (i.e. on histological section, they lack the normal three layers of vessel wall), these lesions contain the basic components of the normal vessel wall and therefore a more appropriate definition would be dissecting aneurysms.

Dissecting aneurysms are more commonly located in the extracranial vertebral or carotid artery but can also involve intracranial arteries. Intracranial dissecting aneurysms have been described to involve virtually any intracranial vessels although by far the most common localization is the intracranial vertebral artery where they characteristically involve the V4 segment of the vessel. Location in the anterior circulation is more typical in children and young adults. Unlike dissecting aneurysms involving the extracranial vessels which do not cause haemorrhage, intracranial dissecting aneurysms can be asymptomatic, present with ischaemic symptoms, headache, or frank haemorrhage (Fig. 47.3).

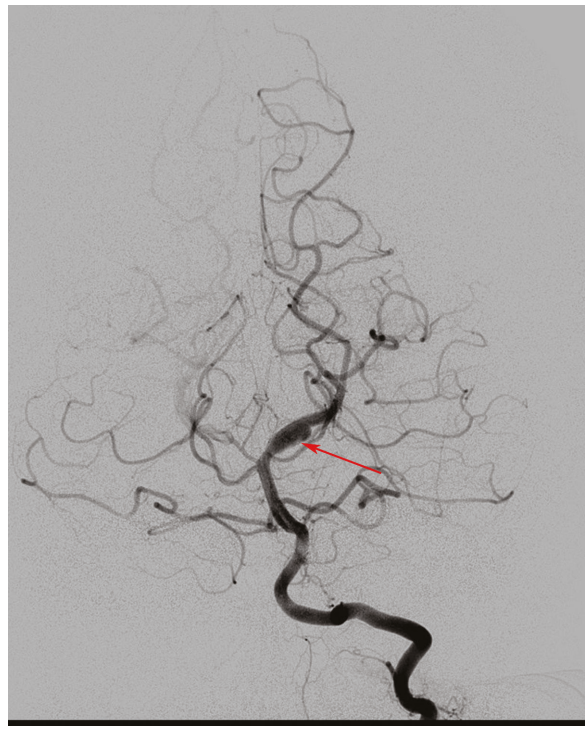

Fig. 47.3 Left vertebral artery angiography shows a dissecting aneurysm involving the proximal left posterior cerebral artery.

Blister-like aneurysms

Over time, the term *blister-like aneurysms* has been misused to indicate very small saccular aneurysms at branching sites of the circle of Willis. However, the term applies only to small dilatations, hemispherical-shaped and bulging, from non-branching sites of the dorsal wall of the supraclinoid ICA opposite to the origin of the PCom and the anterior choroidal arteries (Fig. 47.4). It is controversial whether all blister-like aneurysms represent focal dissections of the ICA or whether there are two distinct types: true blisters which represent a hole in the wall of the vessel and dissecting pseudoaneurysms of the ICA. They represent about 1% of all ruptured aneurysms and are characterized by a very fragile wall which makes treatment challenging. Typically diagnosed after a bleed, blister-like aneurysms can be difficult to identify on the first catheter angiogram and become more evident only at follow-up.

Fusiform aneurysms

The term fusiform aneurysm refers to a dilatation of the arterial wall which involves at least 270° of the vessel wall. Fusiform aneurysms are more commonly seen in the posterior circulation, in patients older than 60 years and have a male predominance. The pathophysiology is unknown, some may be related to prior dissections and it is therefore possible that the umbrella term of 'fusiform' aneurysms includes dilatations of the vessel wall of different aetiology. A particular type of fusiform aneurysm is the so-called dolicoectactic aneurysm characterized by the uniform pathological dilatation of an entire vessel segment often in association with tortuosity of the vessel itself (Fig. 47.5). Fusiform aneurysms can be incidental (in which case have often a fairly benign natural history), but they can also present with ischaemic symptoms, symptoms related to mass effect, and haemorrhage.

Mycotic aneurysms

The term 'mycotic aneurysms' implies the presence of infection and destruction of the walls of the vessels. The most common source of the infection is infective endocarditis. Mycotic aneurysms typically involve distal branches and can occur away from branch points. Antibiotic therapy targeting the offending agent is the main treatment of mycotic aneurysms and all patients should undergo appropriate antibiotic therapy based on the sensitivity of the microbial agent. In some clinical situations, antibiotics can be initiated empirically based on the original infection and standard guidelines. Monitoring of systemic infection should be made through serial blood cultures. Therapy must be continued for 4–6 weeks or until cultures become negative. Endovascular or surgical treatment can be considered in specific situations (Kannoth and Thomas, 2009).

Multiple aneurysms

Multiple IAs (MIAs) are reported with variable incidences in different studies: 13.9% in the UCAS Japan study (Morita et al., 2012), and 35% in the ISUIA study (Wiebers et al., 2003). In patients

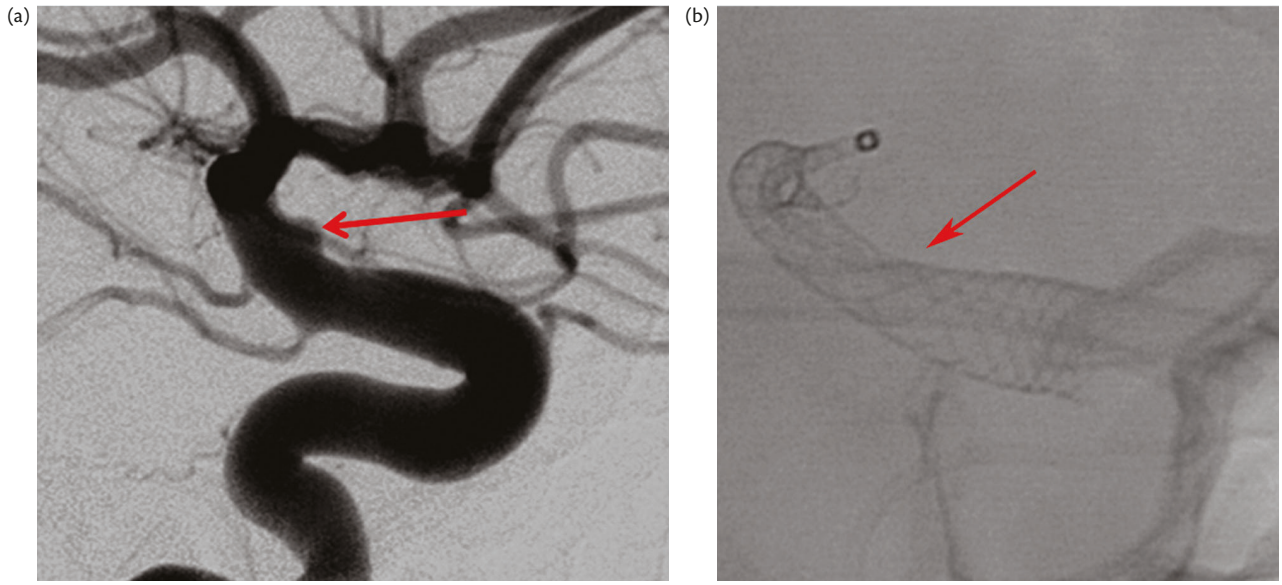

Fig. 47.4 This 30-year-old woman presented with diffuse SAH. Catheter angiography shows a blister-like aneurysm (a) involving the supraclinoid portion of the right ICA (arrow). (B) The blister-like aneurysm was treated with a flow diverter (arrow).

presenting with SAH, MIAs are found in 15–45% of patients. In patients with MIAs, each aneurysm is not at increased risk of rupture, but the cumulative risk of rupture is higher than in patients with only one aneurysm (Morita et al., 2012). The exact mechanism of MIAs' formation is not completely understood. Studies have suggested an association between MIAs and cigarette smoking, hypertension, age, and female sex (Juvela, 2000; Ellamushi et al., 2001; Lu et al., 2013). However, the correlation between MIAs and these risk factors remains controversial. Ostergaard and Hog (Ostergaard and Hog, 1985), in a series of 737 patients with IAs (in which 18% harboured MIAs), found that hypertension and female sex were independent risk factors for MIAs, whereas age had no influence. Qureshi et al. (Qureshi et al., 1998) reported that cigarette smoking and female sex, but not hypertension, correlated with MIAs in a series of 419 patients, of which 30% had multiple IAs. Recently, Lu et al. (Lu et al., 2013) reported the association between risk of rupture from MIAs and age, size, and location. In this study, middle age (45–65 years), ACom site, and increasing aneurysm size correlated with a higher risk of rupture.

Fig. 47.5 Dolichoectatic aneurysm of the vertebrobasilar system.

Screening for intracranial aneurysms

Screening for intracranial aneurysms is controversial but for certain familial conditions there is sufficient evidence to recommend screening (Steiner et al., 2013). These include a strong family history (two or more first-degree relatives with intracranial aneurysms), ADPKD and coarctation of the aorta (see earlier). Screening should start at an age 10 years younger than the age of presentation of the index family member. There are no clear guidelines on the frequency and mode of screening, particularly in ADPKD as they have a high incidence of late *de novo* aneurysm formation (1.4% per patient year) (Cagnazzo et al., 2017). Both CT and MR angiography techniques have developed to a high degree of sensitivity and the choice will depend on age (cumulative radiation burden of CT) and the preference of individual centres. Before starting on a course of screening, patients must be carefully counselled as there is a large, cumulative, psychological burden associated with multiple scans and on identifying small aneurysms that may not require immediate intervention.

Table 47.2 Factors analysed in the UIATS study (for clinical decision-making in the management of the unruptured IAs), and PHASES study (for the prediction of 5-year risk of rupture)

Factors analysed	UIATS	PHASES
Patients factors		
Age	Yes	Yes
Previous SAH from another IA	Yes	Yes
Familial IAs or SAH	Yes	No
Ethnicity	Yes	Yes
Smoking	Yes	No
Hypertension	Yes	Yes
ADPKD	Yes	No
Drug and Alcohol abuse	Yes	No
Clinical symptoms related to IA	Yes	No
Aneurysms multiplicity	Yes	No
Reduced quality of life due to fear of rupture	Yes	No
Life expectancy (for chronic or malignant disease)	Yes	No
Neuropsychiatric disorders	Yes	No
Coagulopathies	Yes	No
Aneurysm factors		
Size	Yes	Yes
Morphology	Yes	No
Location	Yes	Yes
Evolution	Yes	No
Treatment-related factors		
Risks of treatment related to age, size, and complexity of the IA	Yes	No

Controversies

Management of unruptured aneurysms

With widespread utilization of non-invasive imaging, unruptured IAs are being diagnosed with increasing frequency. Management of unruptured IAs is very controversial. While the vast majority of small IAs will remain quiescent for life, a very small number will go on to rupture with potentially disastrous consequences. There is a paucity of true natural data history on IAs because even in the two largest studies conducted so far, the ISUIA study (Wiebers et al., 2003) and the Japanese study (Morita et al., 2012), many patients were treated with either surgery or endovascular treatment based on physician and patient preference. Thus, these studies which are often incorrectly labelled as natural history studies are prospective cohorts of untreated patients. Because of this controversy and the conflicting data, treatment of an unruptured IA continues to be art more than science. In general, small aneurysms (<7 mm) in diameter have an exceedingly low risk of rupture as long as they are asymptomatic and a purely incidental finding. Factors such as location, presence of lobulations, and other risk factors for aneurysm rupture affect the risk of rupture and must be taken into account when deciding between active or conservative management. Treatment recommendations must also take into account the risk of treatment and the patient's degree of anxiety about the knowledge of the IA.

Several studies have tried to come up with algorithms of treatment based on information available (PHASES) (Greving et al., 2014) or a consensus of experts (UIATS) (Etminan et al., 2015) (Table 47.2). Additional controversy clouds the issue about the best treatment modality: surgical versus endovascular. In general, surgery achieves higher rates of complete angiographic occlusion, but it is more invasive. The converse is true for endovascular treatment. There are no studies which have studied this issue directly in unruptured IA. If a patient with an unruptured IA is managed conservatively with no intervention, the question arises about the need, frequency, and type of follow-up. There are no guidelines and follow-up must be individualized in these cases. In general, we recommend repeating a follow-up non-invasive study (usually MRA since no radiation is involved) 6–12 months after the diagnosis. If no interval growth is demonstrated, then further imaging is individualized based on factors such as patient age, risk factors, and aneurysm size and location.

The pathophysiology of subarachnoid haemorrhage

Jason McMillen

Subarachnoid haemorrhage

Spontaneous subarachnoid haemorrhage (SAH) is due to a rupture of an intracranial aneurysm in the majority of cases (85%). In some patients, no underlying cause is identified and approximately 60% of these cases have a perimesencephalic distribution of blood. Other non-aneurysmal SAH aetiologies include pial arteriovenous malformations, tumours, anticoagulants, vascular dissections, and vasculitides.

Perimesencephalic SAH is a specific non-aneurysmal SAH syndrome with a characteristic pattern of haemorrhage on CT scan. Haemorrhage is centred in the prepontine and perimesencephalic cisterns with some extension to the adjacent cisterns, but not distally into the interhemispheric and Sylvian fissures, and without extensive intraventricular extension.

Aneurysmal SAH usually occurs as a consequence of spontaneous rupture of the wall of a saccular intracranial aneurysm. The aetiology of the changes in the arterial wall that predispose to formation, growth, and eventual rupture of an aneurysm are multifactorial, involving changes in the structure and composition of the vessel wall, as well as haemodynamic stresses imposed upon the vessel.

Mortality and morbidity resulting from subarachnoid haemorrhage is common, and an understanding of the mechanisms of the physiological insults resulting from this condition can assist with improving management and outcomes. The main complications of aneurysmal SAH are rebleeding, delayed ischaemia, and hydrocephalus.

Pathophysiology of subarachnoid haemorrhage and brain injury

The precise details of aneurysm formation are poorly understood, but they are thought to arise secondary to an imbalance between local haemodynamic forces and arterial wall integrity, most commonly at vessel bifurcations. No single model explains all aspects of aneurysm formation, growth, and rupture, and there seem to be multiple factors involved in their pathogenesis, including congenital, acquired, and environmental influences.

When aneurysms form, they tend to follow Rhoton's rules for aneurysm formation. They arise from a branch point of a parent artery, and arise from the convex side of turns or curves, where wall shear stresses are greatest. The aneurysms also tend to point in the direction that blood would flow if the turn or curve was not present.

Aneurysm rupture may occur spontaneously, but may also occur with activities such as straining or coitus. In addition to the classical symptoms of headache and meningism, patients may present with changes to sensorium or coma, reflecting early brain injury. Rupture of an aneurysm is accompanied by an acute increase in intracranial pressure secondary to extravasation of blood into the subarachnoid space or the brain parenchyma, as well as a vasodilatory cascade. A reduction of cerebral perfusion pressure may manifest as loss of consciousness. Subsequent acute global ischaemia and cerebral oedema may contribute to the early brain injury after SAH. Less favourable outcomes associated with higher Fisher Grade SAH result from the greater volume of haemorrhage and more severe early brain injury. Intracerebral haemorrhage may cause direct injury to the brain parenchyma with consequent focal deficits.

A complex interaction of pathologies injurious to the brain occur subsequent to the acute global ischaemic insult of SAH (Budohoski et al., 2014). Cell death mechanisms are initiated within 24 hours, including necrosis, autophagy, and programmed cell death. Breakdown of the blood brain barrier and inflammatory mechanisms commence, including release of proinflammatory cytokines and migration of inflammatory cells. As well as direct brain injury, this is associated with cerebral vasospasm. Oxidative stress resulting from release of free radicals results in altered mitochondrial function and other disorders of cellular metabolism, and is associated with increased cell death after SAH. Cerebrovascular autoregulation is impaired, which may exacerbate ischaemia that may otherwise have been avoided by the usual physiological compensatory mechanisms. Electrophysiological abnormalities are associated with severe cerebral metabolic dysfunction, including seizures and cortical spreading depolarization. These may result in hypoperfusion, hypoxia, and may precede delayed ischaemic deficits, even in the absence of later vasospasm. Microthrombi in parenchymal vessels result from an early increase in procoagulant activity, and may exacerbate ischaemia associated with spasm of both larger and microvessels.

Hydrocephalus after SAH is common, and may result in progressive neurological impairment or death. The radiological criteria for the diagnosis of post SAH hydrocephalus vary, but it is thought to be

present in up to 20% of SAH patients on presentation. Approximately half of these patients will show signs of impaired consciousness, and may require acute treatment. A similar number may develop chronic hydrocephalus and may be candidates for permanent cerebrospinal fluid (CSF) diversion.

Hydrocephalus after SAH occurs due to impairment of CSF bulk flow and absorption via its normal physiological and anatomical pathways. Intraventricular blood clot may obstruct CSF flow through the usual circulation pathways such as the cerebral aqueduct of Silvius, resulting in obstructive hydrocephalus. Cellular blood components as well as elevated protein and blood breakdown products such as fibrin can impair CSF outflow and absorption through the arachnoid villi, and cause communicating hydrocephalus.

Acute symptomatic hydrocephalus is typically managed with ventriculostomy and temporary external CSF drainage. The acute change in transmural pressure in an unsecured aneurysm resulting from acute CSF drainage may be associated with an increased risk of rebleeding, and consideration should be given to maintaining a higher intracranial pressure (ICP) than would otherwise be targeted in order to reduce this risk until the aneurysm is secured. Other temporary measures to reduce hydrocephalus include serial lumbar punctures or lumbar CSF drainage. Intraoperative measures during surgical clipping of a ruptured aneurysm to minimize the risk of chronic hydrocephalus include CSF toilet and third ventriculostomy with fenestration of the lamina terminalis. However, despite these measures, some patients will have persistent hydrocephalus necessitating a ventriculoperitoneal shunt. Elevated cell and protein concentrations in CSF following SAH can impact on the function of ventriculoperitoneal shunt hardware, contributing to premature shunt failure. It may be necessary to continue temporary CSF diversion until these parameters reduce before implantation of a ventriculoperitoneal shunt.

Epidemiology and Incidence of aneurysms and risk factors for rupture

The overall incidence of unruptured aneurysms is difficult to determine accurately due to the asymptomatic nature of most of these lesions unless they rupture. Screening large populations accurately with cerebrovascular imaging is costly and not without risk from invasive procedures and radiation, although the numbers of asymptomatic aneurysms being detected are increasing with greater use of increasingly sensitive non-invasive imaging modalities. Both imaging and autopsy studies suggest an incidence of unruptured intracerebral aneurysms ranging from 1% to 9%. An increased incidence of aneurysms has been noted in the Finnish and Japanese populations, females, as well as with increasing age and certain medical conditions (Rinkel et al., 1988).

Subarachnoid haemorrhage from aneurysm rupture is the most devastating complication of intracranial aneurysms, often resulting in morbidity or death. Determining the risk of aneurysm formation, growth, and rupture is critical to balancing this prognostic risk against the risks of intervention.

The baseline incidence of aneurysmal subarachnoid haemorrhage in the general population has been reported to be 6–11 per 100 000 individuals per year. Of more clinical relevance is the risk of rupture and haemorrhage in patients diagnosed with an unruptured intracranial aneurysm. Several factors need to be considered when calculating the risk of subarachnoid haemorrhage. Patient-related factors such as increasing age, female gender, ethnicity, and family history have all been shown to influence the risk of subarachnoid haemorrhage. The presence of multiple aneurysms or a previous aneurysmal haemorrhage also confers greater future risk above the additive risk of more than one aneurysm—so-called type 2 aneurysms in the ISUIA studies discussed later. Modifiable risk factors have been recognized in numerous studies, including tobacco smoking and hypertension. Numerous aneurysm related variables have also been demonstrated to influence the risk of rupture, including anatomical location of the aneurysm, size, morphological characteristics, and demonstrated growth with serial imaging or development of new symptoms related to growth.

The most important studies attempting to quantify these risks are the ISUIA studies (Wiebers et al., 1998; Wiebers et al. 2003). While not without their critics, these prospective multicentre studies have provided useful information to prognosticate aneurysm rupture risk based on anatomical location and size. They determined that small (<7 mm) anterior circulation aneurysms have low rupture rates, as do small type 1 aneurysms of the posterior circulation. Higher rates of rupture were noted for all posterior circulation aneurysms and aneurysms larger than 7 mm in diameter. Earlier suggestions that aneurysms less than 10 mm in diameter have a near-zero risk of haemorrhage are unlikely to be correct.

Studies of the high-risk Finnish and Japanese populations (Juvela et al., 2000; Morita et al., 2012) and others have determined overall annual rupture rates to be between 0.95% and 1.3%. High risk factors identified in these studies in addition to size and location included advanced patient age, smoking, and the presence of a daughter sac. Conflicting findings between studies may be due to methodological differences and different populations.

A more recent investigation pooling the data of several previous large studies was able to generate a statistical tool to assist with prediction of rupture risk according to the variables found to be of clinical significance (Greving et al. 2014). The PHASES score (**Table 48.1**) predicts that patients from Japan and Finland (population), hypertension, age more than 70 years, aneurysm size, a history of earlier subarachnoid haemorrhage, and the aneurysm's anatomical site are all significant risk factors for haemorrhage. Smoking and female gender were not found to reach statistical significance as risk variables.

Some connective tissue and other disorders have been associated with a greater incidence of intracranial aneurysms and aneurysm rupture with subarachnoid haemorrhage. These include autosomal dominant polycystic kidney disease (ADPKD), Ehlers-Danlos syndrome type IV, Marfan's syndrome, fibromuscular dysplasia, and coarctation of the aorta. Aneurysms may occur in as many as 20% of patients with fibromuscular dysplasia, and up to 30% of patients with ADPKD. Familial aneurysms have been recognized, and these are thought to rupture at a smaller size and younger age than sporadic aneurysms.

Overall, it appears that the overall annual risk of rupture of a previously unruptured intracranial aneurysm is approximately 1%. Each patient's individual risk factors for aneurysm rupture need to be assessed and weighed against the risks of treatment in their own institution in order to make a balanced decision about surgical or endovascular management.

Table 48.1 Risk factors for aneurysm rupture

PHASES significant risk factors	P—Population—Japanese or Finnish H—Hypertension A—Age > 70 years S—Size of aneurysm E—Earlier subarachnoid haemorrhage from another aneurysm S—Site—anatomical location of aneurysm
Other postulated risk factors	Female gender Tobacco smoking Familial aneurysms Growth on serial imaging Symptomatic aneurysm

Vasospasm

Vasospasm is one of the most devastating complications of aneurysmal subarachnoid haemorrhage, and is the leading preventable cause of neurological morbidity and mortality in patients who present for medical care. It may lead to death in as many as 7%, and cerebral infarction in 26% of patients with SAH.

By definition, vasospasm is narrowed arterial calibre demonstrated on vascular imaging. This results in delayed or diminished arterial filling distal to the spasm, and resultant ischaemia of the vascular territory supplied by those vessels—delayed ischaemic neurological deficits. The radiological appearances of vasospasm can be detected in 50–90% of patients following SAH, but only half of those patients will show clinical signs of vasospasm such as ischaemic deficits. Conversely, ischaemia can be demonstrated in patients in arterial territories that do not display radiological vasospasm, indicating that other mechanisms are contributing. Additional evidence for this is found in the beneficial action of nimodipine, which has been proven to improve neurological outcomes, but affords little improvement in arterial vasospasm. Conversely, pharmacological reversal of vasospasm with drugs such as endothelin-1 antagonists, have resulted in limited improvement in functional outcomes. It is therefore clear that arterial luminal narrowing is not the sole mechanism of cerebral ischaemia. Additional factors may include tissue inflammation, microvascular thrombosis, and mitochondrial dysfunction. However, from the clinical perspective, vascular narrowing and ischaemia are closely correlated, and strategies to prevent delayed ischaemic neurological deficits are largely based on treatment of the vasospasm.

Vasospasm pathology

Vasospasm appears to occur in intracerebral arteries that have been encased in blood clot, usually within the subarachnoid space. The pathological mechanisms underlying vasospasm are complicated and poorly understood. Oxidation of oxyhaemoglobin to produce methaemoglobin, the formation of superoxide anion radicals, and the release of endothelin 1 have all been implicated. Three main changes that narrow the vessel lumen have been observed. Vascular wall smooth muscle contraction occurs in two phases—an acute phase that is dependent on calcium and adenosine triphosphate (ATP), and a chronic and less reversible phase that is less dependent on calcium and energetic mechanisms. Prolonged muscle contraction is associated with structural damage to the layers of the vessel, including endothelial cell damage, elastic lamina damage, and myonecrosis. The second major change occurs in the endothelium, with loss of synthesis of the vasodilator nitric oxide and increased production of the vasoconstrictor peptide endothelin 1. The final changes result from activation of inflammatory mechanisms within the vessel wall, with increased activity of cytokines and intercellular adhesion molecules leading to remodelling of the vessel wall extracellular matrix and smooth muscle, and direct release of inflammatory cells.

Histological changes in the vessel wall include vacuolization of endothelial cells, and loss of their tight junctions. Breaches in the internal elastic lamina have been noted, as well as necrosis of the smooth muscle of the tunica media. Inflammatory cells and an increase in the extracellular matrix occur in the adventitia. With chronic vasospasm, smooth muscle cells may proliferate in the tunica intima, resulting in intimal thickening.

Incidence

While radiological evidence of vasospasm can be detected in over half of patients with SAH, clinical signs of ischaemia secondary to vasospasm are less common. Delayed ischaemic neurological deficits (DIND) occur in 30–40% of patients with SAH, and seem to occur during the same period post haemorrhage that radiological vasospasm is maximal.

Vasospasm is more common with increased blood volume in the subarachnoid space. The Fisher radiological grade is closely correlated with the frequency of vasospasm, with increasing rates of radiological spasm from Grade 1 (no subarachnoid blood on CT) to Grade 2 (diffuse subarachnoid blood or vertical layers <1 mm thick), and maximal rates of radiological and clinical vasospasm in Fisher Grade 3 (>1 mm vertical layer of subarachnoid blood; 23/24 patients in Fisher's original series developed DINDs). In Fisher Grade 4 (intracerebral or intraventricular blood, with diffuse or no subarachnoid blood) the rate of vasospasm is low.

Increased rates of vasospasm are also reported in higher clinical grades of SAH. Other risk factors may include increasing age, hypertension, and the presence of hydrocephalus.

Time course and natural history

Cerebral vasospasm rarely becomes clinically evident before the third day post ictus, although radiological spasm may be evident earlier than this. The clinical onset is insidious in most cases, but occasionally may become abruptly evident. The peak incidence of onset is between days six and eight post SAH, but may occur as early as day three, or as late as the third week. Clinical signs of vasospasm usually resolve before the radiological signs of vasospasm, which may persist for three to four weeks. The changes of vasospasm are felt to resolve eventually, but if left untreated during their peak may leave a permanent legacy of ischaemic neurological deficits.

Clinical presentation

In the awake patient, changes in neurological status are early signs of clinical vasospasm. The onset of changes can be gradual and subtle, and may include increased headache, slight confusion, agitation or somnolence, or diminished attention and altered cognition. Focal neurological deficits may be difficult initially to detect, and may

progress from a subtle pronator drift or word finding difficulties to more severe deficits if clinical vigilance is not maintained. These clinical changes may have other potential causes such as seizure, rebleeding, hyponatraemia, or hydrocephalus, which may need to be excluded with laboratory and radiological investigations.

Vasospasm affecting large vessels may present with a cluster of signs that reflect the territory of the affected vessel, and may result from the initial distribution of the subarachnoid blood. Anterior cerebral artery vasospasm is the most common. This predominantly affects the frontal lobe, with signs including confusion or agitation, somnolence, abulia, urinary incontinence, and motor weakness in the lower limb. Middle cerebral artery involvement may cause aphasia, monoparesis or hemiparesis, and apraxias. Vertebrobasilar vasospasm is more likely to present with a reduced level of consciousness than with focal deficits.

Other less specific systemic signs of vasospasm include peripheral leucocytosis and pyrexia, which may occur early at the onset of the condition.

In the comatose or intubated patient, clinical signs of vasospasm may be difficult to detect, and the diagnosis of vasospasm is more reliant on ancillary investigations and a high level of vigilance.

Investigation

Other causes of neurological deterioration should be excluded, including electrolyte abnormalities and hydrocephalus or haemorrhage. A positive response to initial vasospasm management, including induced hypertension, is highly suggestive of a diagnosis of vasospasm.

Diagnostic modalities specific for vasospasm measure arterial luminal narrowing, either directly or indirectly by measuring cerebral blood flow and velocity. Transcranial doppler monitoring may detect increased blood flow velocity in large intracranial vessels before the onset of clinical symptoms (Fig. 48.1). While inexpensive and non-invasive, this technique is very operator dependent, and will only detect spasm in large anterior circulation arteries. For example, a flow velocity more than 150 cm/s is considered indicative of vasospasm in the middle cerebral artery (MCA), with a value greater than 200 cm/s indicative of severe vasospasm. As flow velocity is dependent on cardiac output, the Lindegaard ratio (LR) which is the ratio of MCA mean flow velocity to extracranial internal carotid artery mean flow velocity, can be utilized. A LR of more than 3 designates vasospasm, while a LR more than 6 designates severe vasospasm.

Direct radiological measurements of cerebral blood flow can be made with CT perfusion studies (Figs. 48.2A–F), SPECT, or xenon enhanced CT. Cerebral ischaemia or infarction can be diagnosed early using diffusion weighted MRI. Direct imaging of intracerebral vessels is achieved with CT angiography, or catheter digital subtraction cerebral angiography. Catheter angiography is invasive and labour intensive, and is associated with some procedural risk. However, it is the most sensitive modality for detecting both small and large vessel spasm, and interventions such as intra-arterial vasodilator therapies or balloon angioplasty may be instigated in conjunction with the diagnostic procedure.

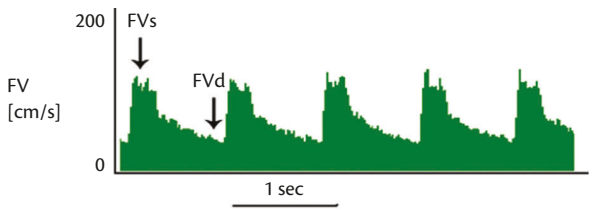

Fig. 48.1 Transcranial Doppler. Indicative waveform from insonation of the middle cerebral artery using transcranial Doppler. The systolic and diastolic flow velocites (FV) are marked. The FVs is used to gauge the progression of vascular spasm or to quantify the Lindegaard ratio (see text).

Invasive measures of cerebral perfusion, oxygenation, and hypoxic cell injury include direct cerebral oxygenation monitoring and microdialysis. These have been used in the critical care setting to detect vasospasm. The techniques only provide information about a focal region of the brain, which may limit their usefulness without appropriate targeting. Other uncommon intensive care techniques include continuous electroencephalography (EEG) monitoring, which may predict the onset of vasospasm.

Monitoring for vasospasm

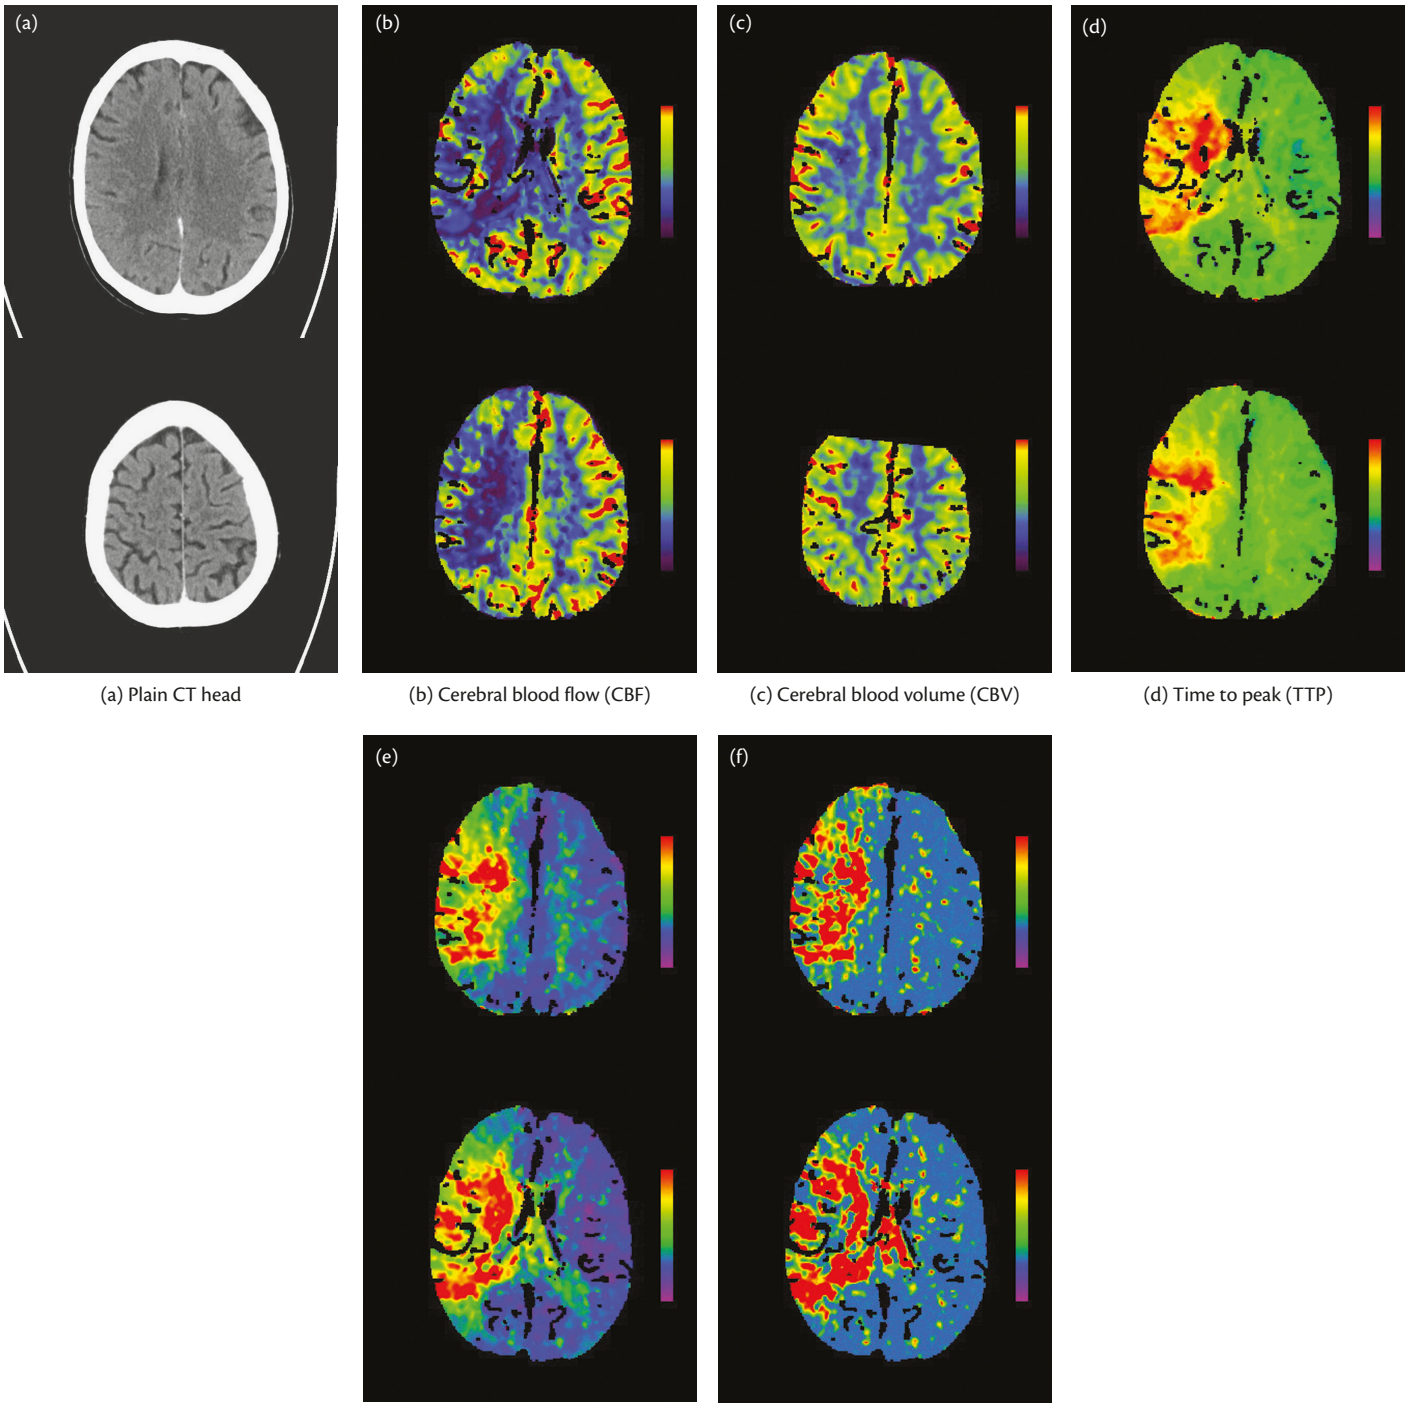
Early detection and treatment of cerebral vasospasm is important to allow rapid initiation of treatment measures to prevent ischaemic deficits. Treatment of vasospasm is not without associated morbidity, so treatment should be reserved for patients in whom the condition has been proven. Radiological spasm may be detectable before the onset of clinical symptoms, and may be the only way of detecting spasm in the unconscious patient, allowing more focussed treatment on those most at risk.

The detection of vasospasm relies heavily on a number of imaging modalities, all of which have different advantages and disadvantages. Transcranial doppler is non-invasive and relatively economical, but it may not be available in every institution, the operator dependent variability may limit its utility and it is anatomically limited with the best acoustic window limited to the MCA artery. Catheter angiography is available in most neurosurgical centres, but is more labour intensive, costly, and indiscriminate use may not be justified due to procedural risks. No evidence exists to determine a single approach to investigation of vasospasm, therefore a protocol for vasospasm investigation and management should be developed in each institution, taking into account the varying resources and expertise available.

Vasospasm prevention and treatment

No single treatment or prevention strategy is entirely effective against the adverse impacts of cerebral vasospasm following SAH. Prevention of neurological deficits relies predominantly upon ensuring adequate cerebral perfusion by avoiding hypovolaemia and hypotension. Three litres of intravenous maintenance fluids should be administered per day. Blood transfusions can be given if the patient is anaemic. Hyperdynamic therapies to prevent vasospasm have not been shown to be of benefit, and hypertension in unsecured aneurysms may increase the risk of rebleeding. Blood pressure should therefore be targeted from normotension to permissive mild hypertension, strictly avoiding hypotension. Close monitoring is mandatory, including blood pressure, fluid balance, and neurological observations.

The calcium channel blocker nimodipine has been shown to be of benefit in the prevention of neurological deficits secondary to cerebral vasospasm following SAH (Pickard et al., 1989). It is administered intravenously or orally, with a dose of 60 mg every four



(a) Plain CT head (b) Cerebral blood flow (CBF) (c) Cerebral blood volume (CBV) (d) Time to peak (TTP)

Fig. 48.2 CT perfusion assessment of vascular spasm. Illustrative CT perfusion scan of patient with Right MCA territory vasospasm. (A) The plain CT head shows no abnormality, while (B) the cerebral blood flow (CBF) map shows reduced flow with maintained cerebral blood volume (CBV), representing ischaemia. A reduced CBV (C) is thought to result from cellular swelling, and compression of the microvasculature indicative of infarction. (D) The time to peak (TTP) map shows the delay in accumulation of contrast caused by the reduced vessel calibre. (E) The TTP map shows the overall delay in exit of contrast from the cerebrovascular bed after the TTP has been reached, typical of vasospasm. (F) The mean transit time (MTT) map demonstrates the mean transit time, the averaged time for transit of contrast through the tissues, with delays being secondary to vasospasm. The colour maps are such that the abnormality is obvious on this parameter map.

hours. It can contribute to hypotension, in which circumstance the dosing can be reduced or changed to a different regime of 30 mg every two hours.

If cerebral vasospasm is diagnosed, early treatment in a neurocritical care unit should be initiated to prevent DIND. The goal of vasospasm treatments is to improve cerebral perfusion by improving blood flow through the narrowed vessel lumen, or increasing the size of the vessel lumen directly. 'HHH' therapy consists of hypertension, hypervolaemia, and haemodilution, and aims to increase cardiac output, improve blood rheology, and improve

cerebral perfusion pressure. Intravascular volume is expanded with intravenous fluids, which also result in haemodilution. Fluid supplementation is titrated to the patient's clinical response, up to a central venous pressure of 8–10 mmHg. Further fluid loading beyond this may not offer further benefit, and may increase the risk of adverse effects such as cardiac pump failure and acute pulmonary oedema. Of most utility is the use of inotropes or vasopressor agents to induce arterial hypertension, similarly titrated to a level that improves the patient's neurological symptoms. Induced hypertension has fewer adverse effects and greater benefits than hypervolaemia and haemodilution.

Other treatment modalities for cerebral vasospasm are aimed at remodelling the arterial lumen to improve cerebral perfusion. Endovascular options include direct intra-arterial injection of vasodilator agents such as verapamil, which may be performed concurrently with diagnostic angiography once vasospasm has been demonstrated. More durable arterial remodelling may be achieved with transluminal balloon angioplasty. Neither of these treatments should be attempted in the presence of an unsecured aneurysm due to the risk of rebleeding.

Early surgical or endovascular interventions to secure the ruptured aneurysm may assist with vasospasm prevention and treatment. Surgical toilet of arachnoid cisterns and evacuation of intracerebral clot may reduce the risk of cerebral vasospasm by removal of spasmogens. Additionally, securing the aneurysm reduces the rebleeding risk and affords greater opportunity for safe use of hyperdynamic therapies and hypertension, as well as endovascular arterial remodelling. There is some evidence that lumbar drainage may also reduce the risk of vasospasm by drawing putative spasmogens into the lumbar cistern (Al-Tamimi et al., 2012), however, this remains controversial.

Outcomes following subarachnoid haemorrhage

Aneurysmal subarachnoid haemorrhage is a serious condition, associated with high rates of morbidity and mortality, even with treatment. As many as 25% of patients with ruptured aneurysms die before reaching medical care. The natural history of untreated ruptured aneurysms is not benign, with the greatest risk of death being associated with secondary rupture and rebleeding. The greatest risk of rebleeding is encountered in the first 24 hours post ictus, with a rate of 4% on day one. Subsequent daily risk of rebleeding is 1.5% per day. Approximately 20% of unsecured aneurysms will re-rupture in the first two weeks, and 50% within the first six months, resulting in an overall late mortality rate of 60%. Even after six months, untreated ruptured aneurysms remain dangerous, with a persistent annual rebleed rate of 3% per annum. It is because of these high rates of adverse outcome in untreated aneurysms that timely treatment is recommended to occlude these lesions.

Even with treatment, mortality rates remain high. Death rates have diminished over recent decades to 5–10% of admissions. Rebleeding can occur prior to aneurysm obliteration, with death rates from rebleeding reportedly as high as 70–90%. Other major causes of death associated with subarachnoid haemorrhage are vasospasm, neurosurgical complications such as hydrocephalus and hyponatraemia, as well as systemic complications including neurogenic pulmonary oedema and neurogenic stunned myocardium (Takotsubo cardiomyopathy, named after the Japanese octopus trap 'Tako-tsubo' which mimics the apical left ventricular ballooning seen on echocardiography). Rates of these complications are decreasing as treatment regimens improve. Electrocardiogram (ECG) changes observed after SAH include dysrhythmias, ST segment changes and tented or 'neurogenic' T waves. These are postulated to be secondary to the effect of excess circulating catecholamines released as a result of hypothalamic insult from SAH on the repolarization phase of the ECG. In severe cases a degree of subendocardial ischaemia which may be detected through measurement of cardiac enzymes occurs as well.

Neurological morbidity is common following aneurysm rupture. The initial haemorrhage, vasospasm-induced ischaemic neurological deficits, and hydrocephalus may all result in neurological damage. Rates of cerebral infarction are as high as 26% at six weeks post ictus. Vasospasm is a major cause of delayed neurological morbidity. Approximately one-third of survivors suffer from moderate to severe disability, and two-thirds of patients who have undergone successful aneurysm clipping never return to their premorbid quality of life, despite the majority of patients surviving with Glasgow Outcome Scores of 4 or 5. Of those that survive with a good neurological outcome, less quantifiable deficits result in only one in four returning to employment at one year.

Predictors of poor outcomes include clinical factors, patient-related variables, and radiological factors. Higher World Federation of Neurosurgical Societies (WFNS) and Hunt and Hess grades (see Chapter 49) on admission are associated with increased mortality and neurological morbidity. Similarly, a higher Fisher radiological grade on the presentation CT is associated with increased rates of vasospasm, and subsequently increased complication rates. Patient age is an independent risk factor for poor outcome, with patients over 70 years suffering significantly higher mortality rates and lower rates of favourable outcome.

Controversies—seizures, their prevention and management

Seizures are common following SAH, usually occurring in the first days following the ictus. The risk of seizures in the acute illness after SAH is approximately 3%. The reported overall long-term incidence of seizures ranges from 5% to 27%, with the ISAT researchers noting a seizure incidence of 5–10% over five years. Risk factors include younger age, ruptured middle cerebral artery aneurysms, intracerebral haematoma, subdural haematoma, and poor clinical or radiological grades. Additionally, surgical treatment of ruptured aneurysms is associated with a higher incidence of seizures than endovascular coiling.

Mechanisms suggested for seizure pathogenesis include acute intracranial hypertension resulting from SAH, vasospasm, and cortical dysfunction, early spreading cortical depolarization, and temporal lobe cortical injury. Adverse effects on the brain during a seizure may result secondary to acute raised intracranial pressure, and haemodynamic and airway instability. There is decreased oxygen utilization by the brain, and metabolic derangements such

as acidosis. A seizure in the setting of an unsecured ruptured aneurysm may be associated with devastating consequences such as rebleeding. All of these secondary adverse effects are associated with negative outcomes, supporting the treatment of seizures when they occur, and raising the option of seizure prevention strategies.

Because of the relatively low rate of seizures in the acute illness following SAH, the use of antiepileptic drugs (AEDs) to prevent seizures after SAH is controversial, with no consensus on their use. AEDs such as phenytoin can be associated with significant side effects that may outweigh their benefits. Agents such as levetiracetam may offer superior anticonvulsive properties with fewer adverse effects, and should be considered as an alternative if seizure prophylaxis is indicated. If prophylactic AEDs are utilized, they should be administered for one week postsurgery. Other strategies to reduce the risk of seizures include prevention of vasospasm and cortical ischaemia, and maintenance of normal metabolic parameters.

Treatment of seizures includes haemodynamic and airway support, and pharmacotherapy to terminate persistent seizure activity. AED use is indicated if a seizure has occurred, and carries a relatively low risk in the acute illness following SAH. As with prophylaxis regimes, the choice of drug should take into consideration its efficacy and side effects.

Management of subarachnoid haemorrhage

Roberto Rodriguez Rubio, Brian P. Walcott, and Michael T. Lawton

Medical management of subarachnoid haemorrhage

Subarachnoid haemorrhage resulting from a ruptured cerebral aneurysm requires advanced medical and surgical care to maximize patient outcomes. In the acute period, care is focused on rapid diagnosis and excluding the aneurysm from the circulation with either clipping or coiling to prevent further haemorrhage. In the days to weeks that follow, the focus shifts to optimizing cerebral perfusion in order to prevent delayed ischaemia. While controversy exists over various treatment modalities and management protocols, widespread advances in surgical and endovascular techniques and vasospasm care continue to decrease morbidity and mortality associated with this challenging disease.

Preoperative

Clinical presentation of subarachnoid haemorrhage

Subarachnoid haemorrhage (SAH), or bleeding surrounding the surface of the brain in the subarachnoid space, can be due to traumatic and non-traumatic aetiologies. While trauma is the most frequent cause of subarachnoid haemorrhage overall, the most common aetiology of non-traumatic (spontaneous) SAH is a ruptured cerebral aneurysm. Other causes of non-traumatic subarachnoid haemorrhage include Call-Fleming syndrome, dural arteriovenous fistulae, arteriovenous malformations, and leptomeningeal metastases, among other conditions. This chapter will focus on the management of subarachnoid haemorrhage resulting from aneurysm rupture, with an emphasis on treatment techniques to prevent aneurysm rebleeding and prevention of neurological and medical complications.

Aneurysmal SAH can be a devastating event, and the presence of a brain aneurysm is often not known (or symptomatic) until it ruptures. An estimated one-third of patients do not survive to reach medical attention, and among survivors of the initial event, there are high rates of morbidity and mortality (van Gijn and Rinkel, 2001). For these reasons, understanding the clinical presentation of SAH and arriving at a rapid diagnosis is essential to prevent or mitigate the secondary insults that can follow.

The most common initial manifestation of a ruptured aneurysm is sudden onset of severe headache, which patients will usually refer to as 'the worst headache of my life'. Occasionally, the headache may be submaximal in intensity, or it may soon dissipate and the patient may not seek rapid medical attention. Other signs and symptoms include nausea, vomiting, meningism, photophobia, and even depressed levels of consciousness (Suarez et al., 2006). Occasionally, focal neurological deficits may be present due to local mass effect from a giant aneurysm, parenchymal brain haemorrhage, subdural haematoma, or a large localized subarachnoid clot. In addition, third and sixth cranial nerve palsies may be present due to aneurysmal compression of the oculomotor nerve or globally increased intracranial pressure, respectively. Seizure activity may also result from aneurysmal SAH (Rhoney et al., 2000). Assessment of a patient's clinical condition with aneurysmal SAH is standardized with the use of the Hunt & Hess grading scale, which is largely of historical interest. This scale is one of the most widely used and classifies the initial manifestations of SAH into five grades. The grade 1 represent an entirely asymptomatic patient, or with slight clinical manifestations such as a minimal headache or nuchal rigidity. Grade 2 relates to a patient with moderate symptoms with no neurological deficit apart from cranial neuropathy. In grade 3, the patient has mild loss of consciousness with a focal neurological deficit. Grade 4 constitutes a moderate loss of consciousness (i.e. stupor), deep focal deficit, or early stages of a vegetative disturbance. Finally, grade 5 which is a patient in a deep coma or clinical evidence of decerebration (data from Hunt & Hess, 1968). Another popular grading scale is the more modern World Federation of Neurologic Surgeons grading scale (**Table 49.1**), which can be used for risk assessment and prognostication (Rosen and Macdonald, 2005). Initial presentation grades are determined after a ventriculostomy is placed when acute hydrocephalus is present.

Investigations and workup

The initial steps in the investigation of a patient with suspected aneurysmal SAH focuses on a variety of radiological assessments with or without spinal fluid analysis. Based on a concordant clinical history, it is important to confirm the presence of subarachnoid haemorrhage.

Table 49.1 World Federation of Neurological Surgeons subarachnoid haemorrhage grading scale

Grade	GCS	Motor deficit
I	15	–
II	14–13	–
III	14–13	+
IV	12–7	±
V	6–3	±

Copyright © 1988 BMJ Publishing Group Ltd.

While spinal fluid analysis (obtained via puncture of the lumbar cistern) has historically been the first step in the work up, the availability and speed at which a non-contrast head computed tomography (CT) scan can be obtained has shifted practice patterns in this direction.

Acute haemorrhage in the subarachnoid space appears as areas of hyperdensity in the basal cisterns, cerebral sulci, or ventricles, and exceeds a sensitivity of 95% in detecting subarachnoid haemorrhage in the first 24 hours (Fig. 49.1). The non-contrast head CT is also useful in determining the presence of acute hydrocephalus if cerebrospinal fluid absorption is impaired as a result of the haemorrhage, as well as excluding a mass lesion that may preclude safe lumbar puncture. The pattern of the haemorrhage on the CT scan can also help to direct attention to particular anatomical regions of interest during subsequent neurovascular imaging (Fig. 49.2).

If the non-contrast CT scan is negative for haemorrhage, in a patient with a classic aneurysmal SAH presentation history, it is necessary to perform further investigation with spinal fluid analysis to maximize diagnostic sensitivity. Spinal fluid analysis is particularly useful in cases of delayed presentation, where the patient experienced the first onset of symptoms several days prior to medical evaluation. In these instances, the sensitivity of a CT scan is decreased (70% after 48 hours, 50% after 7 days) and the presence of xanthochromia in the spinal fluid may help to support the presence of a recent haemorrhage. Xanthochromia can be evaluated with either visual inspection or, ideally, spectrophotometry (which measures light absorbance in the spectrum of oxyhaemoglobin and bilirubin) and its presence can be detected from six hours to three weeks following a subarachnoid haemorrhage. Potential confounders that limit the specificity of xanthochromia are high bilirubin levels, high protein levels, and a traumatic lumbar puncture.

If SAH is confirmed, the next step in the workup is to determine the source, whether it is from a ruptured cerebral aneurysm or other aetiology. Practice patterns vary according to institutional preferences, but neurovascular imaging is generally either obtained via CT angiography or catheter angiography. CT angiography with three-dimensional (3D) reconstruction has the benefit of being rapid, with

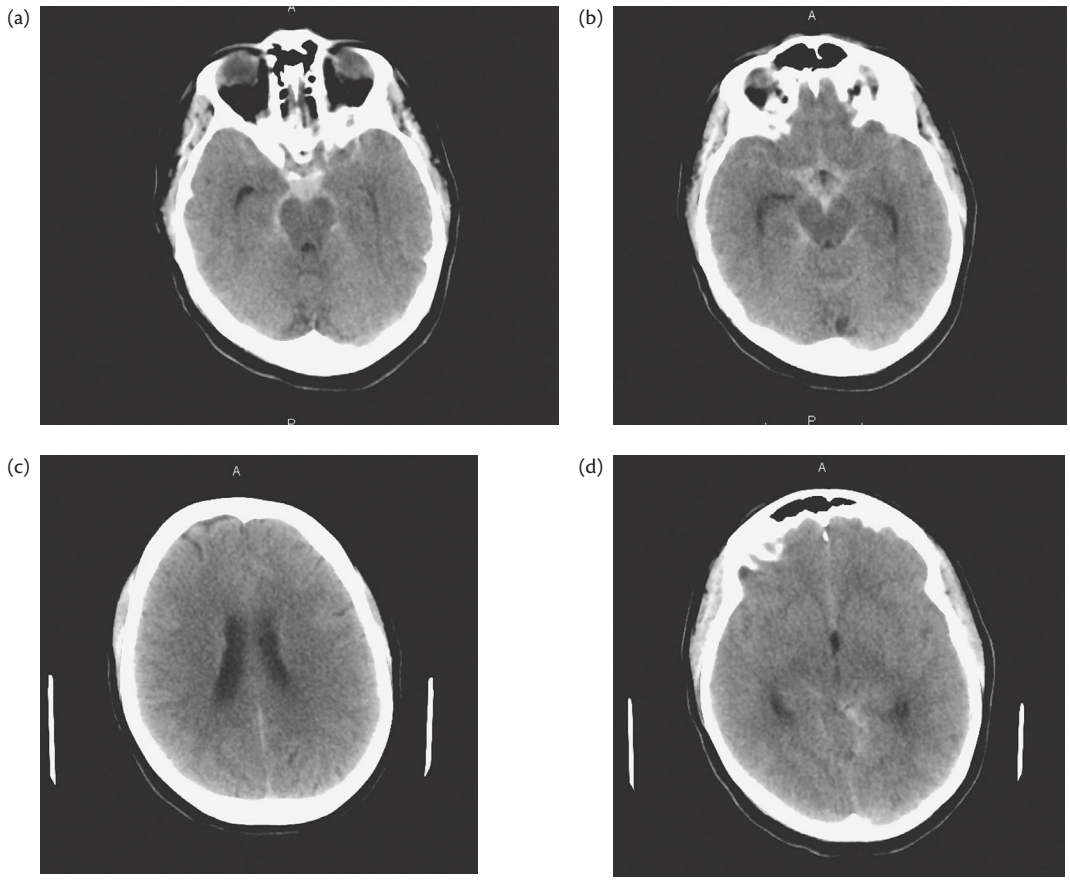

Fig. 49.1 Computed tomography scan of aneurysmal subarachnoid haemorrhage. Non-contrast axial head computed tomography of a patient who experienced an aneurysmal subarachnoid haemorrhage where blood extended into the distal Sylvian and interhemispheric fissures. Representative images are demonstrated in sequence from A to D in their inferior to superior location.

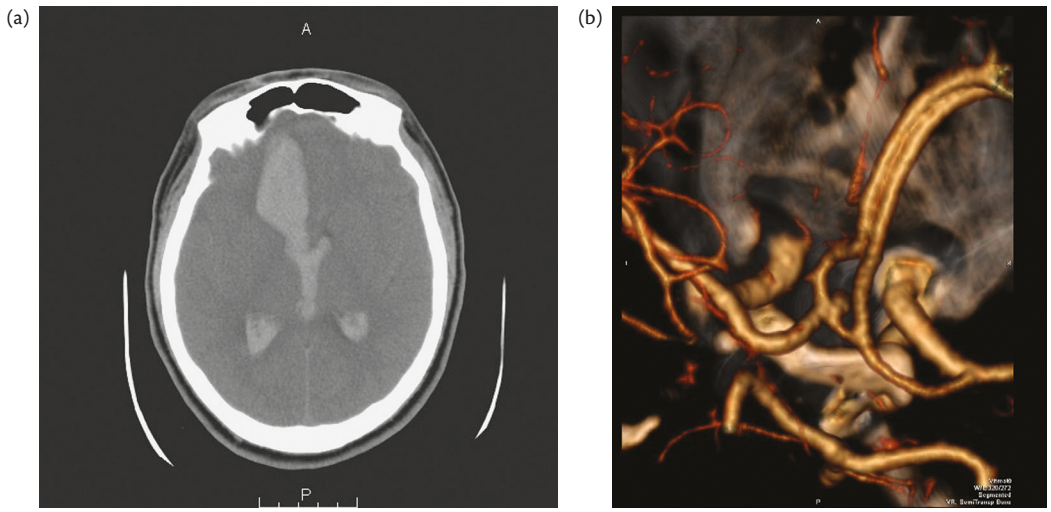

Fig. 49.2 Clip obliteration of aneurysm and haematoma evacuation for comatose patient. A 35-year-old male presented with loss of consciousness while at work in an office. He was found to have hydrocephalus, intraventricular haemorrhage, mild scattered subarachnoid haemorrhage, and a large intraparenchymal haemorrhage of the inferior frontal lobe. This is a characteristic haemorrhage pattern for an anterior communicating artery aneurysm. CTA revealed a 5 mm anterior communicating artery aneurysm in a 'windsock' configuration, pointing anteriorly and inferiorly. He was taken to the operating room emergently for successful haematoma evacuation and clip obliteration of his aneurysm.

a sensitivity and specificity that exceeds 95% in detecting aneurysms 2 mm in diameter or greater. Catheter angiography, also known as digital subtraction angiography (DSA), remains the gold standard for detection of intracranial aneurysms and has a higher sensitivity and specificity than CT angiography. DSA can identify small aneurysms and also demonstrate the surrounding normal blood vessels with better clarity. The limitations of DSA are provider availability, vasospasm preventing adequate contrast filling and a very small risk of procedure-related complications, such as cerebral ischaemia and groin haematoma.

MRI is an additional, supplemental imaging technique that is useful for the investigation of large or giant aneurysms. It can give information about adjacent brain structures such as the optic nerve or brainstem and their relationship to the aneurysm, as well as the degree to which the aneurysm contains thrombosed blood.

Preoperative management

Management of patients with aneurysmal SAH should be in specialized centres. Care delivered by a multidisciplinary team consisting of neurosurgeons, neurointerventional radiologists, neurointensivists, and neurologists, all specializing in neurovascular disease has been shown to improve outcomes (Bardach et al., 2002). The definitive treatment of a ruptured brain aneurysm is the exclusion of the aneurysm from the circulation in order to prevent it from bleeding again. Prior to this, we manage our patients in an intensive care unit in order to immediately institute measures aimed at prevention of aneurysm rerupture, while also optimizing cerebral perfusion.

Central to the core of all resuscitation protocols across many acute central nervous system disease phenotypes is an emphasis on maintenance of airway protection, ventilation, and circulation. Patients presenting in a comatose state require intubation to prevent aspiration, ensure oxygenation, and optimize gas exchange to control potential intracranial hypertension. We recommend that patients have continuous systemic blood pressure monitoring (typically via radial artery catheterization), with maintenance of systolic blood pressure under 140 mmHg in order to prevent aneurysm rebleeding (Connolly et al., 2012). In addition to titratable infusions to lower blood pressure, pain and anxiety can make a substantial contribution and should simultaneously be addressed via non-pharmacologic interventions. If acute hydrocephalus is present, controlled cerebrospinal fluid drainage via a ventriculostomy should be performed in order to reduce intracranial pressure.

Once the diagnosis of aneurysmal SAH has been made, additional evaluation of cardiac function should be obtained with electrocardiography and echocardiography. While most cardiac disturbances are self-limiting, it is important to recognize any potential impairment prior to the supraphysiologic challenges of surgery and potentially vasospasm treatment protocols. Cardiac abnormalities are common in the first 48 hours after SAH; electrocardiographic changes including tall peaked T-waves or cerebral T-waves, ST segment depression, and prolonged QT segments. Cardiac enzymes are often mildly elevated and arrhythmias are very common, but typically benign in nature. Acute neuro-cardiogenic injury or Takotsubo cardiomyopathy can also be seen, with significant left ventricular systolic dysfunction resulting from excessive catecholamine release from sympathetic nerve terminals that mimics myocardial ischaemia (van der Bilt et al., 2014).

Other medical management concerns that take priority during the initial hours following a subarachnoid haemorrhage include optional administration of antiepileptic medication for seizure prophylaxis and administration of the calcium channel blocker nimodipine for prevention of vasospasm (Barker and Ogilvy, 1996). In exceptional circumstances, if definitive aneurysm treatment is not available for several days, antifibrinolytic therapy can be administered.

Non-aneurysmal perimesencephalic subarachnoid haemorrhage

When spontaneous SAH occurs without an aneurysmal source, haemorrhage patterns can be dichotomized into one of two patterns. Firstly, the perimesencephalic pattern (Fig. 49.3), where blood is

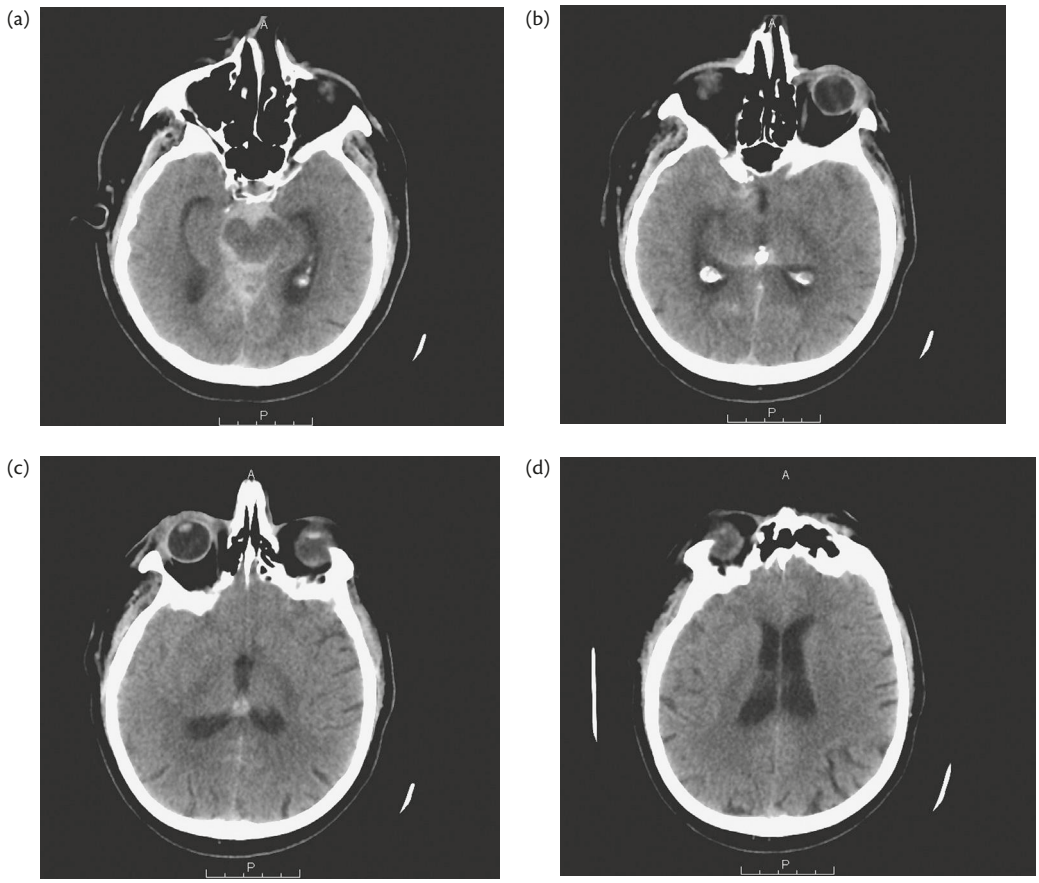

Fig. 49.3 Perimesencephalic haemorrhage pattern. Non-contrast axial head computed tomography of patient who experienced a non-aneurysmal subarachnoid haemorrhage confined to mainly the basal cisterns surrounding the midbrain. Representative images are demonstrated in sequence from A to D in their inferior to superior location.

confined mainly in the basal cisterns surrounding the midbrain and constrained by Liliequist's membrane, but can include the proximal part of the Sylvian fissure. Secondly, diffuse, where blood extends into the distal Sylvian or interhemispheric fissures.

While non-aneurysmal haemorrhage has typically been associated with a benign course, recent evidence has suggested that hydrocephalus, vasospasm, and stroke can all occur, particularly with diffuse haemorrhage patterns (Walcott et al., 2015). Although catheter-based angiography has excellent sensitivity in detecting haemorrhage aetiology, it is certainly not 100% sensitive. Follow-up catheter angiography at intervals of one and six weeks from the time of the haemorrhage has been shown to improve the sensitivity for detecting a vascular lesion when the initial catheter angiogram is negative (Grannan et al., 2014), particularly if there is a high clinical index of suspicion. The exact timing and modality of repeated neurovascular imaging is not supported by prospective trials, and recommendations are based mainly on experience from high-volume centres. An unrecognized aneurysm could have devastating consequences and vigilance must be maintained during the investigation of these patients.

Definitive management of the aneurysm

Endovascular coiling of aneurysms

Endovascular coil embolization is a relatively contemporary means of aneurysm obliteration. The first coiling procedures were used to treat human patients with cerebral aneurysms in the early 1990s (Guglielmi et al., 1992). Compared with microsurgical clipping, there is less cumulative experience and less long-term follow-up. However, both methods have been shown to be effective at the ultimate primary goal of aneurysm treatment—to safely eliminate blood flow into the aneurysm (Molyneux et al., 2015). A recent analysis of the total aneurysm surgical practice in the United States provides strong evidence for the popularity of both techniques, with over half of all aneurysms now treated with endovascular coiling. Certain adjuncts can assist with coiling, such as intraluminal stent devices and balloon assistance. Endovascular therapy with flow-diverting stents, with or without adjunctive coiling, is also an emerging treatment option. With these methods, many previously 'uncoilable' or even 'untreatable' aneurysms are now amenable to endovascular treatment.

Coil embolization

Indications

Most aneurysms can be treated with either microsurgical clipping or coil obliteration. Treatment recommendations are usually made after thorough evaluation of anticipated risks and benefits of the different treatment methods for the same unique aneurysm. This involves evaluation of patient specific factors and aneurysm specific factors. These factors generally relate to the intrinsic aneurysm configuration. Classically, a neck-to-dome ratio of 2:1 (aspect ratio) identifies aneurysms that are likely to be treatable with a coil. Other

considerations include the neck size (<5 mm, favourable) and close relationship to a neighbouring artery (unfavourable). Other factors that generally favour endovascular treatment include aneurysm location (vertebrobasilar circulation) and patient age (older). These generalizations must be considered in the context of all patient and aneurysm specific characteristics on a case-by-case basis. Optimally, review by a multimodality provider capable of performing coiling and clipping allows for a thorough evaluation of each unique clinical scenario and aneurysm configuration.

Technique

The patient is positioned supine then placed under general anaesthesia. Alternatively, the procedure can be done awake in compliant patients if they are able to hold breathing during fluoroscopy and keep still. Both groin sites are prepped in a sterile fashion and the femoral artery (usually right side) is punctured. Next, a sheath is introduced with a Seldinger technique, and this sheath is then connected to an irrigation system consisting of heparinized saline to prevent thromboembolic complications. A guide catheter, also connected to a continuous heparinized flush, is navigated over a 0.35" or 0.38" curved or j-shaped guide wire, from the groin to the aortic arch under fluoroscopic guidance into either internal carotid artery (ICA) or vertebral artery, depending on the target aneurysm location.

Three-dimensional angiography (rotational angiography) is often obtained to better characterize the aneurysm size, configuration, and adjacent neurovascular structures. A microcatheter is chosen according to the desired stiffness or profile, and then navigated the remaining distance between the guide catheter and its final destination, the aneurysm. The size and shape of the first coil to be deployed is determined by the shape and measurements of the aneurysm. Usually the first coil is used to create a framework, which fits well into the aneurysm and can be filled with subsequent coils. Intermittent super-selective angiography before and after coil placement allows confirmation of coil location inside the aneurysm dome and provides information regarding any residual filling of the aneurysm. When the operator is satisfied with coil placement, it is detached, and the decision to proceed with further packing coil placement is made.

Visual-haptic biofeedback during coil deployment, failure to deploy a small coil, packing density of the aneurysm, and any residual filling of the aneurysm are some indicators used to judge when to stop coiling. After coiling is finished, the microcatheter may be removed and a final angiographic run is performed (Fig. 49.4). All catheters are subsequently removed and the groin puncture arteriotomy may be closed with a period of manual pressure or with a vascular closure device.

Balloon-assisted coiling procedure

Indications

Primary coiling can be challenging with wide-necked aneurysms, small aneurysms with a high risk of intraprocedural rupture, bifurcation aneurysms, and aneurysms with a branch vessel originating from the neck of the aneurysm. In these settings, using inflatable balloon techniques can mitigate these factors by remodelling the neck, protecting a parent vessel/side branch, or doing both. It can also help to keep a microcatheter in the aneurysm sac and reduce 'kickback' during coil deployment, potentially resulting in a greater packing density.

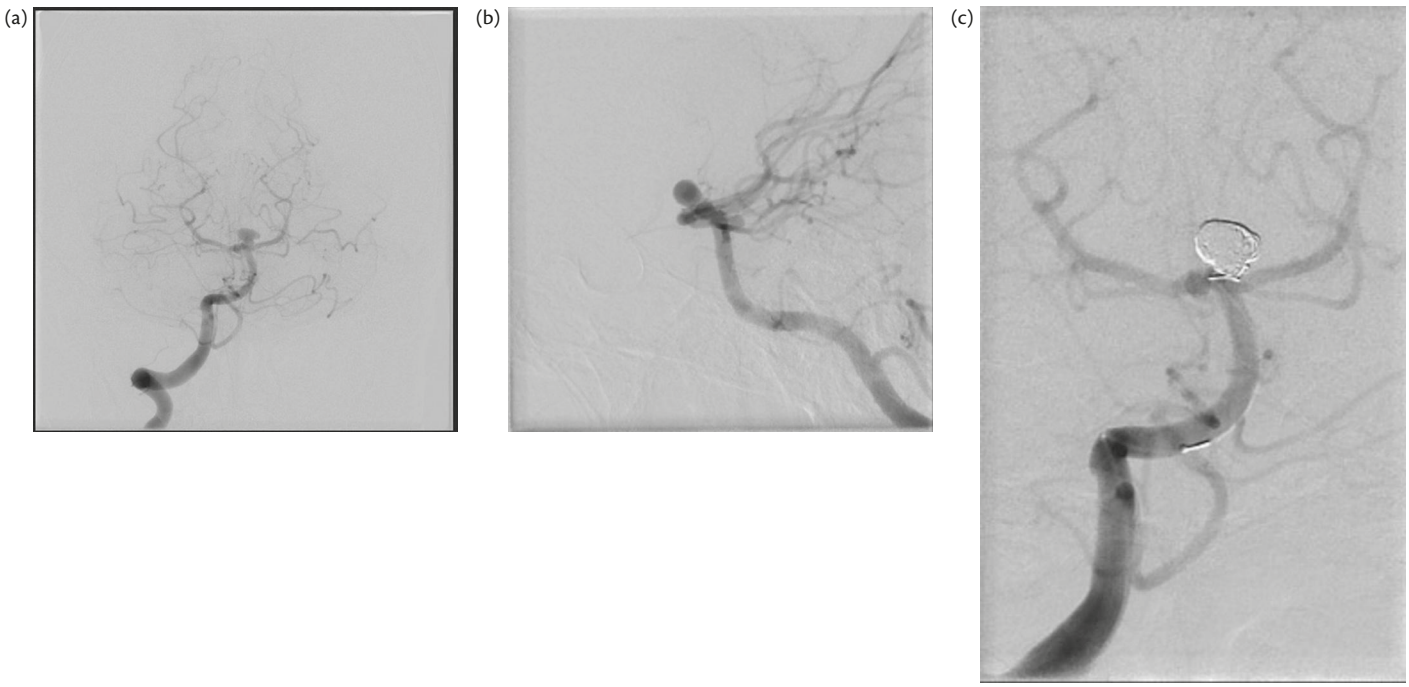

Fig. 49.4 Endovascular coiling of basilar apex aneurysm. A 60-year-old female presented with the 'worst headache of her life' and diffuse subarachnoid haemorrhage. She was found to have a 7 mm basilar artery apex aneurysm (A, B) and smaller superior cerebellar and middle cerebral artery aneurysms. In the context of haemorrhage with a diffuse pattern, it can be predicted that the irregular, largest aneurysm was the source. The basilar apex aneurysm was obliterated with coils (C) and the patient made a full recovery.

Technique

For patients with subarachnoid haemorrhage, heparinization is initially withheld, in comparison with unruptured aneurysms. Once one or two coils are deployed into the aneurysm, then heparin can be administered. The balloon catheter is introduced into the proximal end of the guide catheter, along with the microcatheter (through the side port). When the coil is nearing the aneurysm, the balloon is filled to the appropriate volume with 100% contrast. Subsequent coils can then be delivered, mindful of distal ischaemia time while the balloon is inflated.

Somatosensory evoked potentials and motor evoked potentials can be useful monitoring techniques, particularly in anesthetized patients. When changes occur, the balloon can be deflated. Once the coil mass is delivered, the balloon is deflated to assess the stability of the coil mass. If the coil mass does not herniate out of the aneurysm, then the microcatheter is removed and the device is withdrawn from the guide catheter.

Double-microcatheter technique

Indications

While wide-necked aneurysms can be treated with stent-assisted coiling or balloon-assisted coil delivery and remodelling, these methods have specific risks associated with thromboembolic complications. With stent-assisted coiling, patients require long-term antiplatelet therapy, which can be problematic during the initial management of a ruptured aneurysm. The double-microcatheter technique is a useful alternative in these situations to help achieve a safer and denser coil delivery without the need for antiplatelet therapy.

Technique

Two microcatheters are advanced through the guide catheter and into the aneurysm sac. Since a single microcatheter may deploy coils that herniate back through a wide neck and into the parent artery, a second microcatheter is also placed in the aneurysm to deploy an additional coil prior to detachment of the first framing coil. By doing this, the coils can be thought of as 'locking' onto each other if they are deployed sequentially, or 'weaving' into each other if they are deployed concurrently. One of the coils is then detached. For all subsequent coil deployments, one of the catheters retains a deployed coil that is not detached, thereby acting as a brace since it is connected to the pusher wire. Embolization is continued through the available catheter until aneurysm obliteration is complete. This technique increases the coil stability greatly and allows for coiling of some wide-necked aneurysms without stent placement.

Major complications of endovascular coil embolization

Endovascular coil embolization of ruptured aneurysms is associated with low, but recognized complication rates of thromboembolism resulting in stroke (4–5%), intraprocedural aneurysm rupture (7%) (Fig. 49.5), coil migration, incomplete aneurysm obliteration, aneurysm recurrence (20%), aneurysm rebleeding after treatment, contrast nephropathy, and groin haematoma (Owen et al., 2015; Molyneux et al., 2015; Spetzler et al., 2015; Stapleton et al., 2015a).

As coil embolization has become the accepted first line treatment for ruptured aneurysms, there is an increasing need to consider late retreatment (endovascular and possibly surgical) of recurrent aneurysms. Factors that influence recurrence after coiling include aneurysm size, aspect ratio, absolute neck width, aneurysmal thrombus, smoking, length of follow-up, familial predisposition, quality of coil packing/occlusion and presentation with haemorrhage. Indications for treatment are not well established but may include extent and rate of recurrence, age, rehaemorrhage, and clinician/patient choice.

Microsurgical clipping of aneurysms

Aneurysm clipping is the longest standing method for treatment of cerebral aneurysms. Since the first intracranial aneurysm clipping was performed by Dandy in 1937, and the introduction of microscopic techniques by Yasargil, clipping of aneurysms has developed into a refined and delicate procedure with low rates of complications and proven durability. The recent evolution of endovascular treatments is typified by advances in device technology and technique, and microsurgery is no different. The evolution of new techniques and intraoperative imaging has made open aneurysm surgery less invasive, more appealing to patients, and has progressively lowered procedural risk. Clipping treatments are especially efficacious for complex aneurysms with unfavourable configurations or for those failing endovascular therapy (Davies and Lawton, 2014).

Approaches to aneurysms are determined primarily by the aneurysm location. The majority of aneurysms in the anterior circulation (anterior communicating artery aneurysm, posterior communicating artery aneurysm, middle cerebral artery bifurcation aneurysm) can be accessed through a pterional craniotomy, with slight variations tailored to individual aneurysm anatomy. For aneurysms arising from the distal anterior cerebral artery (A2 segment and beyond), a bifrontal craniotomy and interhemispheric approach is commonly used. For aneurysms arising from the upper basilar trunk (basilar apex aneurysm, superior cerebellar artery aneurysm), a pterional craniotomy with additional removal of the orbitozygomatic unit allows for the wide trans-Sylvian dissection necessary to lessen the working depth needed to reach these lesions safely. Other aneurysms of the posterior circulation, such as the posterior inferior cerebellar artery aneurysm, are classically approached through a far lateral craniotomy, whereas aneurysms of the vertebrobasilar junction can be accessed through a retrosigmoid craniotomy. The full armamentarium of microsurgical approaches includes subtemporal, presigmoid, transpetrosal, suboccipital, supraorbital, transpalpebral, and combinations or variations thereof. The craniotomy type is selected to allow an adequate line of sight to the aneurysm anatomy, while minimizing the need for any brain retraction.

Pterional craniotomy for the trans-Sylvian approach

The frontal-temporal-sphenoidal craniotomy, better known as the pterional craniotomy, is the most common craniotomy type for an aneurysm surgeon, since the majority of aneurysms occur in the anterior circulation. It allows for exposure of the frontoparietal operculum and opening of the Sylvian fissure to access the circle of Willis. In brief, the patient is placed in skull fixation, with the head rotated 15–20 degrees away from the side of the aneurysm. The head

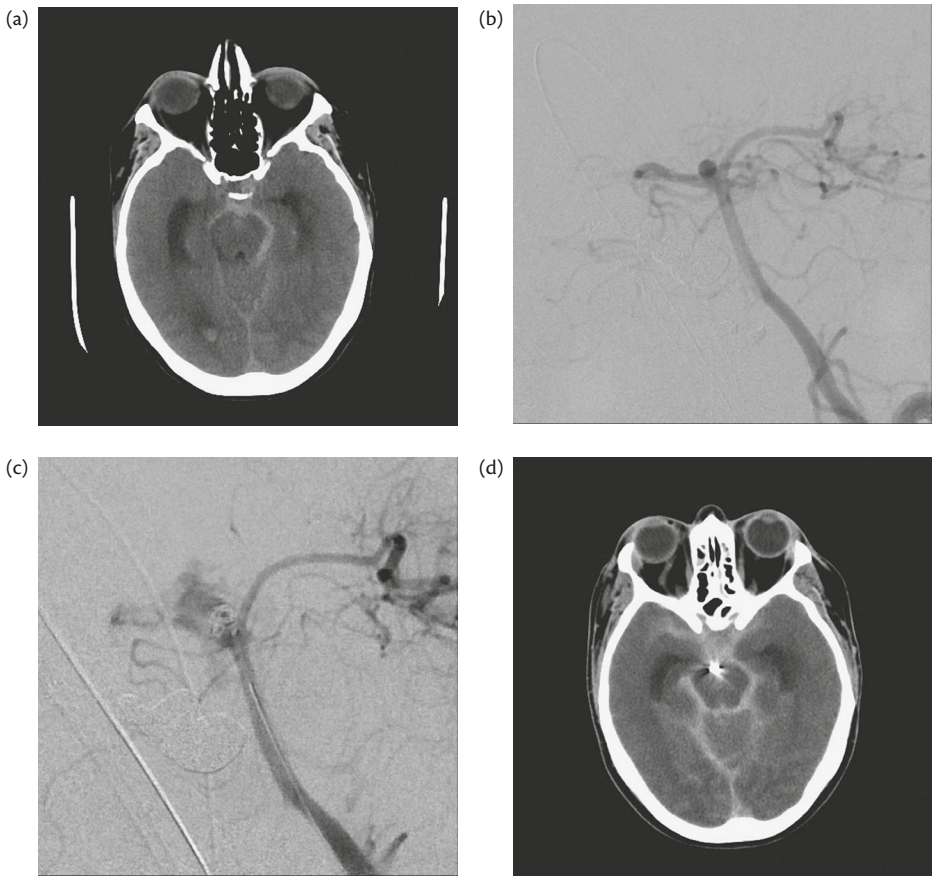

Fig. 49.5 Intraprocedural rupture during coiling of a basilar apex aneurysm. (A) Axial CT image showing SAH from a ruptured basilar apex aneurysm. (B and C) Right anterior oblique catheter angiograms obtained in the same case showing a ruptured basilar apex aneurysm (B) and active contrast extravasation (C) following intraprocedural rupture during coil embolization. (D) Axial CT image showing increased SAH and subarachnoid contrast following intraprocedural rupture of the basilar apex aneurysm.

is extended approximately 20 degrees, making the malar eminence the high point in the surgical field. The head is then lifted above the level of the heart, out of a dependent position. A curvilinear skin incision begins at the zygomatic arch 1 cm anterior to the tragus and curves to the midline, just behind the hairline at the widow's peak. The scalp is elevated only enough to expose the zygomatic root posterior-inferiorly and the keyhole anteriorly. The superficial fat overlying the temporalis fascia should not be entered because the frontalis branch of the facial nerve lies in this tissue plane and can be injured with additional elevation of the scalp flap. The temporalis muscle is incised from the zygomatic arch to the superior temporal line along the skin incision, then anteriorly to the keyhole, running 1 cm below the superior temporal line. The temporalis is flapped anteriorly, leaving a cuff of fascia and muscle along the superior temporal line to suture the muscle to during closure for improved cosmetic outcome. Next, a burr hole is placed below the superior temporal line posteriorly and a frontal-temporal craniotomy is made using a high-speed drill. After bone flap removal, the drill is used to remove the pterion and the lesser wing of the sphenoid medially, all the way to the superior orbital fissure. Bone removal is adequate when there is a flat surface over the orbit connecting the anterior and middle cranial fossa. The dura is opened with a semicircular incision, hinging anteriorly. Multiple stay sutures flatten the dural flap. At the conclusion of the exposure, there should be direct visualization of the frontal and temporal lobes on either side of the Sylvian fissure, permitting an unobstructed view along the dural flap into the carotid cistern.

Bifrontal craniotomy for an anterior interhemispheric approach

Bifrontal craniotomy is a standardized technique to facilitate an interhemispheric approach to distal anterior cerebral artery aneurysms, such as pericallosal artery aneurysms. These aneurysms are typically located in the midline, but deep to the falx. Therefore, the exposure only needs to be on one side. The bifrontal nature (with only a small portion of the craniotomy crossing over to the contralateral side) allows for sutures to retract the superior sagittal sinus, permitting a straight line of view to the aneurysm. The patient is positioned supine with the head in neutral position, or for more distal aneurysms the head can be placed in a lateral position with a 45-degree tilt away from the ground. For right sided approaches, the incision begins at the right zygoma and ends at the contralateral superior temporal line because the craniotomy is eccentric to the right side. The scalp is then pulled forward to expose supraorbital frontal bone from the ipsilateral superior temporal line to the contralateral glabella. The temporalis muscle should be undisturbed. A rectangular craniotomy is made that is two-thirds in front of the coronal suture and just across the midline to the contralateral side. Care

must be taken to strip the dura from the undersurface of the skull to prevent venous sinus injury. The dura is then opened in a semicircular flap with its hinge point being the superior sagittal sinus. The interhemispheric fissure is then in view and subarachnoid dissection can continue down to the aneurysm.

Orbitozygomatic craniotomy for a trans-Sylvian approach

The orbitozygomatic (OZ) approach dramatically enhances the standard pterional craniotomy increasing exposure, minimizing retraction, and improving manoeuvrability for large, giant, or complex anterior circulation aneurysms, and for aneurysms of the upper basilar trunk. Deep bypass procedures benefit from the additional working room of this approach. Removing the orbital walls completely and depressing the eye with the dural flap, along with zygoma resection gives the neurosurgeon a wide sweep of surgical trajectories ranging from supraorbital to trans-Sylvian to pretemporal to subtemporal. The surgical trajectory can then be tailored to the exact aneurysm location. A modified orbitozygomatic approach can be used when the zygoma resection would not meaningfully add to the exposure, and it can be left intact.

Far lateral craniotomy for anterior pontomedullary approaches

The far lateral craniotomy provides an excellent corridor to access most posterior inferior cerebellar artery aneurysms. The patient is placed in a modified park-bench or three-quarter prone position with the lesion side upward. The dependent arm hangs over the end of the table, cradled in a padded sling. Three manoeuvres are then used to position the head: (1) flexion in the anteroposterior plane until the chin is one finger's breadth from sternum; (2) rotation 45 degrees away from the side of the lesion, (bringing the nose down toward the floor); and (3) lateral flexion 30 degrees down toward the floor. These manoeuvres put the clivus perpendicular to the floor, allowing the neurosurgeon to look down the axis of the vertebral artery. The ipsilateral mastoid process becomes the highest point in the operative field. The patient's ipsilateral shoulder is retracted using cloth tape to open the cervical-suboccipital angle. Although variations exist, a classical 'hockey-stick' incision is made beginning in the cervical midline over the C4 spinous process, extending cephalad to the inion, coursing laterally along the superior nuchal line to the mastoid bone, and finishing inferiorly at the mastoid tip. The myocutaneous flap is mobilized inferolaterally as a whole to expose the occipital bone and foramen magnum. Next, a C1 laminectomy is performed all the way laterally to the sulcus arteriosus. Next, a suboccipital craniotomy is extended unilaterally from the foramen magnum in the midline, up to the muscle cuff at the level of the transverse sinus, as far laterally as possible, and then back around to the foramen magnum. After the craniotomy, the foramen magnum is opened up more widely with rongeurs and a high-speed drill, and the suboccipital craniotomy is extended past the midline. Finally, the posteromedial two-thirds of the occipital condyle are drilled away. The anterior extent of the condylar resection is defined either by the condylar emissary vein or by the dura that begins to curve anteromedially, giving a tangential view along this dural plane. Condylar resection enables the dural flap reflected against the condyle to be completely flat, and is analogous to the purpose of pterional flattening in a pterional craniotomy.

The dural incision curves from the cervical midline, across the circular sinus, to the lateral edge of the craniotomy. When completed, the exposure offers a view of the path of the intradural vertebral artery and provides adequate working space in the angle between the lateral medulla and inferior cerebellum (Rodríguez-Hernández and Lawton, 2011).

Intracranial surgical technique

The process of clipping an aneurysm is much more complex than performing a craniotomy and placing a clip across the neck of the aneurysm. There are many nuances to surgery, such as subarachnoid dissection techniques and crisis management, which all can correspond to successful patient outcomes (Lawton, 2011).

During aneurysm surgery, an emphasis must be placed on careful, extensive subarachnoid dissection. By opening up the subarachnoid spaces under high-powered magnification, corridors to the arterial system can be exposed without violating or harming the brain. The technique consists of three basic manoeuvres: cutting with microscissors, spreading with bipolar forceps, and probing with a slightly curved blunt dissector (such Rhoton #6). By opening up these natural cisterns, the frontal and temporal lobes separate, spinal fluid is drained, and the aneurysm can be approached without excessive manipulation or fixed brain retraction. As an example, anterior communicating artery aneurysms are approached by first dissecting the Sylvian fissure, then progressing from the carotid to chiasmatic to lamina terminalis cisterns.

As the surgeon approaches the final dissection of the aneurysm, the orderly sequence exposing afferent arteries, efferent arteries, and the aneurysm neck is often complicated by the presence of the aneurysm dome and difficulty with exposing perforating arteries. During this time, temporary clipping may be used in selected cases to give the surgeon more confidence in the final dissection, soften the aneurysm dome, and allow for better visualization of perforating arteries. Barbiturates to achieve electroencephalography (EEG) burst suppression and raising the systemic blood pressure can help to provide protection from ischaemia, but surgeon efficiency and highly selective use are the most important aspects of temporary clipping.

When ready, permanent clipping can take place under complete visualization from start to finish. Various types of clip configurations have been stereotyped: simple clipping, multiple intersecting clips, stacked clips, overlapping clips, and permutations of these exist. Tandem clipping, with a fenestrated clip to close the distal aspect of the aneurysm neck, followed by a shorter clip to close the proximal portion of the aneurysm neck not covered by the fenestration is also a very effective technique. Tandem clipping exploits a physical characteristic that the force of a fenestrated clip is greatest at the distal end of the clip tines. This allows for an even distribution of force to be applied across the entire aneurysm neck, preventing refilling.

Uncontrolled intraoperative bleeding from an aneurysm is one of the most feared complications in neurosurgery, and knowing what to do during this crisis can be the difference between life and death. The technical response to intraoperative rupture should proceed in a calm and orderly fashion: tamponade, suction, proximal control with temporary clipping, and permanent aneurysm clipping. A small piece of cotton can be placed over the rupture site, and pressure and suction can be applied to clear the surgical field of blood. Proximal control then slows the bleeding and is often

sufficient to finish dissecting and apply permanent clips. After any permanent clip application, whether in the setting of intraoperative rupture or otherwise, the surgeon must spend time inspecting the result. It is important to check for aneurysm occlusion, patency of the parent artery and efferent branches, patency of the perforating arteries, and to determine if any aneurysm neck is remaining. We routinely use intraoperative indocyanine green videoangiography during this inspection process, although some centres continue to use intraoperative catheter-based angiography (Raabe et al., 2005).

Specific aneurysm considerations and locations

Anterior communicating artery aneurysms are among the most challenging. The H configuration of A1 and A2 branches must be identified intraoperatively to ensure that none of the branches are compromised on clip application. During dissection, consideration must be given to the safe corridors of vascular dissection in relation to the dome of the aneurysm. For an anteriorly projecting aneurysm, dissection proceeds as follows: the outer border of the ipsilateral A1 and ipsilateral A2, then the contralateral A1 and A2. In contrast, for an inferiorly projecting aneurysm, the order changes to ipsilateral A1 and A2 then contralateral A2 as the contralateral A1 is obscured by the aneurysm fundus. This aneurysm configuration is at risk of premature rupture with injudicious mobilization of the frontal lobes if adherent to the optic chiasm (see Chapter 46 for anatomical details).

For a superiorly projecting dome, the order changes to both ipsilateral and contralateral A1s to achieve proximal control before identifying both A2s. These aneurysms are potentially the most difficult configuration to clip and often require a fenestrated clip around the ipsilateral A2 to avoid leaving a neck remnant. On occasions, anterior communicating artery aneurysms require trapping of the whole anterior communicating artery, although this risks sacrifice of the associated perforating arteries.

For ICA aneurysms (posterior communicating and anterior choroidal), the degree of head rotation during positioning depends on the projection of the aneurysm fundus. For a posteriorly projecting fundus, a greater degree of head rotation is required to reveal the neck of the aneurysm from behind the ICA. For a laterally projecting fundus, care must be taken with temporal lobe mobilization as it may be adherent to the aneurysm and risks premature rupture. The anterior choroidal artery branches may be duplicated and closely related to the aneurysm neck. It is important to identify and preserve all these branches. Preservation of the posterior communicating artery is most important with a fetal configuration which often occurs in association with aneurysm formation. For ICA bifurcation aneurysms careful identification and dissection of the medial and lateral lenticulostriate perforators is required to avoid incorporation into the aneurysm clip. Aneurysm clips at this location are particularly at risk of kinking the parent vessels.

Middle cerebral artery (MCA) aneurysm clipping requires extensive dissection of the entire fundus as variation in the number of M2 branches is common. These aneurysms may require 'clip reconstruction' (i.e. use of multiple clips to obliterate the entire neck without compromising the distal branches).

Pericallosal aneurysms are a challenge as the aneurysm fundus will be encountered before the parent vessels are identified and controlled. However, the flow through the pericallosal artery is substantially lower than for the large arteries at the base of the circle of Willis and intraoperative rupture is more easily controlled. Image guidance is a useful adjunct in order to plan both the craniotomy and trajectory to the aneurysm.

Advanced techniques for complex lesions

There is no standard definition of what constitutes a difficult aneurysm, although one could consider any aneurysm that could not be treated with straightforward clipping or coiling to be complex. Complex aneurysms have also been described as those more than 10 mm in greatest diameter, or those that have intraluminal thrombosis, were previously coiled, were heavily calcified, or have a fusiform or true blister morphology (Fig. 49.6). Treatment for these lesions often requires advanced techniques or adjunctive devices.

Advanced endovascular techniques

Intracranial stents to assist coiling

The use of stents to support coil placement in the aneurysm dome is required for some wide-necked aneurysms. By 'jailing' the coil mass in the aneurysm, the stent wires prevent prolapse of the coils into the parent vessel (Fig. 49.7). Since endoluminal devices such as stents are prone to thromboembolic complications, patients are typically treated with dual antiplatelet therapy for a period of several months, with at least some form of antiplatelet therapy continuing indefinitely. Newer generations of stents are now available with 'low profile' configurations (use of a braided design) that may provide superior conformability and parent artery apposition, as well as a more reliable and uniform neck bridging than previous neurovascular stents. 'Baby' stents are also under evaluation for use in the coiling of distal intracranial circulation aneurysm.

Endoluminal flow diversion

Flow diverting stents are a relatively new paradigm treatment for brain aneurysms, where intraluminal flow is redirected to the distal parent vessel, rather than into the aneurysm. This is accomplished by using a stent with a low porosity mesh weave. Adjunctive coils are also sometimes placed into the aneurysm to provide immediate aneurysm closure and prevent delayed haemorrhage from a 'ball-valve' haemodynamic effect that has been hypothesized to occur following a small percentage of treatments. Some of the best preliminary results for flow diverting stents have been reported for aneurysms in the cavernous and paraclinoid segments of the carotid artery (Brinjikji et al., 2013). Redirection of parent vessel flow has been associated with perforator artery ischaemia and this has been the major limitation to the widespread application of this treatment in other vascular territories.

Intrasaccular flow disruption devices

Another relatively new endovascular treatment paradigm is intrasaccular flow diversion, where a device is placed inside the aneurysm sac itself (Woven Endovascular Bridge 'WEB' device) which then provides a flow diverting barrier across a wide neck, eventually reconstructing the parent vessel and induces thrombosis and occlusion of the aneurysm. This device has been used mostly for wide-necked bifurcation aneurysms, such as those at the carotid terminus, basilar apex, and MCA bifurcation with promising preliminary results (Lubicz et al., 2013). However, there is still limited clinical experience with this device and it remains under investigational regulation in many countries, such as in the United States.

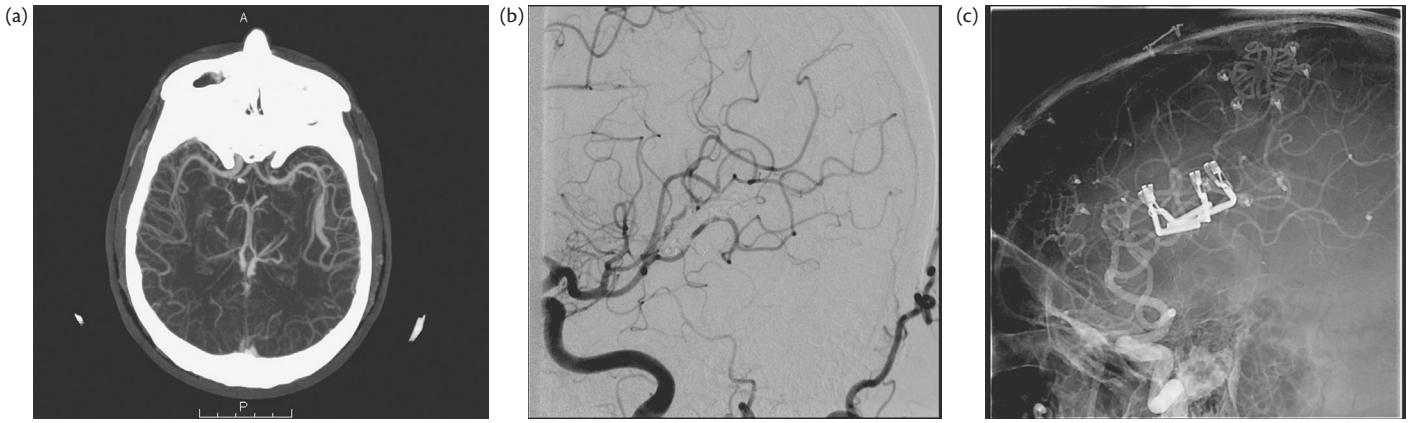

Fig. 49.6 Complex vessel reconstruction of dissecting fusiform aneurysm. A 37-year-old male presented to the emergency room with the 'worst headache of his life'. He was discovered to have subarachnoid haemorrhage resulting from a dissecting, fusiform aneurysm of the left middle cerebral artery. (A) He was taken to the operating room for vessel reconstruction with possible extracranial-to-intracranial bypass. Fenestrated, right-angle aneurysm clips were successfully placed sequentially to reconstruct the wall of the vessel. The patient made a full recovery and has done well since. A two-year follow-up angiogram is shown (B, C) demonstrating no residual aneurysm along the reconstructed M2 segment.

High-flow bypass surgery

For some aneurysms, direct clip reconstruction is not possible. Examples of these situations are relatively infrequent, but can be seen with giant fusiform MCA aneurysms that incorporate multiple MCA branches, blister or dissecting aneurysms, and giant paraclinoid ICA segment aneurysms that extend into the cavernous segment, among others. For these lesions, it is necessary to exclude the aneurysm from the circulation and also to preserve vital blood flow to

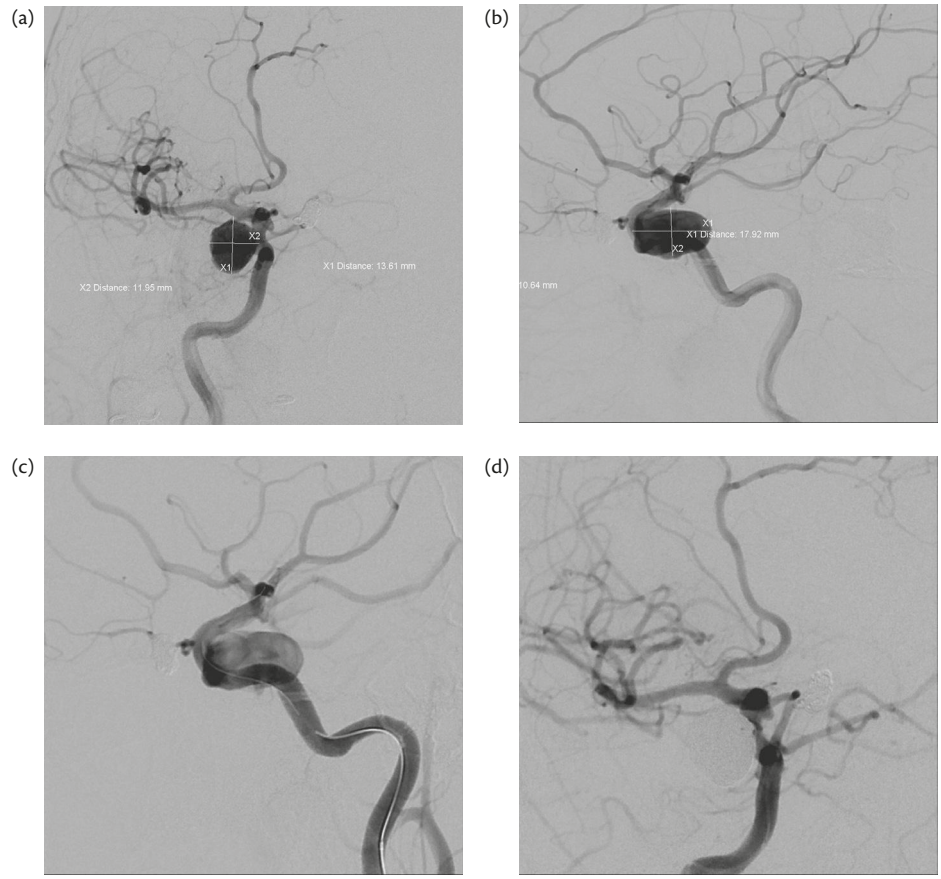

Fig. 49.7 Stent-assisted coiling of a carotid artery aneurysm. Pretreatment angiographic imaging (A and B) revealed a saccular wide-necked cavernous segment aneurysm that would be difficult to treat with standalone coiling. (C) A neuroform stent was successfully navigated, deployed, and subsequent coiling was performed. Immediate post-treatment results (D) demonstrated occlusion of the aneurysm. An additional supraclinoid aneurysm was also coiled.

the distal branches. This can be accomplished with aneurysm trapping and cerebrovascular bypass. By anastomosing a vessel distal to the aneurysm with a donor artery, one replaces the blood flow of the native circulation pattern. Historically, donor artery blood flow has been obtained from the external carotid artery (such as the superficial temporal artery or from the cervical external carotid artery via an interposition graft) and an anastomosis is performed to the intracranial circulation. More recently, intracranial-to-intracranial bypass has been developed as a viable treatment option in many cases, eliminating the need for any interposition grafts and shortening the bypass length (Sanai et al., 2009; Abla and Lawton, 2014; Davies and Lawton, 2014) (Fig. 49.8). As technology evolves and expands the endovascular armamentarium, indications for bypass are expected to decrease but not vanish. For example, many giant

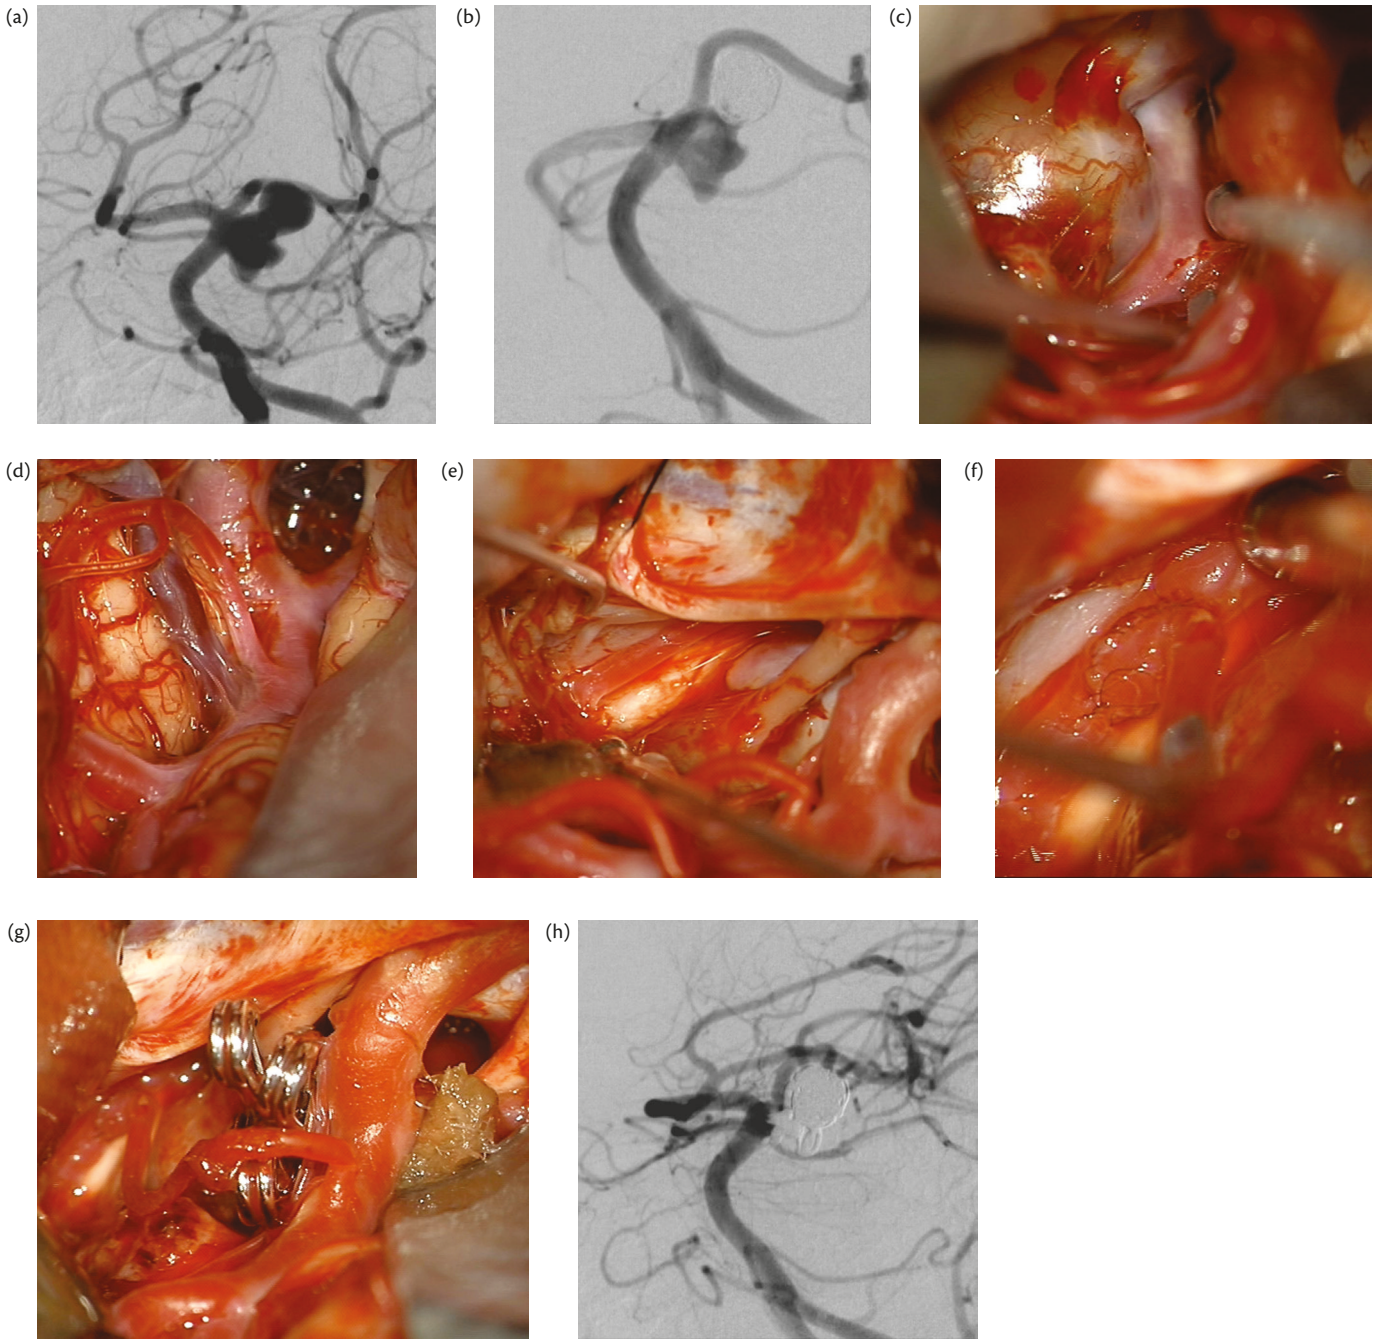

Fig. 49.8 Microsurgical treatment of incompletely coiled complex superior cerebellar artery (SCA) aneurysm with clipping and intracranial-to-intracranial bypass. (A) This ruptured, multilobulated SCA aneurysm (right vertebral artery injection, anterior oblique view) was unable to be completely coiled (B) and then referred for clipping. (C) The coil mass and adherent oculomotor nerve made the aneurysm appear to be unclippable, and a bypass/trapping strategy was pursued. (D) The anterior temporal artery (ATA) branch of the M1 middle cerebral artery was used as a donor artery to the s2 segment of the SCA, (E) which was exposed through an incision in the tentorial edge. (F) An end-to-side anastomosis created an ATA-SCA bypass (G) and the aneurysm neck was clipped successfully with only partial occlusion of the SCA origin. (H) Postoperative angiography demonstrates complete obliteration of the aneurysm with preserved flow through the SCA. Note the washout of contrast on the S2 SCA as the unopacified blood flow from the anterior circulation joins the SCA flow via the bypass.

paraclinoid segment ICA aneurysms are now being treated with flow diverting stents. Therefore, bypass proficiencies should be maintained and advanced, since the need for increasingly complex surgical solutions is growing as a function of the less complex lesions being treated with endovascular techniques, as well as the growing entity of aneurysm recurrences following prior endovascular treatment (Owen et al., 2015).

Medical management of subarachnoid haemorrhage

Vasospasm/delayed cerebral ischaemia

For those that survive the early period following subarachnoid haemorrhage and have their aneurysms treated, cerebral vasospasm can result in impaired cerebral blood flow and is the major cause of delayed ischaemia and stroke (Kassell et al., 1985). Vasospasm is defined as new intracranial arterial narrowing (mild, moderate, or severe) identified on catheter or CT angiography, and is thought to occur as a result of blood product interaction with the vascular smooth muscle of the intracranial arteries. The Fisher scale (**Table 49.2**) is the classical radiographic grading scale that provides a prediction of vasospasm development based on the initial subarachnoid blood pattern and amount following an aneurysm rupture. While many patients develop vasospasm, less than half of these become symptomatic, defined as neurological symptoms referable to a region of radiographic or sonographic vasospasm in the absence of alternative explanations. The only medical therapy in widespread use to prevent vasospasm is oral nimodipine, and it is typically administered for a total of 21 days (Barker and Ogilvy, 1996).

Currently available means of vasospasm detection rely on serial clinical examination, in addition to non-invasive imaging, either with ultrasound or computed tomography angiography (CTA). Perfusion based imaging modalities have also been shown to be useful detecting clinically significant alterations in cerebral blood flow. Additionally, catheter-based digital subtraction angiography can be used to diagnose vasospasm. The purpose of any imaging surveillance for vasospasm is to identify changes in vessel calibre or blood flow prior to neurological deterioration. Knowledge of these changes allows for the rapid institution of medical therapies, including systemic hypertension and intra-arterial vasodilator therapy (**Fig. 49.9**), if patients go on to become symptomatic in order to prevent permanent deficits (Athar and Levine, 2012).

Table 49.2 Fisher Scale

Grade	CT findings
1	No evidence of haemorrhage
2	Subarachnoid haemorrhage less than 1 mm thick
3	Subarachnoid haemorrhage more than 1 mm thick
4	Subarachnoid haemorrhage of any thickness with intraventricular haemorrhage or parenchymal extension

While practice patterns vary, surveillance for vasospasm can be accomplished with daily transcranial Doppler ultrasonography and repeated neurological examinations. CTA should then be performed on patients with elevated or rising transcranial Doppler values or with a change in neurological status thought to be attributed to vasospasm. Catheter angiography with or without pharmacologic or mechanical intra-arterial vasodilation should then be performed on patients with CTA vasospasm or on patients in whom there was a high clinical suspicion for vasospasm despite a negative CTA or in the absence of the same. All patients with vasospasm should receive systemic hypertensive therapy prior to initiation of endovascular intervention. For comatose patients, we routinely obtain a surveillance post haemorrhage day 4–7 catheter angiogram since their clinical examination is less sensitive to detect impending ischaemia.

Hydrocephalus

Hydrocephalus is a relatively common complication of subarachnoid haemorrhage, with an overall incidence of 20–30%. In the acute phase, hydrocephalus can result in coma, decreased cerebral perfusion, and even life-threatening central brainstem herniation syndrome. Emergent treatment with external ventriculostomy drainage corrects this condition, and removes hydrocephalus as a confounder during the initial neurological assessment period.

Eventually, patients with external cerebrospinal fluid drainage systems require an attempt to determine their continued reliance, and attempts to clamp these systems should be immediate rather than gradual (Klopfenstein et al., 2004). For patients that fail a clamp trial, ventriculoperitoneal shunting is the most common method of re-establishing cerebrospinal fluid dynamics (15–20% of SAH patients).

All patients, regardless of whether they required ventriculostomy drainage during their initial hospitalization or not, should be monitored for clinical signs of progressive hydrocephalus in the weeks that follow subarachnoid haemorrhage. The factors that influence the shunt rate include the extent of the SAH, opening of lamina terminalis intraoperatively and ventriculitis following external ventricular drain (EVD) placement.

Serum sodium and volume balance

Hyponatraemia is a common electrolyte disorder in the setting of aneurysmal subarachnoid haemorrhage (Sherlock et al., 2006). Sometimes, this can be attributed to the syndrome of inappropriate antidiuretic hormone secretion (SIADH). SIADH results in impaired water excretion. Any central nervous system disorder, such as SAH, can enhance antidiuretic hormone release (see **Chapter 25**). The retention of water and development of hyponatraemia can have profound effects on the clinical course of patients following aneurysmal haemorrhage. Hyponatraemia can lead to increased cerebral oedema and subsequent increased intracranial pressure and consequent cerebral ischaemia.

Another, less common, cause of hyponatraemia following aneurysm rupture is cerebral salt wasting, and it often heralds the onset of cerebral vasospasm. In this condition, natriuretic peptides are released that result in excessive salt excretion and, critically, relative hypovolemia. In the critical care setting, proper diagnosis and intense control of serum sodium levels and volume status are necessary to optimize outcomes.

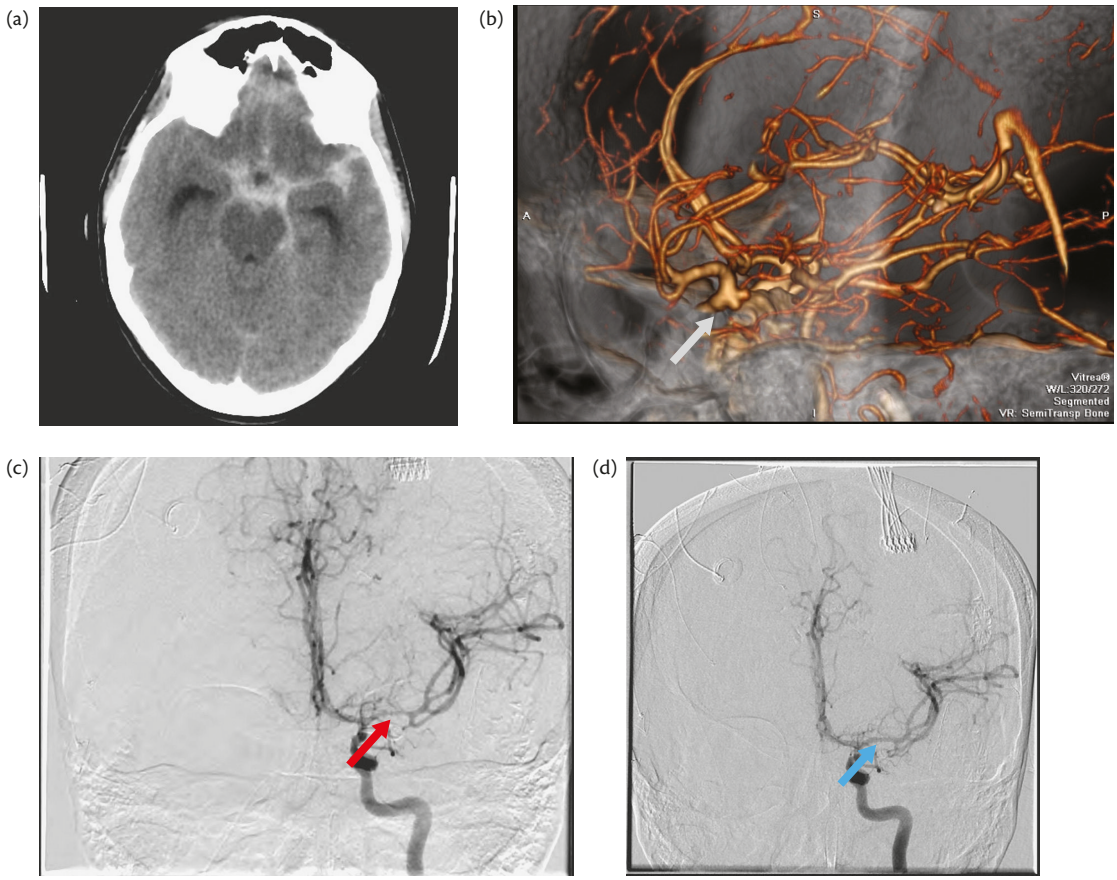

Fig. 49.9 Subarachnoid haemorrhage and vasospasm. (A) Initial non-contrast, axial head computed tomography demonstrated diffuse subarachnoid haemorrhage, and (B) 3D reconstruction of computed tomography angiogram demonstrated an internal carotid artery aneurysm (grey arrow) as the source of the subarachnoid haemorrhage. (C) Four days following presentation, the patient developed motor weakness in the right upper extremity and word finding difficulty. Digital subtraction angiography demonstrated severe vasospasm (red arrow), with narrowing of the left M1 segment of the middle cerebral artery. (D) The patient was treated with intra-arterial nicardipine with resolution of radiographic vasospasm (blue arrow). Alternative agents include intra-arterial verapamil. While balloon angioplasty has a more durable treatment effect, it is associated with a higher procedural complication risk and therefore we reserve it for vasospasm that is focal, proximal, and refractory to intra-arterial medication. All neurological symptoms in this patient resolved following treatment. Treatment of vasospasm can be effective if instituted before infarction occurs, and patients should be treated on an emergent basis if new neurological deficits are present.

Treatment of both these conditions in the context of subarachnoid haemorrhage consists of hypertonic saline, enteral salt repletion, and mineralocorticoids. Fluid restriction is typically not used to normalize serum sodium in critical, symptomatic patients for fear of exacerbating hypovolemia and increasing the risk of cerebral ischaemia.

Outcome from subarachnoid haemorrhage

The primary brain injury from a ruptured aneurysm can be severe, and dictate the overall clinical course (Stapleton et al., 2015b) (Fig. 49.10). Patients with large haematomas, who are elderly in age, or who present in a deep coma are likely to have poor outcomes, regardless of any intervention to prevent aneurysm rerupture. On the other hand, patients with good initial clinical grades may go on to develop vasospasm and suffer profound delayed cerebral ischaemia. The mortality of SAH is approximately 35% but includes patients that never present to hospital or a neurosurgeon. Overall, most patients that survive the initial haemorrhage event will go on to have good functional outcomes (~2/3) (Hop et al., 1997; Vergouwen et al., 2011). Despite this, many patients will show subtle cognitive deficits (~1/2) and emotional problems that impact on their day-to-day living (~1/2 are dissatisfied with life) and prevent their return to employment (only 1/3 return to their previous employment). Despite SAH only accounting for 5% of haemorrhagic stroke a similar number of life years are lost as from ischaemic stroke and intracerebral haemorrhage. Efforts to develop screening protocols for high-risk patients to detect aneurysms prior to haemorrhage, refinements in treatment techniques, and improved management of vasospasm will continue to better outcomes in the future.

Controversy

The longest ongoing controversy in the management of ruptured aneurysms is the decision to treat via either clipping or coiling. Two major trials have addressed this, the International Subarachnoid Aneurysm Trial (ISAT) (Molyneux et al., 2015) and the Barrow

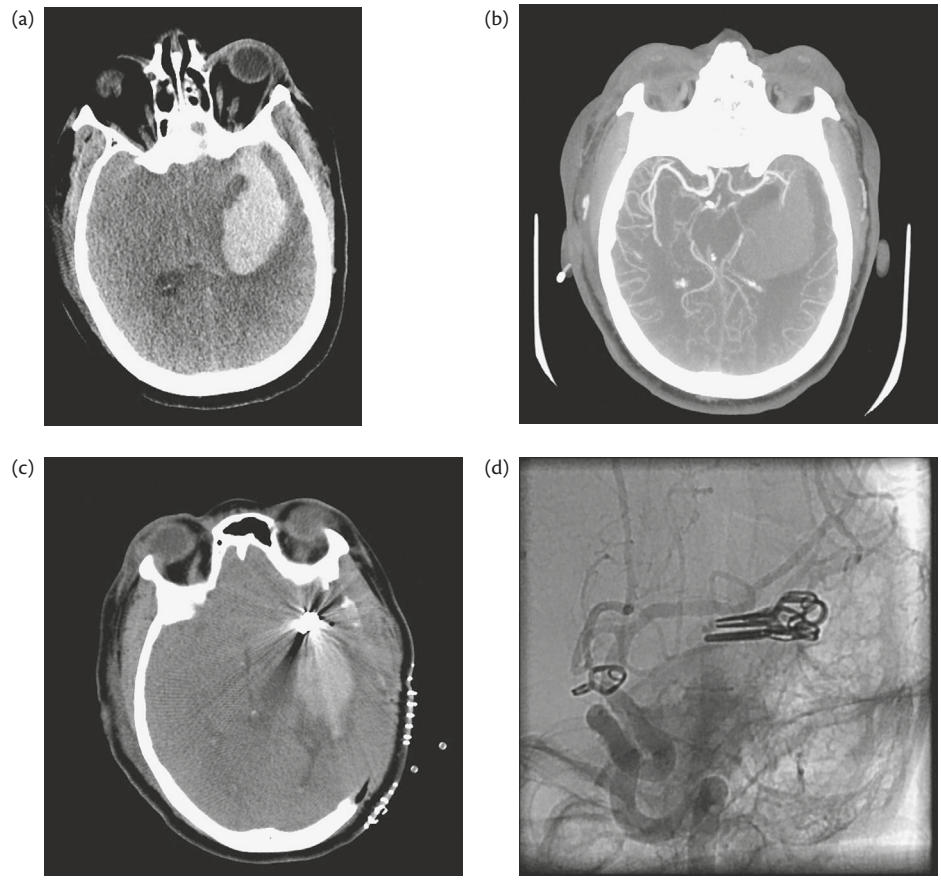

Fig. 49.10 Ruptured brain aneurysm with large Sylvian fissure haematoma. (A) Non-contrasted computed tomography (CT) of the head image showing acute subarachnoid haemorrhage with a large left frontotemporal and Sylvian fissure haematoma. (B) Maximum intensity projection of a CT angiogram of the head demonstrating a left middle cerebral artery (MCA) bifurcation aneurysm. (C) Postoperative head CT demonstrating clip artefact, partial haematoma evacuation, and decompressive craniectomy for control of intracranial pressure. (D) Left internal carotid artery digital subtraction angiogram showing complete MCA aneurysm occlusion after microsurgical clipping. An incidental anterior communicating artery aneurysm was also clipped at the time of surgery.

Ruptured Aneurysm Trial (BRAT) (Spetzler et al., 2015). The eventual long-term follow-up of the ISAT group demonstrated that the probability of dependency was not different between the clip or coil groups, although there was a greater rate of death with the neurosurgical group. However, a meta-analysis of three randomized trials (including ISAT) was unable to show a significant difference between endovascular treatment and neurosurgical clipping in terms of mortality (Lanzino et al., 2013).

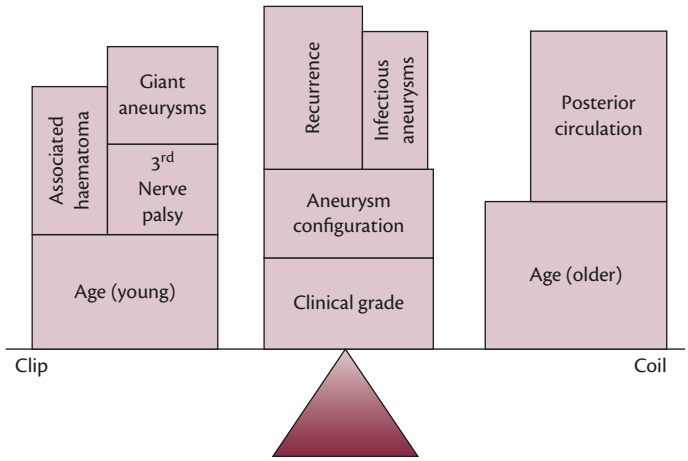

Fig. 49.11 Factors influencing the decision to clip or coil. Many factors must be considered when evaluating a treatment modality for intracranial aneurysms. In the centre of the balance are factors that can influence the decision to clip or coil either way. Farther from the centre are factors that strongly favour one treatment modality over the other. These generalizations must be considered in the context of all patient and aneurysm specific characteristics, in addition to those not shown here.

The BRAT trial, while only providing six years of follow-up, demonstrates little difference between treatment modalities for anterior circulation aneurysms, but a significant advantage of coiling over clipping for vertebrobasilar circulation aneurysms. Selection bias, provider skill set and proficiency, external validity concerns, and crossover between treatment groups have complicated the interpretation of these results.

'To clip or to coil' is at the fulcrum of aneurysm treatment planning (**Fig. 49.11**). Patients are best served by a multimodality team that can weigh the risks and benefits of treatment based on aneurysm characteristics, clinical scenario, best available evidence, and provider skill level.

Cerebral arteriovenous malformations and dural arteriovenous fistulae

Michael Morgan

Pathophysiology, classification, epidemiology, genetics, and natural history of brain AVMs

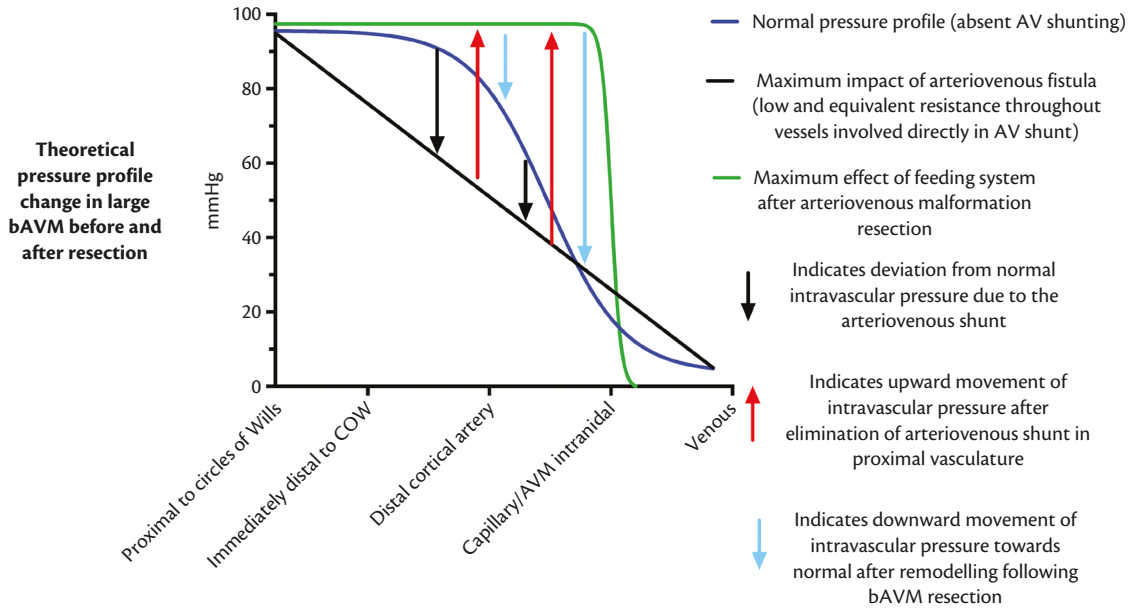
Pathophysiology

Arteriovenous malformations of the brain (bAVM) are intraparenchymal clusters of abnormal connecting blood vessels containing elements of both artery and vein but no capillaries. The abnormal cluster is connected to the normal arterial and venous circulations. This creates a rapid transit of blood within the bAVM between normal arterial and venous circulations (conventionally known as a 'shunt') because of a reduction in the normal impedance to blood flow within the vascular bed. Most of the clinical and pathological consequences of bAVM relate to this arteriovenous shunt. BAVM have no predilection for specific central nervous system locations and are distributed proportionately with brain mass.

The physiological consequences of an arteriovenous shunt in the brain can best be illustrated with a profile of pressures along the length of the vascular system (Fig. 50.1). Because of the reduced impedance (or resistance) to flow, the pressure within arteries directly contributing to the bAVM (feeding) will be less than that of a corresponding normal artery without a bAVM. Similarly, the veins receiving flow from the bAVM (draining) have a greater pressure than for a corresponding normal vein without a bAVM. Furthermore, the branch arteries and tributary veins of these feeding arteries and draining veins will be impacted by this pressure profile. Considering that the collateral circulation is continuously adapting in response to changes in shear stress (in response to pressure gradient change). The pathological changes of the vasculature are proportionate to the physiological changes. The dilatation of the vasculature and disproportionate thinning, and in places degeneration, of vessel walls are associated with greater than normal shear stress, lower than normal local arterial pressures, higher than normal local venous pressures and dampened pulsatility (in comparison to similar vessels in the absence of a bAVM). This is due to the low impedance circulation induced by bAVM. These responses are mediated through up-regulation of eNOS and down-regulation of endothelin along with the remodelling vasculogenesis factors (e.g. vascular endothelial growth factor, VEGF). Because of the consequent transition from normal to abnormal vasculature, there is usually no sharply identifiable point where bAVM can be said to begin or end, rather there is a transition zone reflecting the pathological response to the physiological perturbations. What is called bAVM is often assigned on a pragmatic basis as the central nest of abnormal vessels and is termed 'nidus'. In reality, the surgeon, pathologist, or radiologist can state what is abnormal and what is normal. However, there is often a transition zone that is often ignored because this zone reflects abnormalities of physiology that are difficult to evaluate by direct visual observation.

Several pathophysiological processes follow from the prolonged presence of a bAVM leading to the clinical manifestations. These include:

1. Rupture into the brain parenchyma or subarachnoid space due to failure of integrity of vessels involved in the bAVM caused by wear-and-tear of this high flow system. As a consequence of shear stress and consequent vascular wall degeneration: aneurysms may develop within the interstices of the bAVM (intranidal aneurysms), or on the proximal arteries leading to the aneurysm [associated proximal intracranial aneurysms (APIA)]; and varices and webs can develop in the venous system. The weakened vessel may then rupture at some point in time. A precipitating event for this rupture may be a sudden increase in pressure within the bAVM because of increasing venous outflow stenosis or at a time of venous of thrombosis.
2. The combination of lower than normal pressure in the adjacent parenchymal arteries and greater than normal venous pressure in corresponding veins ('steal') can result in neurological deficits and seizures.
3. Haemoglobin extravasation can result in iron deposition that can lead to epileptic foci.
4. Complex migraines may develop because of fluctuations in calibre of the feeding arteries and or ischaemia induced spreading depression.
5. Headaches may develop from stretching of large veins or their thrombosis leading to stretching of venous walls, raised intracranial pressure or haemorrhage, or be associated with migraine (as mentioned earlier).



Theoretical pressure profile change in large bAVM before and after resection

Indicates upward movement of intravascular pressure after elimination of arteriovenous shunt in proximal vasculature
Indicates downward movement of intravascular pressure towards normal after remodelling following bAVM resection

Fig. 50.1 A hypothetical pressure profile along the vasculature system of the brain containing a bAVM from the arteries proximal to the circle of Willis to the venous outflow. Blue represents the normal profile demonstrating that the majority of resistance in in the smaller arteries and arterioles. When resistance is reduced with the introduction of an arteriovenous shunt, the pressure profile moves towards the black line. This results in reduced pressure in arteries and increased pressure in the veins. On sudden removal of the shunt, when the vasculature is significantly dilated, the pressures overshoot (green line) the normal pressures due to the lower resistance resulting from the larger radii arteries and veins that exist before remodelling. After remodelling of the arteries and veins, the pressure profile returns to normal.

6. Intracranial hypertension and papilloedema may occasionally occur when pressure is elevated within the venous sinuses.
7. Cardiac failure with pulmonary hypertension can occur in neonates and infants.

Epidemiology

There is a congenital origin for at least some cases of bAVM as seen in the occasional metameric involvement of certain tissues related to embryological development (Bonnet-Dechaume Blanc syndrome or Wyburn-Mason syndrome) (Morgan et al., 1985). However, although often regarded as congenital, the evidence for this can be challenged (Stapf and Mohr, 2000; Jeffree and Stoodley, 2009; Davidson and Morgan, 2011) and reports of de novo bAVM occurring late in life confirm that there is a spectrum of age at onset (Bulsara et al., 2002). However, most are likely to be present from early childhood. BAVM are resilient lesions and although spontaneous disappearance has been reported, such occurrence is uncommon (Patel et al., 2001). For the most part, bAVM, unless intentionally obliterated, develop early and remain present throughout life. BAVM are detected in 0.9–1.5 per 100 000 head of population per year (Al-Shahi et al., 2003; Stapf et al., 2003) from a reported prevalence in adults of between 10 and 100 per 100 000 (Morris et al., 2009).

Genetics

BAVMs are usually sporadic (except for those that classify the lesions of hereditary haemorrhagic telangiectasia as bAVM or capillary malformation—AVM). Three models of brain AVM development have been proposed: failure of regression of primitive arteriovenous connections during development; dilation and a primary disorder of venules; and Notch4 induced arteriovenous shunt development from capillaries (Murphy et al., 2014).

As the pathological manifestation of bAVM is a physiological response to the arteriovenous shunting, the disease itself may not be a single disease but a number of genotypes with a common phenotype. This is consistent with hereditary haemorrhagic telangiectasia (HHT), an autosomal dominant disorder with a similar phenotype to bAVM (manifested by arteriovenous shunting with venules and telangiectasia present in skin, mucosal surfaces, lung, liver, and the central nervous system). For HHT, several mutations in two genes have so far been identified that are important in angiogenesis, affecting activin receptor-like kinase-1 (Alk-1) on chromosome 12 (responsible for HHT2) and its coreceptor, endoglin on chromosome 9 (underlying HHT1 – the most common type).

A further closely related familial disorder, the autosomal dominant capillary malformation (AVM) that presents with skin capillary malformations and AVM of the brain, limb, or face (no intra-abdominal or intrathoracic organ involvement) has been described with a RASA1 mutation (Eerola et al., 2003).

Natural history and clinical presentations.

Clinical presentation with haemorrhage occurs in approximately 50% (Stapf et al., 2003; Wedderburn et al., 2008; Gross and Du, 2013; Korja et al., 2014). There are no sex or age predilections for presentation. The annual rate of future haemorrhage is 1–3% for unruptured bAVM and 4–6% for bAVM presenting with recent rupture (Gross and Du, 2013; Kim et al., 2014; Mohr et al., 2014). BAVM specific factors also influence the future risk of rupture. Two factors with the most evidence supporting an increased risk are intracranial aneurysms (Brown et al., 1988; Redekop et al., 1998; Stapf et al., 2002; Da Costa et al., 2009) and deep venous drainage (or exclusive deep venous drainage) into the Galenic system (Gross and Du, 2013). The presence of associated aneurysms in unruptured bAVM increases

the risk to approximate that of ruptured bAVM (Brown et al., 1988; Redekop et al., 1998; Stapf et al., 2002; Da Costa et al., 2009). However, due to the presence of aneurysms or exclusive deep venous drainage occurring in significantly fewer than half of all unruptured bAVM, and the uncommon detection of bAVM cases, the use of more precise estimate of risks should be used with caution.

Although the reported outcome from rupture has a wide variation, it is reasonable to approximate the consequences of rupture to be major morbidity or mortality in 40% of cases. The discrepancy between the low risk of 10% and the high risk of 89% reported in the literature may be largely explained by case identification and whether or not a short follow-up after a single haemorrhage or a long follow-up after multiple haemorrhages is reported (Drake, 1979; Fults and Kelly, 1984; Crawford et al., 1986; Brown et al., 1988; Ondra et al., 1990; Laakso et al., 2008; Da Costa et al., 2009; Van Beijnum et al., 2009; Kano et al., 2014).

Non-haemorrhagic presentations (% incidence of presentations) include seizures (25%), headache (16%), neurological deficits not caused by haemorrhage (8%), intracranial hypertension (1%) and high output cardiac failure (<1% and confined to infants) (Hayashi et al., 1996; Galletti et al., 2011; Gross and Du, 2013; Bervini et al., 2014). The presentation and cause for these presentations are explained earlier.

Approximately 25% of patients that do not experience a haemorrhage will have a decline in function within a 10-year period (Brown et al., 1988). This is likely to be confined to larger bAVM and be due to seizure or progressive neurological deficits.

Diagnosis, grading, and workup

Diagnosis

Definitive diagnosis can best be made on digital subtraction angiography (DSA). This allows both the involved vasculature to be anatomically defined and also the rapid transit of shunted arteriovenous blood to be verified (Fig. 50.2). The appearance of a non-ruptured bAVM by non-contrast CT scan will be of a slightly hyperdense mass with a sharp border with the surrounding normal brain. A small focus of calcification may be present. The appearance of non-ruptured bAVM by non-contrast MRI in T1 and T2 is consistent with vascular flow voids with the dilated arteries and veins often recognized as consistent with bAVM (Fig. 50.2). Ruptured bAVM may be obscured by the haematoma in non-contrast CT scan and may obscure the identification of bAVM on MR. MRI angiography and CT angiography both can define the anatomical appearance while the dynamic sequencing may demonstrate venous filling during the arterial phase, confirming the arteriovenous shunting. However, if treatment is to be considered, DSA is necessary as it clearly identifies the complete arterial contribution (and this may include an external carotid contribution), the venous drainage and angioarchitectural features such as diffuseness, the presence of aneurysms, and venous stenosis. These angioarchitectural features may impact upon the anticipated natural history and the risks of treatment for the patient.

A differential diagnosis of proliferative angiopathy, a response to infarct or intracerebral haemorrhage (ICH) (particularly in the young), should be considered in diffuse vascular lesions that may resemble bAVM but lack the very early venous drainage pattern of bAVM. These are not bAVM and do not share the same propensity to haemorrhage.

Grading

Useful grading systems are the Spetzler-Martin Grading system (Spetzler and Martin, 1986), the Lawton-Young grading system (Lawton et al., 2010), and the Pollock-Flickinger score (Pollock and Flickinger, 2008). The first two of these predict the risk of surgery and the third, the likelihood of obliteration without deficit from focused irradiation (Table 50.1). The five-tier Spetzler-Martin grades can be condensed into Spetzler-Martin grades 1 and 2 combined, Spetzler-Martin grade 3, and Spetzler-Martin grades 4 and 5 combined into Spetzler-Ponce classes A, B, and C, respectively (Spetzler and Ponce, 2011).

Workup

The workup is influenced by demographic, bAVM-related factors, and clinical presentation. The workup may be limited to a diagnostic MRI or CTA because either no further intervention is anticipated (e.g. an elderly patient with an unruptured bAVM) or because of the urgency of intervention is necessary (e.g. patient presenting with a life-threatening brain haemorrhage). However, when such definitive interventions are not immediately apparent, further investigations are appropriate. From the history, a family history of HHT, intracerebral haemorrhage, brain abscess, or lung lesions

Table 50.1 Cerebral arteriovenous malformation grading systems

Grade (reference)		Base score	Additional scores	Range of scores	Implication
Spetzler-Martin grade (Spetzler and Martin., 1986).	Surgical risk ordinal categories	1 = size* <3 cm; 2 = size 3–6 cm 3 = size >6 cm	1 for deep venous drainage** and 1 for eloquent***	1–5	See below for implication
Lawton-Young scale (Lawton et al., 2010).	Surgical risk ordinal categories	Spetzler-Martin grade + 1 for age <20 years; 2 for age 20–40 years; 3 for age >40 years	1 for non-haemorrhagic presentation and 1 for diffuse bAVM	2–10	10%, 20%, 25%, 40%, and 65% adverse outcome risk for Lawton-Young score of 4, 5, 6, 7, and 8, respectively
Spetzler-Ponce scale (Spetzler and Ponce., 2011).	Surgical risk ordinal categories	Simplifies Spetzler-Martin grades (SMG): A = SMG 1 or 2 B = SMG 3 C = SMG 4 or 5		A, B, or C	Risk of <10% adverse outcome rate for SPC A, 20% for SPC B and greater than 30% for SPC C (46). In certain series, the long-term adverse outcome risk for SPC A is no greater than 4% (5, 7, 49, 50, 51)
Pollock-Flickinger score (Pollock and Flickinger., 2008).	Predict radiosurgery obliteration without deficit	= 0.1 x Volume**** (ml) + 0.02 x Age (years)	0.5 if located in basal ganglia, thalamus, or brainstem	Continuous score from <1 to >2	Risk of no obliteration or adverse outcome 10% for ≤1; 30% for Scores >1 and ≤1.5; >40% for Scores >1.5

* size is maximum diameter size in cm

** deep venous drainage includes drainage that communicates with the Galenic system

***eloquent is bAVM located in or adjacent to primary motor or sensory cortices, language cortex, internal capsule, diencephalon, brainstem, cerebellar peduncles, or cerebellar peduncles.

****volume can be approximated by dividing three orthogonal maximal diameters (cm) and dividing by 2.

should raise the possibility of a differential diagnosis of HHT. This may be supported by a history of recurrent nose-bleeds and inspection of mucosal membranes and fingers, confirming evidence of vascular telangiectasia. Furthermore, in cases of metameric bAVM cutaneous or retinal examination may reveal arteriovenous fistulae (e.g. Bonnet-Dechaume Blanc syndrome) (Morgan et al., 1985). However, these clinical observations are not present in most cases of bAVM. From the CTA and MRA, size, location and likelihood of deep venous drainage should allow for the grade to be estimated (although may be altered slightly after DSA). If treatment might be considered, DSA is the appropriate gold-standard investigation (being mindful of renal function).

If the bAVM is small and diffuse (characteristic of HHT), a lung CT is appropriate to investigate whether pulmonary arteriovenous fistulae exist. Pulmonary arteriovenous fistulae may present the greatest risk for the patient with HHT because of their association with the development of brain abscess (and other infected emboli).

Treatment

Surgery

The principles of surgical excision are to eliminate all arteriovenous shunting while minimizing the damage to normal functional brain, avoiding the rupture from the abnormal vasculature during this process (Hernesniemi et al., 2010). This is achieved by, assessing preoperatively the functional brain adjacent to the planned resection margins to establish a safe zone, and staying within the safe zone wherever possible. In the process of eliminating the arteriovenous shunt, the physiological and pathological responses need to be considered. The following principles should be adopted:

1. Minimize collateral brain damage with:
   a. anaesthesia aimed at controlling mean arterial and pulsatile pressure, encouraging brain relaxation and protection from ischaemia;
   b. patient positioning to ensure optimize brain relaxation, retraction can be minimized, and brain herniation on the craniotomy edge is prevented;
   c. craniotomy appropriately positioned and sized for the bAVM and proximal artery exposure (including access across the midline), and allowing for alternate approach if a catastrophe should occur;
   d. retraction minimized on the brain because of the potential for shunt induced ischaemia combined with the low blood pressure associated with the anaesthesia (although retraction is reasonable on the bAVM providing that there is no associated venous outflow compromise);
   e. in the case where critical arterial blood flow continues from feeding arteries to normal brain, inspection of arteries must be made transitioning from normal to abnormal and back to normal.
2. All feeding arteries must be controlled before the venous drainage is disturbed by:
   a. controlling superficial feeding arteries early (including the use of temporary clips until definitive division site is established);

b. controlling deep feeding arteries early by a sulcal dissection and corticotomy to the deepest part of the nose-cone early in surgery along a very limited margin, before the usual corkscrew circumferential dissection that is encouraged for tumour resection;

It should be remembered that although lenticulostriate and choroidal arteries are anatomically considered to be deep, the superficial system also contributes to deep supply. This is because of the high shear stress leading to widening of the angle of flow between arteries and vein. This causes some superficial arteries to dive into the depths of the sulci at some distance from the bAVM to enter the bAVM at a deep location.

c. to prevent injury to the main draining vein, the artery immediately deep to this vein (the usual anatomical arrangement not only present in bAVM but observed where arteries and veins are juxtaposed throughout the body) should be the last artery dissected and secured, often after delivery of the bAVM on its venous umbilicus;

d. control transdural arterial supply, when present, by incising the dura at a distance from the bAVM, completing an island of dura on the bAVM, to prevent tension placed upon these arteries;

The dura should be incised at some distance from the vascular connection point between dura and bAVM. This may best be achieved by approaching from the opposite side of the involved dura when the falx cerebri is involved.

e. in order to minimize haemorrhage when turning the bone flap, in cases where transosseous supply is present, the bone opening can be performed in many narrow strips, enabling bleeding to be controlled at each step.

3. Veins must be left until all arteries have been controlled. Important considerations are:

a. small arterialized vessels connected to the bAVM within the white matter are normally veins;

These veins leave and return to the cluster of vessels of the bAVM due to vascular remodelling aimed at minimizing haemodynamic work caused by higher than normal shear stress and angular momentum. The vast majority of these vessels do not require ligation but should be swept back onto the margin of the bAVM with bipolar and sucker. As perivascular space is only large around small arteries (and not veins) the absence of cerebral spinal fluid (CSF) surrounding these vessels may be a clue to differentiate arteries from veins. Given that the veins are superficial within the bAVM, the cumulative effect of dividing these vessels will be to compromise venous drainage in the bAVM deep nose-cone, making the deep nose-cone tense and prone to problematic bleeding. By eliminating the deep arterial supply early and minimizing the loss of the marginal venous drainage by preserving the veins that sweep in and out of the white matter, the deep component of the bAVM will be more easily resected.

b. the last major vein should be divided after the mass of the bAVM is delivered on its venous umbilicus to ensure that all feeding arteries have been divided.

4. Ligation of vessels is more difficult than usual because of the thinner walls for comparative radii vessels. The ligation technique varies from whether these are within sulci or as part of the corticotomy by:

a. small vessel division within the sulci achieved with fine bipolar or microclips;

i. Bipolar should be fine, with absolutely clean mirror-surfaced points and on low setting (to ensure that the vessel wall does not explode before thrombosis has arrested flow within the vessel). The length of diathermy occlusion needs to be longer than would normally be considered when dealing with other pathologies.

ii. Microclips are a useful adjunct to bipolars, capable of arresting flow in very thin-walled vessels, diathermy of which might lead to bleeding rather than thrombosis (see earlier) (Sundt and Kees, 1986). Furthermore, on a long length of a small critical brain artery with multiple branches terminating in the bAVM, microclips placed at the origin of these terminating branches may cause less endothelial injury to the critical artery than diathermy.

b. small vessel division within the corticotomy achieved with a broader, insulated bipolar utilizing adjacent tissue to assist the reinforcement of the wall to be included in the diathermy target.

5. Suction should be fine (e.g. #3 or 4) utilizing the lowest suction necessary to clear CSF and blood. This reduces the accidental disruption of fine thin-walled vessels during the resection. A separate suction system with larger suckers should be immediately available for use if problematic bleeding occurs.

6. The bed of the bAVM should be free of bleeding before closure. Because of the thin-walled arteries associated with bAVM, there will be minimal vasoconstriction that normally occurs in most resection beds associated with other pathologies. Therefore, all bleeding points need to be arrested and no bleeding point should be covered by material. The later may lead to catastrophic intraparenchymal bleeding. If the bleeding point cannot be easily arrested with bipolar or microclip, the source of the bleeding needs to be followed into the brain to achieve a point where the vessel can be secured. This may be facilitated by utilizing two fine suckers by the surgeon, one for sucking the bleeding point and the second for dissecting around this point. Vascular anatomical details relevant to bAVMs at specific locations are included in Chapter 46.

Radiosurgery

Performed with either Gamma Knife, a linear accelerator, or proton beam radiotherapy, the focusing of the generated radiation to a focal point covering the bAVM sets in place a reaction of the vasculature that leads to the thrombosis of the bAVM over a one to four-year period. A marginal dose, around the nidus of the bAVM, of 18 Gy or more has a high probability of eliminating all shunting (Flickinger et al., 2002). This is an effective treatment modality achieving obliteration over time with a low risk of treatment and an occlusion rate dependent upon both the marginal dose delivered (which is dependent upon bAVM volume and location) and patient age. Because the time delay to obliteration may be considerable, consideration needs to be made of the natural history risk of bAVM haemorrhage during this latent period. The smaller the volume of bAVM irradiated the steeper the fall off in dose of radiation delivered to the surrounding brain

with respect to distance. This is important given that some brain may be adversely affected with doses above 12 Gy (e.g. optic nerves). Volumes are precisely calculated on the radiological assessment generated at the time of radiosurgery planning. However, an approximation can be gained multiplying the three orthogonal largest diameters (in cm) and dividing this by 2. The likelihood of incident free effective treatment can be derived from the Pollock-Flickinger score (PFS) given as (and summarized in Table 50.2):

$$= [0.1 \times \text{Volume(ml)}] + [0.02 \times \text{Age(years)}] + [0.5 \times \text{location}]$$

Location = 0 superficial (hemispheric/corpus callosum/cerebellar)
Location = 1 deep (basal ganglia/thalamus/brainstem).

The timeframe for obliteration resembles a sigmoid curve. Fitting a sigmoid curve to data provided by reports specifically for SPC A and B bAVM (and incorporating into the sigmoid curve generation the assumptions that there is no obliteration in the first 6 months following radiosurgery and there is no further obliteration beyond 5 years), produces an obliteration rate as illustrated in Figure 50.3 (Flickinger et al., 2002; Kano et al., 2014). The 50% cumulative obliteration rate is approximately 2 years 9 months for the smaller bAVM and 3 to 3 years 6 months for larger bAVM. During the latency period (between treatment and complete obliteration), the rate of haemorrhage is similar to that of the natural history without treatment. By incorporating the natural history of future haemorrhage into the obliteration rate curves allows a generation of predicted haemorrhage rate (Fig. 50.4). Therefore, it is unusual to recommend large bAVM for radiosurgery. However, strategies to perform planned staged volumetric treatment by radiosurgery, proton beam or fractionated delivery of radiotherapy are used for these larger bAVM (Karlsson et al., 2005; Huang et al., 2012; Kano et al., 2012a; Ding et al., 2014; Hattangadi-Gluth et al., 2014). Despite such strategies, evidence supporting this rationale is minimal. A prospective, intention to treat, cohort series of this management strategy had fewer cases cured than died from haemorrhage (Kano et al., 2012a). Therefore, it is difficult to find support for radiosurgery strategies for cases that are unlikely to respond to a single treatment.

Embolization

Embolization by the selective catheterization and endovascular occlusion of bAVM is commonly performed for bAVM treatment as: an adjunct to surgery to attempt to reduce the risk of intraoperative bleeding; an adjunct to radiosurgery to reduce bAVM target volume; an adjunct to radiosurgery or conservative management by eliminating regions of the bAVM or proximal vasculature (e.g. aneurysms) that is deemed to be the site of greatest risk of haemorrhage; or as the sole and definitive ablative management. The bAVM is most commonly accessed by the antegrade selective catheterization of arteries (although retrograde access through the veins is possible) (Kessler et al., 2011; Perreira et al., 2013). Currently, the most common agent employed for the purpose of occlusion is ethylene vinyl alcohol copolymer embolization (EVACE) that has the advantage over previous glue agents as having greater control with release due to its non-adhesive properties.

Table 50.2 Expected outcomes from radiosurgery based upon Pollock-Flickinger score calculated by (Pollock and Flickinger., 2008)
$= [0.1 \times \text{Volume (ml)}] + [0.02 \times \text{Age (years)}]$
$+ 0.5$ (if basal ganglia, thalamus or brainstem)

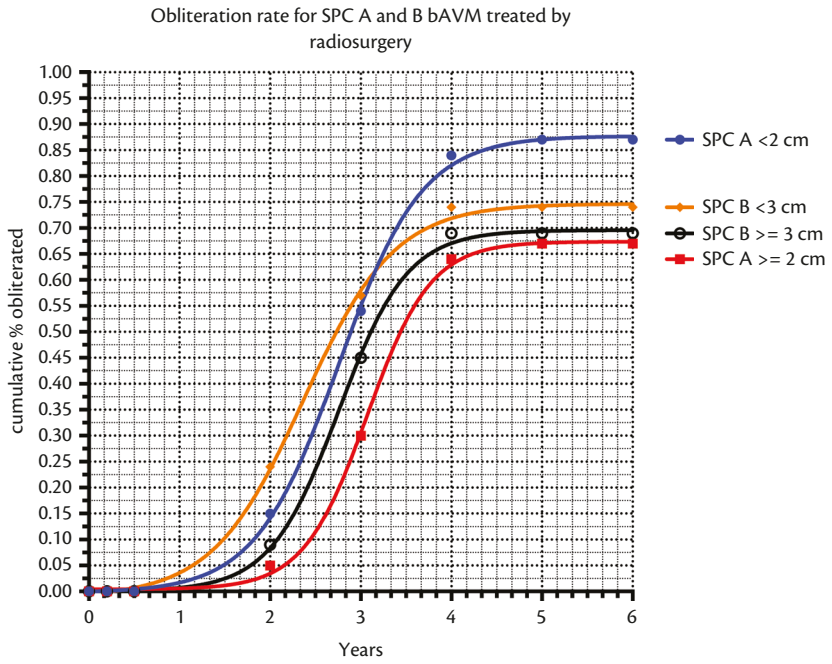
Pollock-Flickinger score	Incident free effective treatment at 70 months	mRS decline in neurological function (95% confidence interval range)
≤1	90%	0–10%
>1 and ≤1.5	70%	10–20%
>1.5 and ≤2	60%	15–30%
>2	<50%	25–50%

Defining specific roles for embolization in management of bAVM is particularly difficult due to the variety of strategies to which it is put, in contrast to surgery and radiosurgery in which ablation is usually the single goal. As a primary treatment to achieve complete occlusion, there is limited data. This is due to the potential for treatment to commence with embolization with a number of possible outcomes (complete obliteration, prepared for radiosurgery, or prepared for surgery). This shifting approach to intention of treatment is appropriate but frustrates the analysis of outcomes. From what information we have with regards agents prior to EVACE, permanent morbidity occurred in 8%, mortality in 1% and a cure rate of 5% (Frizzel and Fisher, 1995). For EVACE, disabling morbidity, mortality, and urgent surgery occurred in 6.6% of cases and complete ablation of arteriovenous shunting in 27% (Morgan et al., 2013). In a prospective, multicentre study, morbidity was reported in 5.1%, mortality in 4.3% and bAVM obliteration in 23.5% (Pierot et al., 2013). From what information that we have, EVACE of SPC A bAVM selected for planned cure is possible and commonly performed in some centres. An obliteration rate of 98% with a 3% combined mortality and morbidity for SPC A has been reported for those selected to be treated in this way (Saatci et al., 2011). However, selection bias is an important consideration when analysing these data from cohort series as cases may be found unsuitable for embolization because of concerns with regards agent reflux or access and not included in the analysis of results.

A more common role for embolization, than achieving complete bAVM obliteration, is in a sequential preparatory treatment prior to surgery or radiosurgery. The beneficial outcomes of embolization for the surgeon may include: a targeted ablation of difficult to access feeding arteries; a reduction in blood flow; a reduction in intraoperative haemorrhage; assistance with intraoperative identification of feeding vessels; the production of limited perinidal infarction of adjacent brain facilitating easy blunt dissection; and the treatment of feeder artery aneurysms subject to an increase in pressure upon AVM ablation (i.e. reducing the risk of aneurysm rupture at the time of surgery).

The benefits of preoperative embolization in the reduction of haemorrhage during surgical resection is well accepted but difficult to quantify. However, the overall management morbidity, mortality and success may not be improved with this approach as compared with surgery alone (Morgan et al., 2013; Bervini et al., 2014; Korja et al., 2014) and the subsequent radiosurgery is less likely to obliterate residual volume bAVM than equivalent volumes of bAVM treated by radiosurgery without prior embolization (Andrade-Souza et al., 2007).

The myriad of subtle variations in surgical and endovascular techniques compounded by operator dependent factors for a variety of lesions of different complexity make it impossible to quantify the contribution of embolization to the management of bAVM without



Assumptions:
1 No obliteration rate in first 6 months.
2 No further obliteration beyond 5 years.
3 Oblieration rate is best represented by sigmoid curve fit

Data derivation:
Kano 2012 (for SPC A) and Kano 2014 (for SPC B).

Fig. 50.3 Anticipated obliteration rates for SPC A and SPC B bAVM treated by radiosurgery extrapolated from a report by Kano and colleagues. They also identified that bAVM of small diameters were more likely to obliterate within each of these two groups.

Data from Kano H, Flickinger JC, Yang H-C, et al., Stereotactic radiosurgery for Spetzler-Martin Grade III arteriovenous malformations, *Journal of Neurosurgery*, Volume 120, Issue 4, pp. 973–81, 2014; and Kano H, Lunsford LD, Flickinger JC, et al., Stereotactic radiosurgery for arteriovenous malformations, Part 1:management of Spetzler-Martin Grade I and II arteriovenous malformations, *Journal of Neurosurgery*, Volume 116, Issue 1, pp. 11–20, 2012.

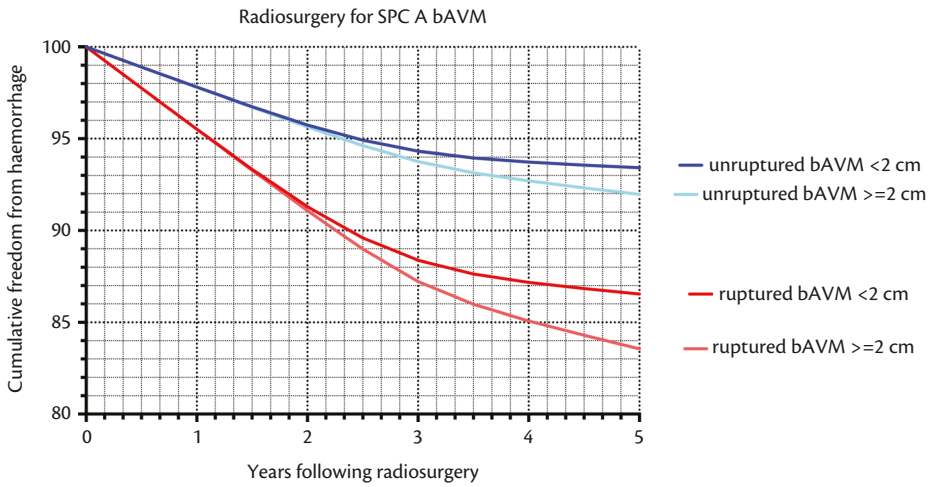


Fig. 50.4 The cumulative freedom from haemorrhage following radiosurgery for SPC A bAVM is extrapolated from combining the natural history of haemorrhage after diagnosis derived from a meta-analysis, with the proportion that is not obliterated as reported from Kano and colleagues.

Data from Gross B, Du R, Natural history of cerebral arteriovenous malformations: a meta-analysis, *Journal of Neurosurgery*, Volume 118, Issue 2, pp. 437–43, 2013; and Kano H, Lunsford LD, Flickinger JC, et al., Stereotactic radiosurgery for arteriovenous malformations, Part 1:management of Spetzler-Martin Grade I and II arteriovenous malformations, *Journal of Neurosurgery*, Volume 116, Issue 1, pp. 11–20, 2012.

knowing the institutional outcomes and place this within its correct context. Therefore, in order to plan a management pathway, both the whole-of-management outcomes as well as the individual procedure outcomes need to be understood for the institution responsible for treating a patient with bAVM. When a fluid approach to management occurs and the individual procedural outcomes are known but the whole-of-management outcomes are not known, there is a risk of hyperbolic discounting by those making the treatment decisions in that the risks of the first procedure loom larger than risks of subsequent procedures. With regards understanding this bias, the role of embolization in the outcomes of unruptured bAVM in the RCT, ARUBA, deserves some reflection (Mohr et al., 2014). The conservative arm had a better outcome at 33 months than the treatment arm. Of the three treatment modalities in the treatment arm, radiosurgery was used as an intervention in 48% (and as a single modality in 32%), embolization was used as an intervention in 44% (and as single modality in 31%), and surgery in 18% (and as a single modality in 5%) of cases. Given the brief duration of follow-up, one would not expect that radiosurgery contributed significantly to the inferiority of treatment over conservative management of unruptured bAVM. Given the small proportion of cases undergoing surgery alone, this does suggest that the treatment strategy of embolization prior to further treatment, or embolization alone, most likely contributed to the inferiority of treatment. Therefore, embolization may be inappropriate in the management of most unruptured bAVM.

In the management of ruptured bAVM, it is sometimes evident that the source of haemorrhage is from an associated proximal intracranial aneurysm or an intranidal aneurysm. In such cases, it is reasonable to consider targeted embolization of the feeding artery or intranidal aneurysm particularly if definitive obliteration of the BAVM will be delayed or not possible.

Combined management

The case for multimodality treatment may be made for individual cases but the evidence that this is appropriate for most cases is, so far, not extant. The fluid management strategy, where the next intervention is not determined until after a previous intervention, has a risk of hyperbolic discounting bias with respect to assessing risk (*vide supra* embolization). To avoid this bias, it is important to have planned the subsequent course (or potential courses) of treatments and account for the complication and likely outcomes from total management. The decision to embark on combined treatments is highly nuanced requiring a clinician with significant experience and expertise in bAVM management.

Complications of management

Surgical complications that occur with any craniotomy such as infection, subdural haemorrhage and peripheral thrombotic disorders occur with surgical resection of bAVM (Morgan et al., 1993). The incidence of these complications is often related to how intensely they are sought and, although are serious and provide management challenges, they often do not impact upon the ultimate outcome modified Rankin scale score (mRS). Microsurgery for bAVM have specific complications that relate resection of functional brain and to haemodynamic perturbations that arise in response to elimination of the arteriovenous shunt. These may be interactive and dependent upon size, location, and the magnitude of the arteriovenous shunt. To reduce the potential for direct brain damage from a resection margin containing functional brain, judgement needs to be made by the surgeon as to the site along these arteries feeding the bAVM, beyond the last branch to normal brain, that can be safely ligated without the proximal feeding artery rupturing or other complication related to arterial-capillary-venous hypertensive syndrome (ACVHS) (Morgan et al., 1999; Morgan and Winder, 2001; Morgan et al., 2003). ACVHS is haemorrhage (or oedema) occurring during or after resection caused by the physiological response of arteriovenous shunt ablation. With the resection of bAVM in a dilated arterial and venous bed, a predictable physiological response occurs that requires remodelling of the vessels (that may take approximately 10 days) or thrombosis to reduce this risk. Because it is a physiological response to the degree to arteriovenous shunting, this complication is not expected in small bAVM. It is seldom, if ever seen, in SPC A bAVM (Morgan et al., 2003). The site of vascular disruption responsible for ACVHS can be from unrecognized residual bAVM with occluded outflow (this cannot always be discerned by DSA as there may be no inflow if there is no outflow), venous occlusion ('occlusive hyperaemia') (Al-Rodhan et al., 1993), microcirculation autoregulation incompetence (normal perfusion pressure breakthrough) (Spetzler et al., 1978; Sekhon et al., 1997), or proximal thin-walled small dilated artery wall disruption (Drake, 1979; Sekhon et al., 1997). The unifying disrupting force is the proximal arterial pressure projected distally into regions of prior low pressure (see **Fig. 50.1**). This is particularly pronounced where the proximal vasculature is markedly dilated and unable to respond by vasoconstriction that should normally follow a dramatic reduction in shear stress (inhibiting eNOS expression) and increase in pulsatility (increasing the release of endothelin-1) (Faraci et al., 1995; Mazzuca and Khalil, 2012). The exaggerated increased pressure is also facilitated by the very low resistance in the dilated proximal vasculature because of the radius size of these vessels. The projected pressure is transmitted to the point of occlusion and therefore, many proximal vascular regions may be vulnerable to this sudden elevation in pressure until such time as the arterial remodelling removes this threat. This is in accord with the Poiseuillie's equation given as:

$$Flow \propto \frac{Pressure\ gradient \times radius^4}{length\ of\ tube}.$$

Where the flow equals zero after bAVM ligation the pressure gradient between the artery and outflow must equal zero.

SPC A bAVM have little risk for ACVHS unless there is extensive redundant venous drainage over a considerable surface of the brain (predisposing to the risk of propagated venous occlusion and venous infarction, or occlusive hyperaemia). In such cases, when the risk of postoperative bleeding in bAVM bed is minimal, judicious use of anticoagulant or antiplatelet therapy could be considered. For more complex bAVM this regimen of antiplatelet or anticoagulant therapy is inappropriate. The cornerstone of preventing and managing ACVHS is blood pressure control. For SPC A and SPC B less than 4 cm preventing high blood pressure is essential (e.g. prevention of systolic pressure rise above 140 mmHg). However, for large SPC B or SPC C, lowering of blood pressure may be desirable. Maintaining a cerebral perfusion pressure of at least 50 mmHg and a mean blood pressure (at the brain level) less than 70 mmHg appears successful in

Table 50.3 Management protocol and prevention of arterio-capillary-venous hypertensive syndrome (ACVHS)

Strategy	Approach	Possible agents	Limitation of use	Amelioration of potential adverse effects
Avoiding sudden elevations in blood pressure	Seizure and pain prevention to reduce momentary episodes of raised blood pressure		Induced constipation may potentiate GIT problems	
Lower mean blood pressure	Moment to moment titration of blood pressure to ensure safe perfusion of brain (e.g. cerebral perfusion pressure >50 mmHg) with mean pressures <70 mmHg	Nitroprusside for continuous titration control and other baseline agents (e.g. ACE inhibitors and beta-blockade)	Cumulative high dose toxic; Straightens the autoregulation curve making vulnerable normal brain at lower blood pressure	Addition of other antihypertensive to minimize the dose needed for moment to moment blood pressure reduction
Reduce rate of upstroke of systolic pressure	Due to the greater pulsatility in the dilated proximal redundant vasculature, dampening of the upstroke in systole is appropriate	Beta-blockade	Reducing pulse rate will increase stroke volume that might be counterproductive	Mild (but safe) reduction in cardiac output may assist
Reduction in cardiac output	Mild reduction in cardiac to reduce stroke volume	Barbiturates	Need to ensure adequate end-organ perfusion and induced coma increases the complexity of management including monitoring of intracranial pressure (ICP) and protection against immunosuppression. Prolonged use will accumulate considerable reservoir of barbiturates in fat storage leading to a considerable time of ventilator support	Fluid retention may require the addition of diuresis; ICU management; Vigilant assessment of infection status; altered metabolism of many drugs

reducing the risk of catastrophic ACVHS (Morgan et al., 2003). By a combination of lowering blood pressure, dampening the systolic peaks, reducing the rate of upstroke in the systolic wave, and reducing cardiac output (if necessary), the risks of ACVHS can be minimized (Table 50.3). However, it is critical that at all times, ischaemia is not therapeutically induced in normal brain.

Preserving normal functioning brain is critical to avoiding complications. This requires: preservation of arterial supply to, and venous drainage from, functioning brain; minimization of trauma (e.g. judicious use of retraction and dissection respecting the maximum preservation) to functional brain; avoidance of evolving haematoma concealed by cottonoids or other haemostatic material (it is best to allow haemorrhage direct access to the cavity); and avoidance of venous infarction and brain contusion from inappropriate head positioning resulting in herniation of brain over the craniotomy margin.

The major complication of radiosurgery is the development of adverse radiation effects (ARE) in approximately 7–10% of cases due to inflammatory response occurring 4 to 40 months after treatment (Boothe et al., 2013; Kano et al., 2014). The risk of this developing is related to bAVM size and complexity and is far less common for SPC A bAVM (Kano et al., 2012b). ARE relates to the volume of brain receiving 12 Gy. ARE results in oedema and neurological deficits and usually resolves. However, ARE may be life-threatening and permanently disabling. Treatment of this condition may include corticosteroids, vitamin E, phosphodiesterase inhibitors and VEGF inhibitors (Boothe et al., 2013). In addition, late cyst formation can occur in 2% of cases up to 18 years after treatment that may require surgical intervention (Kano et al., 2014). The combined morbidity and mortality following treatment by radiosurgery (including the natural history of rupture during the latency period) is given in Fig. 50.4.

The major complications from embolization include haemorrhage (from premature occlusion of outflow vein and wire perforation of the arterial wall) and occlusion of arteries supplying critical brain. Occasionally, complications related to arterial access problems (femoral artery occlusion, dissection, false aneurysm formation), embolic complications (from femoral, iliac, aortic, and cervical arterial catheterization) and arterial dissection occur. The risk of this occurrence will depend upon the complexity and number of embolization procedures performed on each patient. Therefore, risks will vary considerably between institutions because the distribution of shared responsibility for treatment varies between surgery, radiosurgery, and embolization. From large series of treatment by EVACE, in which the goal is likely to be aggressive role for embolization, the risks of major morbidity and mortality averages 7% (range 1% to greater than 10%) (Morgan et al., 2013).

Outcomes/Prognosis

For a summary of the outcomes for various management pathways, see Table 50.4. Surgical risk for SPC A bAVM is reported to be 6–10% and has been reported to be less than 3% (Gross and Du, 2013; Korja et al., 2014). This risk is likely to be generalizable to all SPC A as a group (Korja et al., 2014). The risk of surgery for SPC B is significantly worse in older patients, unruptured bAVM and diffuse bAVM (Kim et al., 2015). The Lawton-Young scale allows stratification of risks for SPC B around these factors (Table 50.4) (Kim et al., 2015). Surgical treatment for SPC C is seldom warranted in those of 20 years of age and older because of risk and usually precluded in patients under 20 years unless there is a highly nuanced reason.

Table 50.4 Comparison of management of bAVM (source reference in brackets)

Management pathway	Modifying factors	Adverse outcome leading to permanent neurological deficit (mRS >1) from treatment	Annual risk of rupture (references)	Approximate cumulative rupture rate projected for 5 years	Time to 50% of case obliteration	Obliterated on delayed studies at 5 years, % (references)
Untreated	Presentation with haemorrhage	NA	3.7–5.9% (Gross and Du., 2013., Kim et al., 2014)	20%	NA	NA
	Unruptured	NA	1–2.7% (Gross and Du., 2013., Kim et al., 2014)	10%	NA	NA
	Unruptured with aneurysm	NA	Similar to ruptured (Gross and Du., 2013., Brown et al., 1990)	>10%; <20%	NA	NA
Radiosurgery	Unruptured SPC A or B <2 cm	<3%	Unchanged until obliterated	7%	2.5 to 3.0 years	85% (Kano et al., 2014., Kano et al., 2012b)
	Unruptured SPC A or B >2 cm	<3%	Unchanged until obliterated	8%	3.0 to 3.5 years	70% (Kano et al., 2014., Kano et al., 2012b)
	Ruptured SPC A or B <2 cm	<3%	Unchanged until obliterated	14%	2.5 to 3.0 years	85% (Kano et al., 2014., Kano et al., 2012b)
	Ruptured SPC A or B >2 cm	<3%	Unchanged until obliterated	16%	3.0 to 3.5 years	70% (Kano et al., 2014., Kano et al., 2012b)
Surgery	SPC A	6–10% (34); possibly <3% (Korja et al., 2014; Spetzler and Ponce, 2011)	<1%	<1%	NA	>99%
	SPC B: 1) any <20 years of age; 2) 20 to 40 years of age ruptured or compact (not both).	10–24% (Spetzler and Ponce., 2011).); possibly closer to 20% (Korja et al., 2014; Kim et al., 2015)	<1%	<1%	NA	97%
	Other SPC B (Lawton-Young grades >6)	>39% (Kim et al., 2015)	<1%	<1%	NA	97%
	SPC C	>50% (Korja et al., 2014)	<1%	<1%	NA	96%

Combined morbidity and mortality is reported to be greater than 20% for SPC C bAVM cases (Korja et al., 2014). However, given that these are from highly selected cases, they do not represent a generalizable risk for these cases and it is reasonable to suggest that the risk of surgery for SPC C is at least 50% (with half of the adverse outcomes leading to an mRS >2).

The outcomes of radiosurgery are dependent upon the dose of radiation received by the bAVM and the dose of radiation received by the brain (*vide supra*).

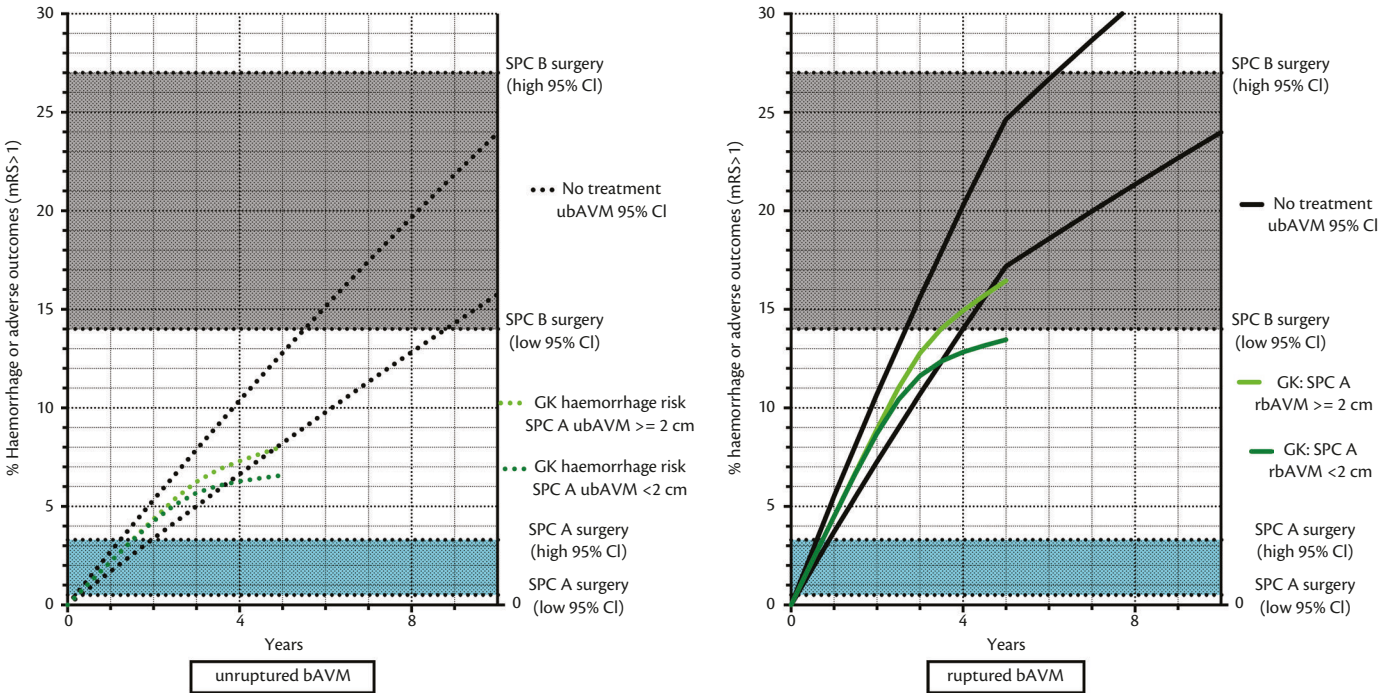
Overlaying the risks of surgery with that of the natural history and that of radiosurgery (including the anticipated risk of haemorrhage in the latency period between treatment and obliteration) allows a comparison between treatment options (Fig. 50.5). It would appear that if a 10-year time horizon is considered, surgery and radiosurgery appear to be favourable options in comparison to natural history for SPC A. A distinct advantage of surgery over that of radiosurgery is apparent for ruptured SPC A bAVM. It is likely that unruptured SPC B bAVM are likely best treated by radiosurgery providing there is a high expectation of obliteration. For surgery to be appropriate for SPC B bAVM, a time horizon considerably longer than 10 years needs to be considered. Although the selection of treatment modalities should best be answered by a randomized control trial, and one has been done (Mohr et al., 2014), the external validity is questioned limiting its interpretation (*vide supra* under embolization) (Korja et al., 2014).

Dural arteriovenous fistulae

Pathophysiology, classification, and natural history of AV fistulae

Dural arteriovenous fistulae (DAVF) form part of a spectrum of arteriovenous abnormalities with bAVM (*vide supra*). BAVM have the fistula point within the venous system before the bridging veins whereas DAVF locate their fistula beyond this point. DAVF comprise one or more fistulae centred either on the bridging vein (bridging between the leptomeningeal veins and dural venous sinus) as well as fistulae within the wall of veins contained within dura (including dural venous sinuses). They are usually acquired but may be congenital (e.g. some types of vein of Galen aneurysms; see Johnston et al., 1987). DAVF are detected at a rate one-third that of bAVM (Satomi and Satoh, 2008).

The aetiology of DAVF is likely to be venous thrombosis (Houser et al., 1972; Morales et al., 2010). That the dural venous stenosis/occlusion is aetiological rather than an epiphenomenon is supported by the finding that some patients (although a minority) have been identified with acquired or genetically determined prothrombotic disorders (Kraus et al., 2002; Wenderoth and Phatouros, 2003; Saito et al., 2008; Wysokinska et al., 2008; Pasi et al., 2014; Hwang, 2015). However, prothrombotic states constitute no more than 30% of cases of DAVF (Izumi et al., 2007; Wysokinska et al., 2008).



Surgery outcomes include sensitivity analysis for unoperated cases (11)
Radiosurgery outcomes derived from series classified by Spetzler-Martin grade (21, 39) incorporating natural history of haemorrhage derived from Gross and Du (12).
Natural history of rupture (12) assumed to return to that of uruptured after 5 years.

Fig. 50.5 Overlaying the risks of surgery that result in complications leading to a permanent mRS greater than 1 (the blue band representing the 95% confidence interval range for surgery on SPC A and the grey band representing the 95% confidence interval range for surgery on SPC B) (data from with the time-dependent outcomes of haemorrhage without treatment, black line) (data from or following radiosurgery, dark green <2 cm diameter; light green >2 cm) (see Fig. 50.4).

Data from Korja M, Bervini D, Assaad N, Morgan MK, The role of surgery in the management of brain arteriovenous malformations: A prospective cohort study, *Stroke*, Volume 45, Issue 12, pp. 3549–55, 2014; and Gross B, Du R, Natural history of cerebral arteriovenous malformations: a meta-analysis, *Journal of Neurosurgery*, Volume 118, Issue 2, pp. 437–43, 2013; and Kano H, Flickinger JC, Yang H-C, et al., Stereotactic radiosurgery for Spetzler-Martin Grade III arteriovenous malformations, *Journal of Neurosurgery*, Volume 120, Issue 4, pp. 973–81, 2014; and Kano H, Lunsford LD, Flickinger JC, et al., Stereotactic radiosurgery for arteriovenous malformations, Part 1: management of Spetzler-Martin Grade I and II arteriovenous malformations, *Journal of Neurosurgery*, Volume 116, Issue 1, pp. 11–20, 2012.

DAVF may induce venous stenosis. The production of endothelial growth factors from the high shear stress may induce subsequent dural venous sinus wall changes. Arterial levels of shear stress within veins may predispose to venous intimal hyperplasia (Fitts et al., 2014). The formation and progression of dural arteriovenous fistulae may be mutually interdependent (Casa et al., 2015). A cycle of veno-occlusive disease predisposing to the development of a DAVF predisposing to veno-occlusive disease suggests a very dynamic disease process that can change with time and, in at least 13% of cases, spontaneously occlude (Gross and Du, 2012).

The most feared consequence of DAVF is intraparenchymal (or occasional spontaneous acute subdural) haemorrhage (Duffau et al., 1999). Haemorrhage is recognized to occur only in the presence of cortical venous drainage and when present has an annual risk of haemorrhage of approximately 4–11% (Davies et al., 1997a; Davies et al., 1997b). Furthermore, when either exclusive cortical venous drainage or cortical venous drainage with strain (ectasia or extensive cortical venous ramification) is present, the risk of haemorrhage is significantly higher than in their absence (Baltsavias et al., 2015). In the case where cortical venous drainage is associated with ectasia, the annual risk is at least 10% and may approach 50% (Butlers et al., 2012; Gross and Du, 2012). The time to next haemorrhage is highest shortly after haemorrhage necessitating an urgency to definitive management (Butlers et al., 2012). Mortality from haemorrhage is reported to be 40% (Gross and Du, 2012). It is possible for venous drainage patterns to change with time, warranting surveillance on those deemed to pose a low risk of haemorrhage. Sites of DAVF more commonly associated with exclusive retrograde leptomeningeal venous drainage are usually deep median or paramedian locations such as anterior skull base in the ethmoidal region, tentorial edge, anterior straight sinus, and petrosal sinus. Whereas, cavernous and transverse sigmoid sinus locations are less likely to have (although may still have) retrograde leptomeningeal venous drainage.

The non-haemorrhagic venous hypertensive syndromes can be focal or generalized venous hypertensive encephalopathy due to leptomeningeal venous hypertension; generalized venous sinus hypertensive syndromes (resulting in intracranial hypertension); and focal venous sinus hypertensive syndromes (the most notable being cavernous sinus syndrome with a threat to eye health). Occasionally, deep venous variceal development may lead to hydrocephalus from aqueduct obstruction. The incidence of presentation with neurological deficits is similar in proportion to that of haemorrhage and occurs in patients with a similar pattern of venous drainage (Gross and Du, 2012).

Clinical presentation, diagnosis, classification, and workup of AV fistulae

The mode of clinical presentation of DAVF can vary considerably. A list of these and their underlying cause are included in Table 50.5.

Useful classifications of DAVF are based upon the angioarchitectural relationships of venous drainage patterns and the presence of venous ectasia and thus, reflect their natural history (Borden et al., 1995; Cognard et al., 1995; Baltsavias et al., 2015). Three useful classification systems are described and compared in Table 50.6.

The workup for those suspected of harbouring a DAVF reflects the clinical presentation. The diagnosis may be made on MRI/A and CT/CTA (Figs. 50.6 and 50.7). Of importance is the identification of retrograde cortical venous drainage (and whether there exists ectasia of the venous system) (Fig. 50.6). Although this may be apparent from dilatation of the cortical venous system, it may not be easily seen and it should be excluded by DSA. The DSA requires the external carotid circulation to be included and should be bilateral as the arterial contribution may be bilateral and more than one fistula may be present (Fig. 50.6).

In addition to establishing the angioarchitecture of the arteriovenous fistula, an assessment of the prothrombotic predisposition, if any, should be made. In the case of very young patients, an assessment of the impact of the fistula on the heart should also be made (see section on paediatrics).

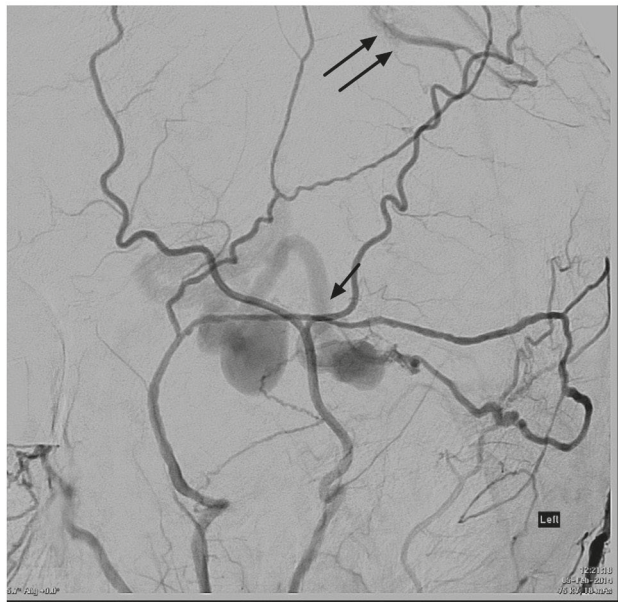
Table 50.5 Clinical presentation of DAVF

Clinical presentation	Clinical nuance	Explanation
Bruit	This is typically localized to the ear on affected side of a transverse sigmoid sinus. However, it may be on the contralateral ear to the fistula where the sigmoid sinus is occluded. The bruit may be very loud and keep the patient awake at night. It may even be audible to those close to the patient when quiet. The bruit peaks in systole but is often continuous through diastole. It is audible with a stethoscope and compression of the ipsilateral internal jugular vein may suppress the bruit	Arising from turbulence or high flow within the sigmoid sinus.
Pulsatile mass	Palpated behind mastoid processes in course of occipital artery	Dilation feeding arteries (e.g. occipital artery).
Headaches	Certain considerations need to be made	1. recruitment and dilatation of meningeal vessels. 2. thrombosis within dural venous sinus 3. trigeminal neuralgia from dilatation of superior petrosal vein. 4. intracranial hypertension (see below). 5. coincidental.
Neurological deficits	1. Focal neurological deficits of the brain 2. Global cognitive neurological deficits 3. Walking difficulty from cord venous hypertensive encephalopathy or hydrocephalus 4. Cavernous sinus syndrome or cranial nerve deficits (partial or complete)	1. Focal venous hypertensive encephalopathy. This may lead to fleeting, fluctuating, or progressive focal neurological deficits. This is due to cortical venous hypertension resulting in ischaemia. 2. Generalized venous hypertensive encephalopathy. This causes generalized cognitive decline and coma. DAVF with deep retrograde venous drainage into the internal cerebral veins or bilateral cortical veins that are impeded from superior sagittal sinus drainage are the usual cause. In such cases, there is usually significant impediment to intracranial venous outflow such as bilateral transverse venous sinus stenoses. 3. Compression or ischaemia of cranial nerves. This is a common mode of presentation with cavernous sinus DAVF. This may be related to the interaction of cavernous sinus thrombosis (total or partial) with venous hypertension within the cavernous sinus. In addition, dilated draining veins within the subarachnoid space may lead to cranial nerve compression and be responsible for, as an example, hemifacial spasm. 4. Hydrocephalus from venous variceal obstruction to aqueduct of Sylvius. 5. Venous hypertensive myelopathy from intracranial DAVF predominant drainage to the spinal cord (which may be manifest from conus involvement typical of cord DAVF).
Haemorrhage	Usually intraparenchymal but may be spontaneous acute subdual haemorrhage	See natural history.
Seizures	Focal or generalized	Occur only in the presence of supratentorial retrograde leptomeningeal venous drainage.
Intracranial hypertension, with papilloedema and headache	May occur with large DAVF	Occurs as a consequence of an increase in pressure within the venous sinuses. Due to the maintenance of the subarachnoid space pressure-venous sinus pressure gradient that drive CSF absorption.
High output cardiac failure in infants	Infants with large fistula	Direct shunts into bridging veins in the absence of venous outflow obstruction can develop a very significant proportion of the cardiac output in infants and neonates. When present in neonates, they may present as a primary cardiac problem as the high output flow to the intracranial fistula may be typical of congestive cardiac failure with pulmonary hypertension (81).

Table 50.6 Useful classifications of DAVF revolve around the association with risk of intracranial haemorrhage venous hypertensive encephalopathy

Pathology	Borden-Wu-Shucart Classification (Borden et al., 1995)	Cognard et al. modification of Djindjian and Merland Classification (Cognard et al., 1995)	DES system (direct leptomeningeal venous drainage; Exclusive leptomeningeal venous drainage; leptomeningeal venous Strain) n = not/no (Baltsavias et al., 2015)	Presentation	Sex and two most common sites	% of group presentating with haemorrhage or neurologic deficit (excluding cranial nerve deficits) (Baltsavias 4)	Prognosis (Gross and Du 2012)
Direct into dural venous sinus or meningeal veins antegrade venous flow only and no retrograde cortical venous drainage	I	I	nD, nE, nS	bruit	Female predilection; transverse sigmoid sinus or cavernous sinus	0%	Unlikely to haemorrhage
Direct into dural venous sinus or meningeal veins with retrograde dural venous outflow and no retrograde cortical venous drainage	I	IIa	nD, nE, nS	bruit	Female predilection; transverse sigmoid sinus or cavernous sinus	0%	Unlikely to haemorrhage
Direct into dural venous sinus or meningeal veins with both retrograde venous sinus outflow and retrograde drainage into cortical veins that do not exhibit ectasia	II	IIa and IIb	nD, nE, nS	Bruit, venous hypertensive encephalopathy, haemorrhage, intracranial hypertension	Female predilection; transverse sigmoid sinus or cavernous sinus	0%	6% annual risk
Direct into dural venous sinus or meningeal veins with both retrograde venous sinus outflow and retrograde drainage into cortical veins that exhibits ectasia	II	IIa and IIb	nD, nE, S	Bruit, venous hypertensive encephalopathy, haemorrhage, intracranial hypertension	Female predilection; transverse sigmoid sinus or cavernous sinus	66%	6% annual risk
Direct into dural venous sinus or meningeal veins with exclusive retrograde drainage into cortical veins that do not exhibit ectasia	II	IIb	nD, E, nS	Bruit, venous hypertensive encephalopathy, haemorrhage, intracranial hypertension	Female predilection; transverse sigmoid sinus or cavernous sinus	15%	6% (95% CI: 0.1 to 19%) annual risk
Direct into dural venous sinus or meningeal veins with exclusive retrograde drainage into cortical veins that exhibits ectasia	II	IIb	nD, E, S	Bruit, venous hypertensive encephalopathy, haemorrhage, intracranial hypertension	Female predilection; transverse sigmoid sinus or cavernous sinus	90%	6% (95% CI: 0.1 to 19%) annual risk
Direct into bridging vein and both retrograde cortical venous drainage and venous sinus drainage	Not defined	Not defined	D, nE, nS	venous hypertensive encephalopathy, haemorrhage, intracranial hypertension			
Direct into bridging vein and only retrograde cortical venous drainage without venous ectasia	III	III	D, E, nS	venous hypertensive encephalopathy, haemorrhage,	Male predilection; tentorial and petrosal	75%	10% (95% CI: 4 to 20%) annual risk;
Direct into bridging vein and only retrograde cortical venous drainage with cortical venous ectasia	III	IV	D, E, S	venous hypertensive encephalopathy, haemorrhage	Male predilection; tentorial and petrosal	>90%	21% (95% CI: 4 to 66%) annual risk
Perimedullary venous drainage (spinal)		V					

CTA sagittal plane of DAVF located within the straight sinus tentorial edge border, Borden type III presenting with gobal cognitive impairment and absence of straight sinus filling.



External carotid arterial DSA demonstrating retrograde parenchymal venous drainage (arrow). A second fistula is identified associated with the falx (double arrow).

Fig. 50.6 CTA and external carotid DSA demonstrating the features of a DAVF with retrograde leptomeningeal venous drainage. This adult male patient in his sixties presented with global cognitive decline. There was a second small DAVF associated with the falx communicating with the superior sagittal sinus.

Treatment

Treatment should normally only be recommended when there is the presence of retrograde cortical venous drainage (because of the risk of haemorrhage in these patients), venous sinus hypertension (causing intracranial hypertension) or cavernous sinus syndrome (causing a threat to eye health). However, occasionally treatment is aimed at palliating symptoms (e.g. audible bruit). It should be remembered that there may be alternative ways of palliating

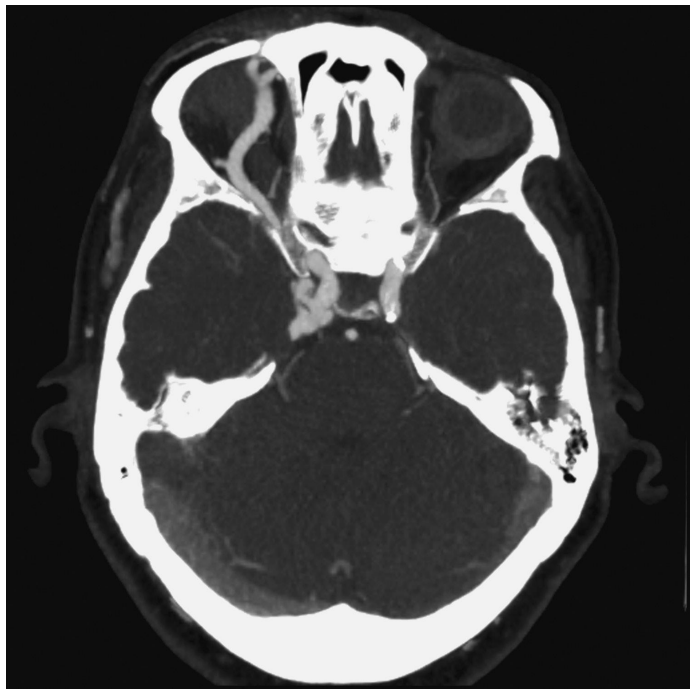


Fig. 50.7 CTA demonstrating a right cavernous DAVF by the evidence of the enlarged superior ophthalmic vein filling during the arterial phase (note: the transverse sinus is less opacified, making it possible to state that the superior ophthalmic vein is filling early).

symptoms (e.g. sleeping with background white noise) and with time, DAVF may spontaneously thrombose. When palliating a bruit, it is important to keep in mind that cure may not be necessary to alleviate the symptoms and it is critical that a benign fistula is not converted to a sinister DAVF by altering venous drainage.

Surgery

Two general approaches can be considered surgically. The first is the disconnection of the retrograde cortical venous drainage from the DAVF leaving the DAVF intact but without any cortical venous reflux. This removes the danger from haemorrhage. The second approach is to remove the DAVF itself. In this procedure, it is critical that the sinus resection does not interfere with normal cortical venous drainage.

1. *Disconnection of cortical venous drainage.* This can be applied for all locations providing that retrograde flow is established and is the optimal treatment in most situations. This is similar for both spinal dural AVF and cranial DAVF. The smallest approach possible, with a clip applied as close to the entry of the vein to the dura, will obliterate the risk of haemorrhage. However, some difficulties in performing this must be considered:
   a. Because the arterialized vein may have tributaries close to the exit point from the dura, the clip placement must be close enough to the dura to prevent continued shunting.
   b. When closing the clip at this point, it is important not to tear the draining vein exiting the dura (made possible because of the fixed venous circumference in the relatively rigid dura). Therefore, slow closure of the clip blades is important to allow the tense vein to slide within the clip blades to avoid excess wall tension.
   c. The grossly dilated and tense arterialized veins may extensively obstruct the approach to the clip target point. Consideration of this access obstruction needs to be made in planning the surgical approach. As an example, when the entry of the superior petrosal vein is the target, this might be more readily achieved by a supratentorial subtemporal approach with division of the tentorium from medial to lateral to expose the superior petrosal vein from above without the vein itself obstructing the approach.
2. *Venous sinus resection involved in the DAVF.* This approach is rarely required since the introduction of liquid embolic agents and intravenous sinus temporary balloon protection of the venous sinus lumen. However, for completeness, if the involved venous sinus is no longer functioning with normal venous drainage (i.e. it is thrombosed, or the involved segment contains no important tributaries from the brain and collateral venous drainage exists) the DAVF with the venous sinus can be excised. Although rarely performed if an endovascular or simple disconnection procedure is available, it may still have an occasional place in management. This approach was first proposed by Dr Sundt in the management of transverse sigmoid sinus DAVF (Sundt and Piepgras, 1983; Eftekhar and Morgan, 2013). Careful consideration must be made of veins that must be included within the excised segment to ensure they do not carry normal antegrade blood flow.

Embolization

The key to curing DAVF is to obliterate the 'foot of the vein' involved in the DAVF. This can be achieved with liquid embolic agents either from a transarterial or a transvenous route. A number of approaches may be taken to obliterate arteriovenous shunting by embolization including transarterial as well as transvenous routes. The transarterial route is similar to that for obliterating bAVM. However, there are additional concerns that need to be considered. Chief among these are ischaemia of the scalp and reflux into collateral supply to normal brain. Although most meningeal branches make no contribution to the brain, this is not always the case and of particular concern is reflux backward into a brain-supplying artery. Furthermore, cranial nerves may be supplied by meningeal arteries. Therefore, careful consideration of potential collateral supply (and the potential impact upon future management, such as a surgical approach) needs to be made prior to endovascular intervention. The transvenous route, although reasonable, may be complicated by the DAVF feeding into channels running parallel to a normal venous sinus. This may make obliteration of the sinus potentially non-curative. Stenting of the sinus (pinning the feeding arteries into the sinus) or balloon inflation of the sinus during embolization may allow protection of functioning venous sinuses. An important consideration while conducting the transvenous ablation is to avoid causing venous hypertensive encephalopathy during the procedure by increasing the outflow into the cortical venous drainage without having reduced the arterial inflow. This may precipitate haemorrhage or exacerbate neurological deficits (e.g. **Fig. 50.8**). When performing liquid embolic embolization of the venous foot of the DAVF, in the presence of a patent venous sinus, there is a risk for sinus occlusion. This can be prevented by concurrent balloon inflation within the venous sinus during the injection of the liquid embolic agent. However, the balloon may impede normal venous drainage during the period of inflation and should be reserved for the more aggressive DAVF when the goal is to cure the fistula rather than the lesser goal of palliation of symptoms.

Focused irradiation

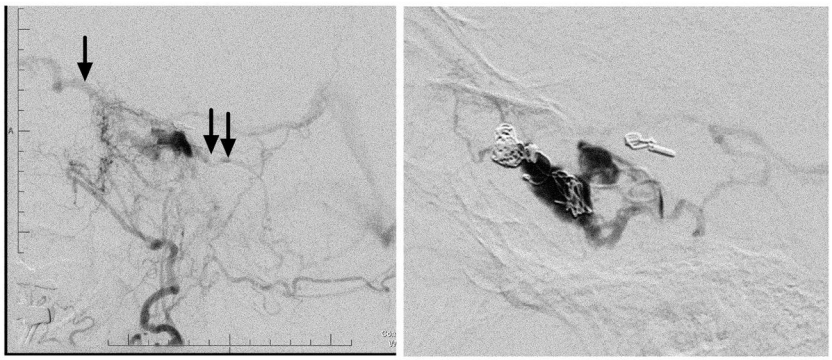
Although yet to be validated for DAVF treatment, it has been reported to be successful when combined with embolization in some cases of transverse sigmoid sinus DAVF (Loumiotis et al., 2011). This may prove to be an important component of management for disabling symptomatic bruits when there is no retrograde leptomeningeal venous drainage (and therefore no immediate threat of haemorrhage). For such cases, the role of particulate arterial embolization to reduce the bruit followed by radiosurgery offers a very low risk and promising treatment for transverse sigmoid sinus DAVF (Loumiotis et al., 2011).

Conclusion with regards management of DAVF can be seen in a decision-making algorithm illustrated in **Figure 50.9**.

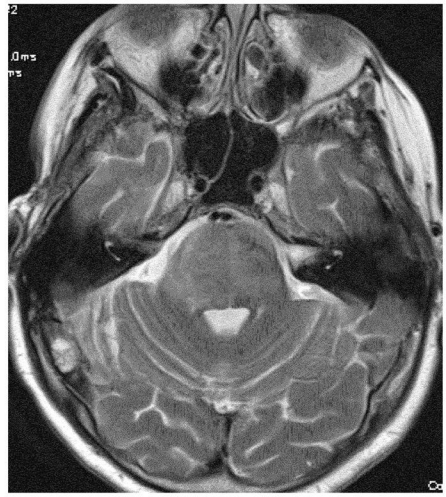
Complication management

The most frequent complications common to both surgical and endovascular management are:

1. *Haemorrhage at the time of treatment.*
   a. Haemorrhage may occur due to retraction in the presence of venous hypertension. When venous hypertensive encephalopathy is present great care must be taken in manipulating the brain before retrograde cortical venous drainage is eliminated. On opening the craniotomy, relaxation may be difficult due to venous hypertension. However, the additional



Left external carotid injection (left) demonstrating cavernous DAVF with filling of the superior ophthalmic vein (arrow) and retrogrde parenchymal venous drainage to the posterior fossa (double arrow). During the embolisation procedure via a venous transpetrosal access (right), the superior ophthalmic vein was occluded early with consequent DAVF flow entirely retrograde into the posterior fossa cortical veins (before finally occluding this outflow). Aneurysm clip placed on coincidental ICA aneurysm.



T2 MRI demonstrating hyperintensity and swelling of pons from venous hypertensive encephalopathy due to the redirection of outflow into the cortical veins of the posterior fossa during embolisation. Patient had a prolonged loss of consciousness and awoke with a hemiparesis.

Fig. 50.8 DAVF of the left cavernous sinus presenting with orbital congestion and eye threatening secondary glaucoma. The external carotid arterial injection (left) demonstrates the characteristic enlargement of the superior ophthalmic vein (arrow) with the sinister venous outflow from the inferior petrosal sinus into the prepontine veins (double arrow). This was treated by the transvenous catheterization and coil occlusion of the cavernous sinus initially packing anteriorly near the superior ophthalmic vein. Retrograde flow into the pontine venous system followed until this was eventually occluded (middle image). Slow to awake and eventually awakening with a hemiparesis, it can be seen by MRI (right image) that an episode of significant venous hypertension resulted in the clinical and radiological features (hyperintensity and swelling of pons on T2).

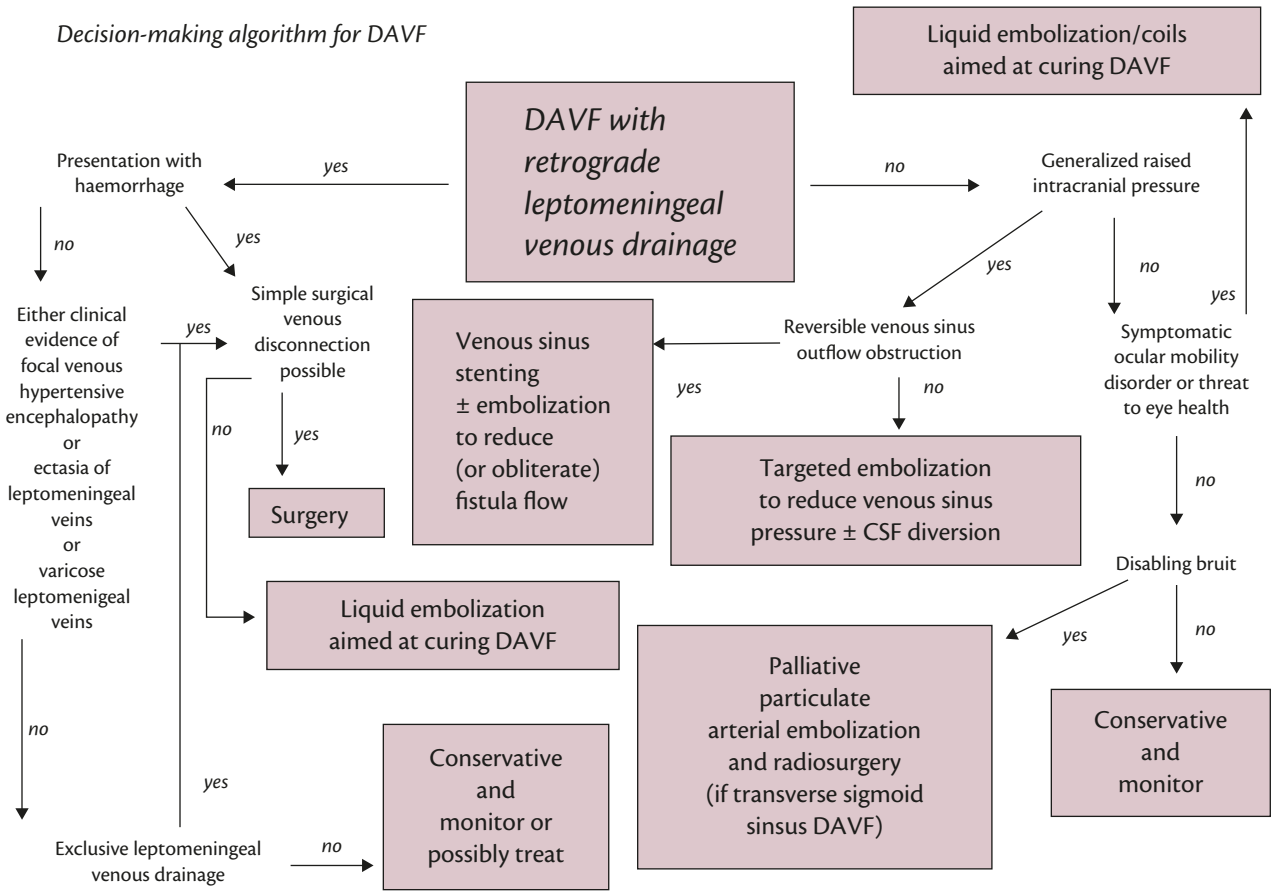


Fig. 50.9 DAVF decision-making algorithm for management.

venous obstruction that may result from retraction can result in venous infarction and haemorrhage. This is particularly the case in surgery of the torcula where the addition of a prone position accentuates the problem and a sitting position may result in herniation of brain through the craniotomy. Retraction should be kept to a minimum when venous hypertension is significant.

   b. With regards the risk of haemorrhage associated with endovascular repair, this most likely occurs with venous occlusion in which there is a momentary rise in pressure in the retrograde cortical venous outflow (e.g. in the distribution of the vein of Labbe) occurring before complete occlusion has been achieved.

2. *Venous infarction*. This arises with loss of normal antegrade flowing veins due to inadvertent occlusion or from propagated venous thrombosis. It is essential that only veins draining retrogradely can be safely disconnected.
3. *Venous hypertensive encephalopathy*. This occurs on the same basis as haemorrhage. An example can be seen in Figure 50.7.
4. *Propagated venous sinus thrombosis* (particularly at points of venous stenosis). Progressive venous sinus occlusion may occur with the reduction of flow. Particularly vulnerable are sinuses with multiple stenoses. When this is extended to, but not beyond, the next normal tributary inflow, no clinical consequences will occur. However, if this propagation extends beyond this point (e.g. across the torcula, catastrophic consequences may ensue). Monitoring the thrombosis in the post-treatment period with CT scan with and without contrast will assist in evaluating this risk. Furthermore, prophylaxis against venous thrombosis is important to consider especially as a prothrombotic state may exist (*vide supra*).
5. *Deep venous thrombosis.* Due to the propensity for some patients with DAVF to have a prothrombotic state, prophylaxis, and vigilance for deep venous thrombosis (DVT) is appropriate.

In addition, surgery carries a risk of:

6. *Pseudomeningocele formation.* This occurs with the excision of superficial sinuses (superior sagittal sinus and the transverse sigmoid sinuses) and the subsequent problem of dural closure. This will usually resolve after a period of weeks (to months) unless there is associated CSF circulation disorder.
7. *Poor wound healing.* Wound healing may be problematic if scalp artery embolization preceded surgery. This can be avoided with embolization confined to meningeal vessels.

Outcomes

Both surgery and endovascular repair have a high rate of success with a low risk (e.g. Eftekhar and Morgan, 2013). Due to the variety of approaches and the limited number of large series, quantification of risks is difficult. In the case of surgery aimed at simply excluding the cortical venous drainage from the DAVF, the limited approach of clipping the arterialized vein, reduces the surgical complexity, and therefore reduces the potential for complications. From the limited case series, treatment is likely to be superior to the natural history for DAVF in which retrograde cortical venous drainage with ectasia is present.

Carotico-cavernous fistulae (CCF)

Pathophysiology, classification, and natural history of CCF

The underpinning pathophysiology for the clinical consequences of all carotico-cavernous fistula (CCF) is elevated intracavernous venous sinus pressure. This is likely to also lead to retrograde venous drainage to the eye by the superior ophthalmic vein (Fig. 50.7). Because of the interconnections between the two cavernous sinuses, contralateral eye involvement is common. Occasionally, due to occlusion of the superior ophthalmic vein by anterior intracavernous thrombosis, the clinical presentation may only occur contralateral to the fistula.

The natural history for the eye and vision is poor in the extreme case. Threats to vision can arise from secondary glaucoma and the extreme exophthalmos with consequent corneal damage. In the case of indirect CCF, the clinical manifestations may be due to the combination of a cavernous sinus thrombosis and DAVF. In such cases, an extremely small DAVF may be responsible for extreme clinical manifestations. In the case of direct CCF, retrograde flow in the ophthalmic artery may occur contributing to retinal ischaemia that, when combined with the high venous pressure, may lead to immediate permanent loss of vision.

Problems other than that with the eye can occur. Retrograde cortical venous drainage may be present (middle cerebral veins or pontine venous tributaries to the inferior petrosal sinus). When present, the considerations discussed with DAVF (see earlier) need to be considered.

CCF can be direct or indirect. The Barrow classification is used by some authors and divides CCF into four types (A—direct, B—indirect with internal carotid supply, C—indirect with external carotid supply, D—indirect with internal and external carotid supply) (Barrow et al., 1982).

1. Indirect CCF are DAVF and can be considered with the aforementioned discussion. DAVF account for the vast majority of CCF. They are located in the wall of the cavernous sinus and may (on occasions) be associated with retrograde cortical venous drainage (Davies et al., 1997a; Davies et al., 1997b).
2. Direct CCF may be spontaneous or traumatic. These fistulae usually have a dramatic and profound onset due to a potentially very high flow that may include contributions from the internal carotid artery (ICA) (both antegrade and retrograde) ophthalmic artery and the posterior circulation through the posterior communicating artery. Therefore, depending on the size of flow and the circle of Willis competence various brain regions as well as vision can be threatened with ischaemia. Due to their size, and the interconnection between cavernous sinuses, both eyes can be affected equally, making lateralization of the offending artery difficult (also keeping in mind that bilateral fistulae may occur in traumatic cases).
   a. Spontaneous direct CCF is caused by ruptured intracavernous ICA aneurysms. These include both berry aneurysms and fungal mycotic aneurysms (Lu et al., 2014). Ruptured berry aneurysms are the most common cause of spontaneous direct CCF but are rare in comparison to DAVF as a cause

for CCF. Fungal mycotic aneurysms are far less common than berry aneurysms but when they occur they can be devastating, not only because of the large CCF occurring, but also because of the sheet of infection that tends to progress (without respecting boundaries) with the potential for brain infection. The occurrence of such aneurysms in the cavernous sinus is due to the proximity to the ethmoid sinus as well as the potential for propagated infected thrombus to the cavernous sinus from the face. This should be considered in immunocompromised patients, diabetics with poor control, and those with suspected long-standing sinusitis.

b. Traumatic CCF may be due to either rupture or dissection of the ICA. Direct CCF may be associated with fracture or erosion into the ethmoid sinus and catastrophic epistaxis may occur. They can be associated with transsphenoidal surgery for pituitary tumours. In the case of traumatic origin from head injury or ICA dissection, bilateral ICA damage is present in a significant proportion of cases (Mokri et al., 1988; Mokri, 1990). Therefore, rapid assessment of both ICAs is of importance. Clinical clues may assist, such as a Horner's syndrome. However, making a diagnosis of Horner's syndrome in the presence of a contralateral cavernous syndrome, is extremely challenging but when made should raise immediate concerns that the clinical situation may be very unstable.

Clinical presentation, diagnosis, and workup of CCF

The high venous pressure may produce a swollen red eye from venous engorgement, secondary glaucoma with the potential for vision loss, exophthalmos, and restrictive globe movement. In the case of direct CCF, the onset is dramatic, and the clinical presentation is extreme. However, when an intracavernous aneurysm is responsible for a direct CCF after rupture, there may have been a preceding sixth nerve palsy and pain prior to the development of the florid cavernous sinus syndrome (in the case of berry aneurysms) or a cavernous sinus syndrome from thrombosed sinus (in the case of fungal mycotic aneurysms). For indirect CCF, the onset may be gradual and may become extreme but is, generally, subtle at the onset. Furthermore, preceding cavernous sinus thrombosis may have been clinically apparent. Failure to improve with a known cavernous sinus thrombosis may herald the presence of a DAVF. CCF can be confirmed clinically as there is often an audible bruit detected with stethoscope placed over the closed eye.

The clinical setting may make the diagnosis difficult. For head injured patients, fractures adjacent to the ICA course should undergo a CTA. A delayed onset of the development of a sudden onset of chemosis and proptosis after head injury should immediately raise suspicion of a direct CCF.

Diagnosis can be confirmed by CT or MRI by identification of enlargement of the superior ophthalmic vein (**Fig. 50.8**). Contrast compared with non-contrast studies are useful, not only to more readily identify the dilated superior ophthalmic vein, but also to assess whether there is thrombosis within the cavernous sinus and retrograde cortical venous drainage.

In the case of suspected indirect CCF, the rush to treatment should be informed by the health of the eye as there is a greater than 10% chance of spontaneous resolution of the CCF (Gross and Du, 2012). Workup must include an evaluation by an ophthalmologist regarding state of vision, pressures, and adequacy of eye protection. If it is clear that vision or the eye is threatened or progressively worsening, or there is evidence of retrograde cortical venous drainage, DSA is appropriate with consideration to treatment.

DSA confirms the diagnosis. In the case of direct CCF, workup needs to be urgent and proceed to DSA with a potential for intervention at this time. Both internal carotid and external carotid vessels need to be examined to assess contributions. For direct CCF without retrograde arterial flow in the distal ICA, establishing the potential for adequate collaterals to the ICA should be made. This might be evident by retrograde ICA flow distal to the intracavernous ICA breach. A balloon test occlusion at the time of the DSA should be considered when antegrade distal ICA flow is present and the test is safe to perform. Indirect CCF may only be evident on external carotid angiography and may be contralateral to the eye clinically involved. Therefore, bilateral external and internal carotid DSA should be performed for indirect CCF (cavernous DAVF) (**Fig. 50.7**) to ensure an accurate diagnosis and for direct CCF to assess adequacy of potential superficial temporal arteries if bypass is considered.

Treatment

Indirect CCF management

Management of indirect CCF needs to be coordinated with an ophthalmologist. Unless there is an imminent threat to vision or the eye, a conservative approach is reasonable (providing there is no retrograde cortical venous drainage with ectasia) as there is greater than a 10% chance of spontaneous resolution. Earlier consideration should, however, be given to treatment when both eyes are affected.

When a decision has been reached that intervention is appropriate, endovascular treatment is preferred. The surgical option of opening the cavernous sinus and packing with material promoting thrombosis is of historical interest only. In the case where the outflow is exclusively into the middle cerebral veins, consideration can be given to surgical disconnection of the arterialized veins as they enter the cavernous sinus. Given that, for the most part, only the eye is at risk, surgical intervention with bypass is inappropriate.

The endovascular repair is usually transvenous, either accessing the cavernous sinus by the superior ophthalmic vein (via the superior eyelid) or by the inferior petrosal sinus. The aim is to occlude the sinus in a way that obliterates retrograde flow into either the superior ophthalmic vein, contralateral cavernous sinus, cortical veins through the middle cerebral vein or the pontine veins through the inferior petrosal sinus. Access may be difficult due to partial thrombosis of the sinus and a single approach may prove to be insufficient.

Direct CCF management

Direct CCF can be managed either by reconstructing (endovascularly) or occluding (either endovascularly or surgically) the ICA. In the case of reconstruction, flow diverter stents, covered stents, detachable balloons or coiling the point of breach with stent deployment can be performed (Lu et al., 2014). Transvenous routes are more problematic than with DAVF because of the greater flow. However, they may be used following stenting of the ICA if the transarterial route has failed to completely close the fistula (Lin et al., 2015). The choice of procedure depends upon the health of the arterial wall. Placing coils into a false aneurysm may be problematic and unless

healing of the artery is anticipated occluding the ICA may be the preferred option. When endovascular reconstruction has been performed, delayed studies are important to exclude the development of false aneurysms.

Direct CCF treatment by occlusion can be performed having established the adequacy of collaterals. In the event that existing collaterals are assessed to be inadequate, high flow or low flow bypass should be considered prior to artery occlusion. This may also influence the technique of occlusion. If bypass is considered unnecessary, occlusion can be readily achieved by endovascular means at the time of the DSA. It is critical that the point of arterial rupture is included in the territory occluded. Proximal occlusion may result in exacerbation of retrograde flows in the ophthalmic artery or ICA and consequent ischaemia. Where bypass is necessary, a low flow bypass by STA-MCA is reasonable if there is confidence that minimal additional flow is required. An example of such a scenario is when there is no clinical problem during the test balloon occlusion but there is significant delay in capillary or venous filling of the targeted hemisphere on contralateral DSA (delayed cross flow). In the case where the ICA flow needs to be replaced because of clinical indicators, test balloon occlusion, or DSA, high flow bypass is appropriate. To supply a minimum 150 cc/min to replace ICA flow and prevent infarction, interposition saphenous vein, or radial artery bypass graft is appropriate. High flow bypass has a considerably greater procedural risk than STA-MCA bypass but have similar long-term patency after the first week (Sia et al., 2011).

Complication management

Ophthalmological supervision and management are of paramount importance to assess and manage secondary glaucoma and corneal protection.

Indirect CCF complication management

For cavernous DAVF managed by transvenous approach, the complications applicable to the earlier section on DAVF are relevant. The most typical relates to a cavernous sinus syndrome (causing venous insufficiency of the orbit and globe until collaterals develop) and venous hypertension of the brain during the procedure before complete occlusion is achieved that may result in a venous hypertensive encephalopathy of brain (usually pontine) or haemorrhage within the same brain region (**Fig. 50.7**).

Direct CCF complication management

For direct CCF, managed by preserving the ICA, several complications need to be considered and avoided (or managed). Among the most feared are:

1. *Embolization.* Due to the rarity of these lesions no large series of treatment can address the incidence of embolization. However, extrapolation from the treatment of aneurysms is appropriate. Silent embolization is a relatively common phenomenon following the endovascular treatment of aneurysms and has been documented to be evident on as many as half of brain MRI scans in the event of complex aneurysm repair such as stent-assisted coiling (Hahnemann et al., 2014). However, few of these events result in adverse clinical outcomes and following flow diverter stent deployment, this incidence may be 1–5% (Saatci et al., 2012; McDonald et al., 2015). This can arise during the procedure of deploying stents and coils or shortly thereafter. Preloading with antiplatelet medications and continuing these for up to 6 months is appropriate prophylaxis against emboli. However, even with this prophylaxis, the proceduralist must be prepared to check for emboli and retrieve or dissolve them. There is a significant incidence of inadequate response to the initial recommended clopidogrel management in approximately 25% of cases (Oran et al., 2015). Therefore, attention to individual patient specific responses to the loading may decrease the embolization rate.
2. *Recurrence of the aneurysm (or false aneurysm).* Due to the rarity of these lesions no large series of treatment can address recurrence. However, extrapolation from the treatment of aneurysms is appropriate. For aneurysm management, inadequate or recurrent aneurysm may occur in 10–40% of aneurysms with flow diverters (McAuliffe et al., 2012; Saatci et al., 2012; Toma et al., 2013; Fischer et al., 2014).
3. *Occlusion of the ICA.* Although occlusion may be an effective treatment of these lesions catastrophic consequences may ensue when this is inappropriate, is unplanned, or it has been established that occlusion will not be tolerated. Emergency revascularization is possible and may prevent catastrophic stroke if performed early enough (see section on stroke). Because of the likely preloading with clopidogrel and aspirin, surgical revascularization with high flow bypass is less desirable than an endovascular solution. As for endovascular treatments, time is of the element and if revascularization cannot be achieved within 6 hours of the occlusion, attempted revascularization may do more harm than good.
4. *Remote haemorrhage.* Documented distal haemorrhage has been reported following flow diverter stent deployment. The mechanism for this may be as a consequence of embolization or from alterations of the arterial wall stiffness with the consequent failure to dampen the arterial pressure wave in the circle of Willis.

For direct CCF managed by occlusion. Having established that the ICA can be sacrificed without a risk of haemodynamic-induced stroke, either from DSA evidence (e.g. retrograde flow in the ICA without neurologic deficit) or test balloon occlusion, sacrifice of the ICA at the point of ICA breach can be performed. However, consideration should be given to the following complications:

1. *Embolization.* Propagated thrombosis from the point of occlusion will be expected to progress to the next most significant branch point. This is normally the ophthalmic artery. However, if there is insufficient flow induced shear stress in the distal ICA arising as a result of the continued supply of the ophthalmic artery, thrombus propagation may cross the ophthalmic artery and progress. This process may continue to incorporate clinically important arteries, together with the ophthalmic artery, including the anterior choroidal artery and the terminal ICA. At a point where collateral flow to the ICA supply enters the ICA (i.e. the posterior communicating artery) or the termination of the ICA (i.e. the anterior cerebral artery) and provides normal antegrade flow to the distal vasculature, the thrombus-flow interface may provide a source of embolus. The prevention of this requires the use of antiplatelet prophylaxis and the maintenance of, at least, normal blood pressure. Embolization, if small, may be managed

by anticoagulation but if large is not easily treated by clot retrieval in the presence of the proximal occlusion. In experienced hands, and if time to procedure is short, catheter access to the site of embolization by the anterior communicating artery or posterior communicating artery (without compromising the collateral flow for significant periods of time) may allow clot lysis.

2. *Recanalization of the fistula.* Incomplete occlusion or recanalization should be suspected with recurrence or failure to improve visual symptoms. A CT scan showing a continued enlargement of the superior ophthalmic artery may confirm this suspicion. A DSA to confirm and plan management is necessary when recanalization is suspected.
3. *Haemodynamic ischaemia.* Although the test balloon occlusion is reliable, it is possible that it may have been interpreted inaccurately (due to technical issues or clinical threshold error of what is deemed to be a failure) and the patient does not tolerate subsequent occlusion. Removal of the occluding agent may be inadvisable because of thrombus embolization if reversal of the occlusion is attempted after more than a short period of time. Haemodynamically induced ischaemia should be recognized quickly with blood pressure elevation commenced as an emergency. If this fails to rapidly reverse the ischaemia, induced barbiturate coma (with normal to high blood pressure maintained at all times) and revascularization with superficial temporal to middle cerebral artery bypass should immediately follow. High flow bypass in this scenario is potentially dangerous due to the time required to revascularize and the potential for hyperaemia and haemorrhagic conversion of stroke in this clinical scenario (Sia et al., 2011).
4. *Late aneurysm formation* following occlusion without flow replacement bypass. ICA occlusion can be associated with contralateral ICA, ipsilateral PCA (posterior communicating and anterior communicating) artery aneurysm development from increase shear stress (Roski et al., 1981). This important complication, though uncommon, deserves long-term surveillance for those treated by occlusion without bypass.

For direct CCF managed with bypass, there is a considerable difference in the complexity of surgery between superficial temporal to middle cerebral artery bypass and high flow bypass (with radial or saphenous vein as a conduit between the extracranial circulation and either the ICA or MCA). The complication rate for high flow bypass is 5 to 13% compared with 0.5 to 5% for superficial temporal to middle cerebral artery bypass (Sia et al., 2011). Managing these complications is very complex and normally involves rapid recognition and urgent surgical revision and for this reason treatment should be in a centre with considerable expertise in cerebrovascular surgery.

Outcomes

Indirect CCF outcomes

Clinical assessment of the eye, in most cases is an accurate way of evaluating arteriovenous fistula ablation. The exception is when the eye improves but fistula persists with retrograde cortical venous drainage or petrosal drainage and, the reverse, where the eye remains injected because of concomitant inferior ophthalmic vein obstruction. However, collateral venous capacity generally improves with time with a gradual subsequent improvement in eye problems. Most patients rapidly improve and recurrence is uncommon.

Direct CCF outcomes

Direct CCF have a number of outcomes to consider. These include the eye, the local arterial site, the distal ICA supply, the direct or indirect contralateral arterial systems and concomitant structural damage when trauma or infection is involved (including cranial nerve and potential for CSF leak). When the ICA is preserved, healing of the artery needs to be followed and seen to have occurred. For trauma or any pseudoaneurysm, it is difficult to predict the chance of healthy healed artery. There is less concern with regards healing of the local site when direct CCF are treated by occlusion, but there are greater concerns with regards potential for distal ischaemia. There is a small risk of aneurysm formation in the posterior communicating artery or anterior communicating artery due to increased flow and sheer stress. A consideration for both direct and indirect CCF elimination is that the eye symptoms and signs may commence to improve quickly but then fail to continue to resolve. This can sometimes be explained by the development of cavernous sinus thrombosis. It can take some time for the venous insufficiency from cavernous sinus thrombosis to resolve and for the eye to recover.

Patients with direct CCF treated with ICA occlusion and bypass have, in addition to eye outcomes, outcomes related to their bypass. The most common reason for adverse outcome for the high flow bypass is acute occlusion of the bypass (occurring in approximately 7% of cases). That this would be responsible for significant morbidity is not surprising, given that these cases have either failed a test balloon occlusion, or there was clinical or radiological evidence that identified an inability to tolerate ICA occlusion. Patency of superficial temporal to middle cerebral artery bypass in experienced hands is expected to be 98% (Sia et al., 2011). Having survived the first week, the long-term patency is excellent for both high flow bypass and superficial temporal bypass and these patency's are similar (Sia et al., 2011).

Carotid artery disease and cerebral ischaemia

Kieron Sweeney, A. O'Hare, and Mohsen Javadpour

Introduction

Due to the high incidence carotid artery disease and cerebral ischaemia, accurate and timely diagnosis and treatment is required to reduce the significant morbidity and mortality associated with these conditions. Here, we discuss the epidemiology, pathophysiology, clinical presentation, investigation, and treatment of these conditions. We also discuss the current evidence for medical, interventional, and surgical treatment options.

Cerebral ischaemia and stroke/infarction

Aetiology

Cerebral ischaemia and stroke can occur due to a heterogeneous number of pathological processes. These pathological processes can affect either large or small vessels and can be broadly classified into thrombotic, embolic, or occlusive causes. The most common cause of thrombotic ischaemic is due to atherosclerosis (discussed next). The most common cause of embolic ischaemia is cardiogenic due to atrial fibrillation followed by extracranial atherosclerosis of the aorta or carotids. Both of these causes can affect both the large and small vessels. Occlusive diseases such as fibrinoid necrosis or lipohyalinosis principally affected the small vessels leading to lacunar strokes or white matter disease due to thickening of the tunica media. Lacunar strokes are also due to atheroma plaques on the parent vessel occluding the origins of the penetrating small vessels.

All these processes share common risk factors. Common non-modifiable risk factors include age, sex, race, family history, and genetics. Common modifiable risk factors include, hypertension, smoking, diabetes, dyslipidaemia, and diet.

Rare causes of thrombotic stroke include cerebral venous sinus thrombosis (Ferro and Canhao, 2014) or hypercoagulopathic states (inherited and acquired), traumatic occlusion due dissection of vessels or traumatic space occupying lesions leading to mass effect and therefore subfalcine herniation which may lead to anterior cerebral artery (ACA) infarction or transtentorial herniation causing posterior cerebral artery (PCA) infarction, vasogenic occlusive causes such as migraine or vasospasm, inflammatory vasculitides, and other occlusive disease processes such as the delayed effects of radiation, Moya fibromuscular dysplasia, cerebral amyloid angiopathy, and CADASIL (Caplan, 2015).

Incidence

Ischaemic stroke accounts for approximately 87% of all cerebrovascular accidents (CVA). Globally, there is wide variation in the incidence of ischaemic stroke as there is wide variation in risk factors such as age, smoking, and diet. The Global Burden of Disease working group have published their findings regarding ischaemic stroke. This systematic review compares reported incidence in various countries globally and stratifies them according to income (Bennett et al., 2014). From 1990 to 2010 there has been a reduction in the incidence of ischaemic stroke in high income countries while there has been persistently high incidence in low-to middle income countries. Western Europe had an incidence of 127.65/100 000 dropping to 102.39/100 000 in 2010. Sub-Saharan central Africa had an incidence of 136.36/100 000 in 1990, increasing to 166.69/100 000 in 2010. This has been attributed to rates of smoking and increasing life expectancy.

Pathophysiology of cerebral ischaemia and stroke

The brain is one of the most metabolically active organs in the human body. Comprising only 2% total body weight, it demands 15–20% of the cardiac output and 20% of total oxygen consumption. Unlike other organs the brain has limited energy reserves and relies exclusively on blood supply (Clarke and Sokoloff, 1999). The functional unit of the brain is the neuron. Neuronal metabolism is heavily dependent on aerobic mitochondrial metabolism expending large amounts of energy for the ion pump systems to maintain membrane potentials and participate in action potentials. The substrates for neuronal aerobic metabolism are glucose, lactate, and ketone bodies while the end-products of neuronal activity are extruded into the extracellular environment. These are K+ and glutamate, among others. Astrocytes act as metabolic sensors for the neuron (↑K+, ↑glutamate, ↓glucose, ↓lactate) which in turn is coupled to the microvascular endothelium allowing alteration of local blood flow related to local neuronal activity (regulation of cerebral blood flow (CBF) is discussed elsewhere). There are regional differences in metabolic demand with grey matter and cortex more metabolically

active than white matter tracts. On average CBF is approx. 50 ml/100 g of white matter 20 ml/100 g and 70 ml/100 g of grey matter.

Cerebral ischaemia is the reduction in blood flow and therefore oxygen and glucose to the cerebral tissues. Infarction is the irreversible death of cerebral tissue. When CBF drops to 30 ml/100 g/minute neurological symptoms can occur. Further drop in CBF to 15–20 ml/100 g/minute will lead to reversible injury or 'electrical failure'. This can only be tolerated for a few hours. CBF rates of 10–15 ml/100 g/minute cause irreversible neuronal damage. Within 2 minutes of this, ATP levels are depleted, and subsequent failure of the Na/K ATPase pump occurs. This prevents restoration of the normal membrane potential and the cell depolarizes with an influx of Ca. This depolarization spreads out leading to an ischaemic cascade with release of glutamate. Neuronal death is triggered by apoptosis.

The penumbra model of ischaemia is the most widely used model. This model consists of an irrigating artery or arteriole with a core of irreversibly damaged cerebral tissue (neurons, astrocytes/oligodendrocytes) around which there is an area of hypoperfused tissue that can be salvaged. The main factors that influence the volume of penumbral tissue salvaged is quality of collateral circulation and time to reperfusion (Jung et al., 2013). Collateral circulations include the circle of Willis, leptomeningeal connections between adjacent arterial territories, and anastomoses between the external carotid and internal carotid circulations.

Clinical presentation of vertebrobasilar and carotid insufficiency syndromes

Ischaemic stoke is defined as the abrupt onset of neurological symptoms producing a permanent deficit and can be classified according to aetiology and clinical symptoms (TOAST—Trial of Org 10172 in Acute Stroke Treatment) or vascular territory and presenting symptoms (OCSP—Oxford Community Stroke Project classification). The signs and symptoms of presentation correspond to the vascular territory affected.

Anterior circulation signs and symptoms

Anterior cerebral artery stroke symptoms

ACA territory infarcts are infrequent and account for only 1.3% of strokes (Arboix et al., 2009). The ACA is divided into three segments. A1 gives rise to the medial lenticulostriates and occasionally the recurrent artery of Heubner. Occlusion of the A1 segment tends to be less severe than distal occlusions due to cross flow via the anterior communicating artery and can result in any of the five lacunar stroke syndromes: pure motor, pure sensory, mixed motor-sensory, ataxic hemiparesis, and clumsy hand dysarthria. The distal segments supply the anterior corpus callosum, medial frontal, and parietal lobes, The A2 can sometimes give rise to the recurrent artery of Heubner. Therefore, an occlusion from A2 distally can result in a lacunar stroke syndrome, disconnection syndrome, urinary incontinence, hemiparesis affecting the contralateral lower limb, hemisensory loss affecting the contralateral lower limb, and apraxia.

Middle cerebral artery (MCA) stroke symptoms

MCA territory infarcts are by far the most common type of stroke. The MCA is divided into four segments and supplies the majority of the cerebral convexity cortex and subcortical white matter of the frontal, parietal, and temporal lobes, majority of the basal ganglia and anterior and posterior internal capsule. M1 gives rise to the lateral lenticulostriate vessels and occlusion of these can give result in a lacunar stroke syndrome (see earlier). M2 bifurcates into superior and inferior divisions. Occlusion of the inferior division results in a visual field loss such as a contralateral homonymous hemianopia or upper quadrantanopia. In the dominant hemisphere it results in a receptive dysphasia and in the non-dominant hemisphere it results in constructional apraxia. Occlusion of the superior division results in a contralateral hemiparesis with arm and face more affected than the leg, hemisensory loss, and expressive dysphasia in the dominant lobe and hemineglect in the non- dominant lobe. Occlusion of the superior M4 branches to the dominant inferior parietal lobe can result in Gerstmann syndrome, which is agraphia, acalculia, left-right confusion, and finger agnosia.

However, M1/stem occlusion can result in malignant MCA syndrome, in which the infarcted tissue swells over 2–5 days leading to progressive mass effect with subfalcine and uncal herniation. This results in compression of the mesencephalon and may compromise ACA and PCA territories which will further exacerbate the condition. Untreated, this condition has an 80% mortality rate. The role of decompressive craniectomy in this condition is discussed later.

Posterior circulation signs and symptoms

Posterior cerebral artery (PCA) stroke symptoms

PCA occlusion accounts for 5–10% of all ischaemic strokes. The PCA can be divided into four segments. P1: occlusion of the paramedian perforators give rise to thalamomescencephalic infarction characterized by hypersomnolence, cognitive deficits, and vertical oculomotor paresis. When there is a single dominant thalamic perforator, a rare variant, this artery is referred to as the artery of Percheron, occlusion of which leads to bilateral medial thalamic infarction. When the blood supply to the cerebral peduncles arises from perforators of the P1 segment, infarction results in hemiplegia or hemiparesis. P2: occlusion of the thalamogeniculate arteries causes severe contralateral hyperesthesia and ataxia. If the infarction causes hemisensory loss and hemi-body pain the syndrome is referred to as thalamic pain syndrome or Dejerine–Roussy syndrome. Infarction of the ventromedial midbrain involving the oculomotor fascicle and/or nucleus, along with cerebral peduncle (corticospinal and/or corticobulbar tracts) leading to ipsilateral oculomotor nerve and contralateral hemiparesis is referred to as Weber syndrome. When the infarction involves the midbrain dorsal tegmentum including the oculomotor nucleus, red nucleus, brachium conjunctivum, or decussation of the fibres of the superior cerebellar peduncle resulting in oculomotor palsy and contralateral cerebellar ataxia, it is known as Benedikts's syndrome. When the extent of the infraction within the midbrain tegmentum also involves the cerebral peduncle resulting in oculomotor, contralateral hemiparesis, and contralateral cerebellar ataxia, the stroke syndrome is Claude's syndrome. These syndromes may feature symptoms of Parkinson's disease due to involvement of the substantia nigra (Ruchalski and Hathout, 2012). Occlusion of the posterior choroidal arteries with involvement of the lateral geniculate body results in sectoranopia, a wedge, or sector-shaped visual field defect. P3 and P4 supply the occipital cortex (calcarine, cuneus), parietal lobe (percuneus), parts of the temporal lobe (uncus, anterior

fusiform gyrus, inferior temporal gyrus) and splenium of corpus callosum. Occlusion of these vessels can produce an array of visual symptoms from visual field loss such as homonymous hemianopia with or without macular sparing (collateral from MCA), visual agnosia, prosopagnosia, and alexia with or without agraphia. Anton (-Babinski) syndrome is visual anosognosia (cortical blindness with confabulation) where the patient denies that they are blind due to bilateral PCA infarcts. Balint syndrome involves optic ataxia, simultaneous and loss of voluntary but not reflexive eye moments due to bilateral parieto-occipital lobe infarction (Cereda and Carrera, 2012; Ruchalski and Hathout, 2012).

Vertebrobasilar stroke symptoms (rostral to caudal)

The rostral portion of the basilar artery gives rise to the P1s. Therefore, occlusion at this point leads to ischaemia in mesencephalon, thalamus, temporal, and occipital lobes and can give rise to a constellation of signs referred to as top of the Basilar syndrome. These include disturbances of consciousness, hypersomnia, and vertical gaze palsy, with quadriplegia being uncommon (Caplan, 1980).

The superior cerebellar artery (SCA) can be divided into four segments (prepontine, ambient, quadrigeminal, and cortical). Perforating branches from the proximal SCA supply the pons, mesencephalon, and inferior colliculus and therefore proximal occlusion can give rise to a combination of rostral brainstem, such as ipsilateral Horner's syndrome, contralateral pain, and temperature sensory loss and contralateral trochlear nerve palsy (superior lateral tegmentum of pons), and cerebellar signs such as ipsilateral limb dysmetria, dysarthria, and ataxia.

The anterior inferior cerebellar artery (AICA) arises from the middle to caudal third of the basilar artery and supplies the inferior lateral tegmentum of the pons (trigeminal, facial, vestibular, cochlear nuclei, and the spinothalamic tract), middle cerebellar peduncle, and flocculus. Occlusion can give rise to vertigo, vomiting, tinnitus, dysarthria, facial paralysis, hearing loss, Horner's syndrome, loss of pain, and temperature, ipsilateral conjugate gaze palsy (due to flocculus) and dysmetria. When all these symptoms and signs are found together, the syndrome is referred to as lateral pontine syndrome or Marie-Foix syndrome.

The basilar artery is formed by the union of the vertebral arteries and ends in the bifurcation of the P1s. It gives off median perforating pontine branches which supply medial basis pontis (corticospinal tracts); paramedian perforating pontine branches which supply medial pontine tegmentum (including the floor of the fourth ventricle, abducens nucleus, medial longitudinal fasciculus, and paramedian pontine reticular formation; short circumferential pontine branches which supply lateral basis pontis and tegmentum); and finally the long circumferential pontine branches which supply the most lateral part of the pontine base and tegmentum. The other branches of the basilar artery, SCA, and AICA are discussed earlier. Occlusion of the perforators can give rise to ataxic hemiparesis characterized by contralateral weakness and contralateral ataxia. Occlusion of paramedian and short circumferential branches can cause contralateral hemiparesis, ipsilateral facial weakness, and ipsilateral lateral gaze palsy. This is known as inferior medial pontine syndrome or Foville syndrome (Kataoka et al., 1997). If the face is spared the syndrome is referred to as the ventral pontine syndrome/Raymond syndrome. If the gaze palsy is due to abducens palsy, then it is called ventral pontine syndrome/Millard–Gubler syndrome. Locked-in syndrome results from bilateral damage to basis pontis and sparing of the tegmentum of the pons resulting in damage to the corticospinal and corticobulbar tracts with preservation of the supranuclear ocular motor pathways and the reticular formation leaving vertical eye movements, blinking, and consciousness intact.

The intracranial vertebral artery or V4 segment gives rise to two main groups of branches. The medial group comprise the anterior spinal artery (which supplies the medial medulla oblongata), and branches to the foramen caecum (which lies at the pontomedullary junction and supply as far back as tegmentum and the floor of the fourth ventricle). The lateral group comprise the posterior inferior cerebellar artery (PICA) and circumferential branches to the inferior cerebellar peduncle, lateral medulla, and the olivary structures (Akar et al., 1994). PICA is divided into four segments and supplies the lateral medulla, posteroinferior cerebellar hemisphere, and inferior vermis. Occlusion of the anterior spinal artery can result in contralateral hemiparesis, contralateral hemisensory loss, and ipsilateral hypoglossal weakness, also known as medial medullary syndrome or Dejerien syndrome. Occlusion of PICA can result in a constellation of signs and symptoms referable to the lateral medulla, which includes caudal trigeminal nucleus, vestibular nucleus, nucleus ambiguus, spinothalamic tracts, descending sympathetics) and cerebellum (restiform body). These include ipsilateral pain and temperature loss of the face, ataxia, nystagmus, vertigo, hoarseness, dysphagia, Horner's syndrome, and contralateral hemisensory loss. This is known as lateral medullary syndrome or Wallenberg syndrome.

Investigation of cerebral ischaemia and stroke

Evaluation of the acute stroke patient can be considered in two phases. The emergent evaluation consists of clinical scoring using a system such as NIHS scale (see **Table 51.1**) and imaging investigations. The imaging modality may be dictated by the treatment facilities available such as access to endovascular interventional therapies and rapid access to advanced imaging modalities. Non-emergent evaluation includes workup for the 'metabolic syndrome'.

The standard imaging modality is non-contrast CT (see **Fig. 51.1**). This is used as a screening tool to exclude ischaemic stroke mimics such as haemorrhagic strokes or space occupying lesions. Other information obtainable from a non-contrast CT is evidence of early ischaemia in the MCA territory allowing calculation of the Alberta Stroke Programme Early CT Score (ASPECTS) (see **Table 51.2**; **Fig. 51.2**), overt hypodensity and its volume, and the hyperdense artery sign. In centres with neurovascular intervention, CT angiography (CTA) can provide information regarding location of occlusion, quality of collateral supply, and stenosis of vessels (see **Figs. 51.3** and **51.4**). If the CTA incorporates the aortic arch and neck vessels, important information is obtained regarding aetiology of stroke and technical difficulty for intervention. CTA was used in four of the main endovascular trials, ESCAPE, MR CLEAN, EXTEND-IA, and SWIFT. CT perfusion provides information regarding the volume of infarct core via cerebral blood flow or cerebral blood volume, volume of penumbra rescuable via MTT or Tmax and ratio of penumbra to infarct via a mismatch ratio. MR imaging modalities such as MRA, DWI, and MR perfusion provide similar information to

Table 51.1 NIHS scale

Instructions	Scale definition
1a: Level of consciousness (LOC)	0 = Alert 1 = Not alert but rousable with minor stimulation 2 = Not alert; requires repeated painful stimulation 3 = Unresponsive
1b: LOC questions—two orientation questions	0 = Answers both correctly 1 = Answers one correctly 2 = Answers neither question correctly
1c: LOC commands—two-stage commands	0 = Performs both correctly 1 = Performs one correctly 2= Performs neither correctly
2: Best gaze	0 = Normal 1 = Partial gaze palsy 2 = Forced deviation
3: Visual	0 = Visual loss 1 = Partial hemianopia 2 = Complete hemianopia 3 = Bilateral hemianopia
4: Facial palsy	0 = Normal 1 = Minor paresis 2 = Major paresis 3 = Complete paralysis
5: Motor arm 5a: Left 5b: Right	0 = No drift 1 = Drift 2 = Some effort against gravity 3 = No effort against gravity 4 = No movement UN/X = untestable
6: Motor leg 6a: Left 6b: Right	0 = No drift 1 = Drift 2 = Some effort against gravity 3 = No effort against gravity 4 = No movement UN/X = untestable
7: Limb ataxia	0 = Absent 1 = Present in one limb 2 = Present in two limbs UN/X = untestable
8: Sensory	0 = Normal 1 = Mild-to-moderate loss 2 = Severe-to-total sensory loss
9: Best language	0 = No aphasia 1 = Mild-to-moderate aphasia 2 = Severe aphasia 3 = Mute global aphasia
10: Dysarthria	0 = Normal 1 = Mild-to-moderate dysarthria 2 = Severe dysarthria UN/X = Untestable
11: Extinction and inattention	0 = No abnormality 1= Visual, tactile, auditory, spatial, or personal inattention 2 = Profound hemi-inattention or extinction to more than one modality

CTA and CT perfusion. However, there are still considerable logistical issues regarding the use of MRI in acute stroke workup such as out of hours access, scan time, and monitoring of unstable patients (Menon et al., 2015; Na et al., 2015).

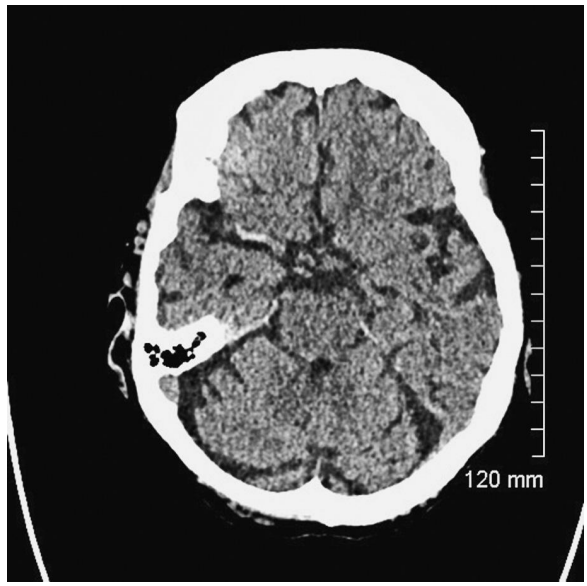

Fig. 51.1 Non-contrast CT brain demonstrating a right hyperdense middle cerebral artery (MCA).

Medical management of cerebral ischaemia and stroke

The goal of treatment is prompt restoration of blood supply by recanalization of the occluded vessel to rescue the penumbra and systemic measures to support perfusion of the penumbra, pending recanalization, by avoiding hypotension, hyperthermia, and strict glycaemic control. For effective treatment outcomes, correct and timely patient selection is imperative. In hypertensive patients who are candidates for reperfusion treatment lowering the systolic BP to less than 185 mmHg or diastolic BP to below 110 mmHg and after treatment maintain systolic BP below 180 mmHg or diastolic BP below 105 mmHg is essential using labetalol, nicardipine, or sodium nitroprusside (Jauch et al., 2013). After reperfusion therapy, patients should also undergo workup and treatment for aetiological factors.

Table 51.2 ASPECTS score for determining degree of severity of MCA infraction. Starting with an initial score of 10, one point is deducted for each structure or territory involved at two standard axial CT levels, ganglionic and supraganglionic. A score <=7 denotes a poor outcome

CT level	
Ganglionic level	Caudate, putamen, Internal capsule, insular cortex, M1 (frontal operculum/anterior MCA cortex), M2 (anterior temporal pole/cortex lateral to insular ribbon), M3 (posterior temporal pole/posterior MCA cortex
Supraganglionic level	M4 (anterior MCA territory immediately superior to M1), M5 (middle MCA territory immediately superior to M2), M6 (posterior MCA territory immediately superior to M3)

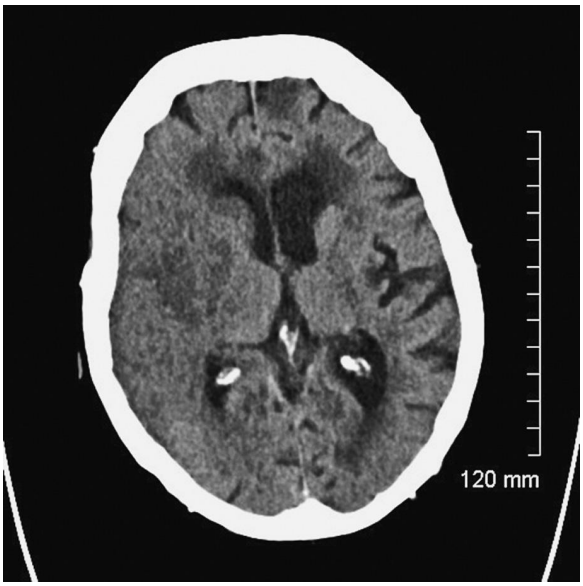

Fig. 51.2 Non-contrast CT brain at the ganglionic level demonstrating ASPECTs score of 7.

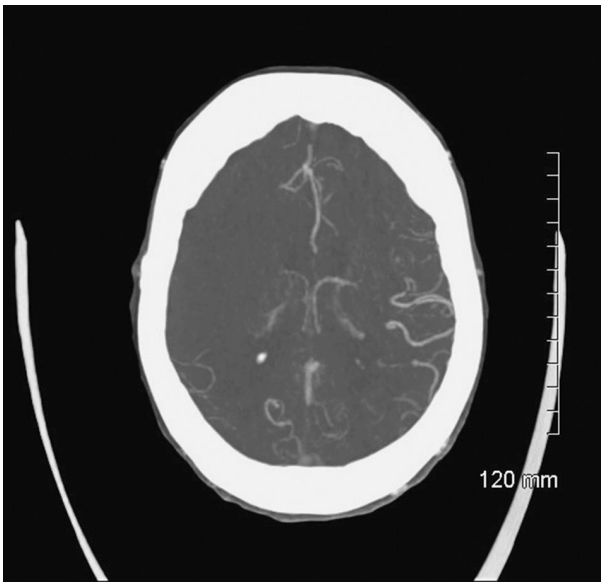

Fig. 51.4 CT angiogram of intracranial vessels demonstrating reduced and asymmetric distal filling in the right MCA territory.

Thrombolysis

The use of intravenous (IV) thrombolysis using recombinant tissue plasminogen activator (rt-PA) was established with the landmark paper published by NIND in 1995. This trial randomly assigned 600 patients into treatment and placebo groups. A single dose of rt-PA at 0.9 mg/kg (max 90 mg) was administered within three hours of symptom onset. The treatment group demonstrated improved outcomes in all outcome measures, NIHSS, Barthel index, GOS, and mRS, with acceptable increase in intracerebral haemorrhage. The recent ECASS-III trial has increased the time window to 4.5 hours (see Table 51.3 for inclusion and exclusion criteria for patient selection for IV rt-PA). This time window may be pushed out further with the use of perfusion imaging to select patients with salvageable penumbras beyond 4.5 hours (Burton et al., 2015). However, administering IV rt-PA outside the 4.5 h time window is associated with a higher SICH rate. Recanalization rates for IV rt-PA is reduced in large vessel occlusion such as internal carotid artery (ICA) and proximal MCA.

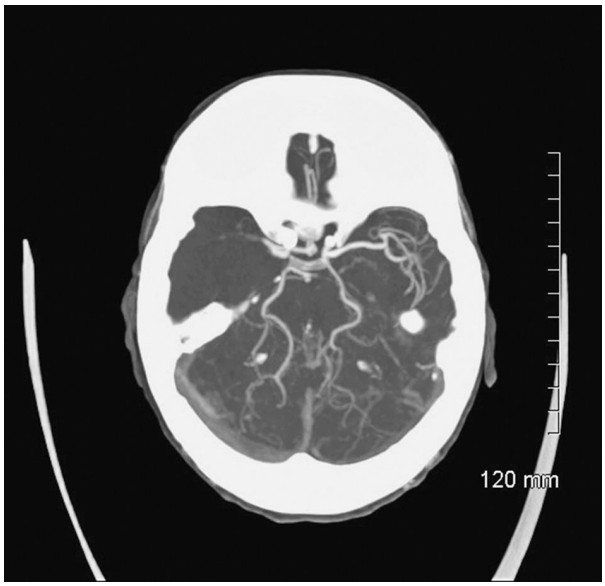

Fig. 51.3 CT angiogram on intracranial vessels (maximum intensity projection 5 mm) demonstrating a filling defect in the right MCA.

Operative and interventional management

Intra-arterial (IA) thrombolysis is a neurovascular interventional procedure where there is direct delivery of the thrombolytic agent to the site of occlusion. To date, only one trial has been published, the PROACT II trial. It established the efficacy of IA recombinant prourokinase up to 6 hours from symptom onset, despite increased SICH rates. This drug has not received Food and Drug Administration (FDA) approval and the results have been extrapolated to rt-PA.

Thrombectomy has been made possible with the development of various devices such as the coil retriever-MERCI and the stent retrievers such as TREVO® from Stryker and Solitaire FR™ from Covidien. Stent retrievers have been demonstrated to be superior to coil retrievers. Numerous recent randomized clinical trials have demonstrated improved outcomes of thrombectomy up to 6 hours from symptom onset against standard medical management with IV r-tPA. These randomized trials include MR CLEAN, ESCAPE, SWIFT PRIME, EXTEND-IA, REVASCT, and THRACE (Ding, 2015). All these trials demonstrated statistically significant improvement in mRS (0–2) at 90 days and were halted prematurely due to their efficacy in the treatment of large arterial occlusion against best medical management with and without IV r-tPA. Current recommendations are that thrombectomy, with a stent retriever, should be performed (up to 6 h) as an adjunct to thrombolysis (given within 4.5 h) for large artery occlusions. If thrombolysis is contra-indicated, then thrombectomy alone is recommended for large artery occlusion (see Fig. 51.5).

Table 51.3 Indications, relative contraindications, and absolute contraindications for r-tPA administration

Indications	Relative contraindications	Absolute contraindications
Age: >18 y	Major surgery or serious trauma within the past 14 days	Evidence of intracranial haemorrhage
Diagnosis of ischaemic cerebrovascular accidents CVA		History of intracranial haemorrhage
Time from onset 3–4.5 h	Blood glucose <2.7 mmol/litre or >22.2 mmol/litre	Intraspinal surgery, serious head trauma, or previous stroke within the past 3 months
	Platelet count <100 000	Clinical presentation suggestive of a subarachnoid haemorrhage, even with normal CT
	Coagulopathy: INR >1.7 aPTT> 40s	Active internal bleeding or acute trauma, such as a fracture
	Recent gastrointestinal (GI) or urogenital (GU) bleed within 3 weeks	Arterial puncture at a non-compressible site within the past 7 days
	Recent myocardial infarction (MI) within 3 months	Known atrioventricular malformation (AVM), neoplasm, or aneurysm
		Systolic BP > 185, diastolic >110 mmHg
		Seizure in acute setting
		Known AVM, tumour, or aneurysm

Data from Demaerschalk, B.M., et al., Scientific Rationale for the Inclusion and Exclusion Criteria for Intravenous Alteplase in Acute Ischemic Stroke: A Statement for Healthcare Professionals from the American Heart Association/American Stroke Association. *Stroke*, volume 47, Issue 2, pp. 581–641. 2016.

Patient's ineligible to receive thrombolytic and/or thrombectomy should receive antiplatelet therapy immediately. In these patients systolic BP exceeding 220 mmHg or diastolic BP more than 120 mmHg should be treated. Those patients that received reperfusion therapy should wait a minimum of 24 h and after a follow CT or MRI before antiplatelet therapy is commenced.

Decompressive craniectomy for stroke

Supratentorial

Malignant MCA syndrome (discussed earlier) accounts for 5–10% of all ischaemic strokes and can have up to 80% mortality. The natural history of malignant MCA stroke can follow one of three clinical courses (i) rapidly progressive deterioration within 96 hours; (ii) progressive deterioration over days; (iii) initially worsening course followed by a plateau then improvement. There are several reported predictors of the development of malignant MCA syndrome, NIHS score above 20 for dominant, 15 for non-dominant, elevated WBC, serum markers such as elevated serum S100B or MMP-9, early involvement (within 48 h) of more than 50% of the MCA territory on CT, more than 4 mm pineal shift, or 7.5 mm anteroseptal shift within 96 h, MRI DWI volume more than 80 cm^3 at 6 hours, or more than 145 cm^3 at 14 hours and symptoms of raised ICP such as nausea and vomiting (Staykov and Gupta, 2011; Wijdicks et al., 2014). To date there have been approximately seven RCTs published (Hatefi et al., 2014). Decompression for malignant MCA syndrome unequivocally reduces mortality. By reducing mortality, it not only increases the number of patients with good outcome (mRS 1–3) but also those with poor outcome (mRS >3). There remains controversy surrounding functional outcomes of the surviving patients. Functional outcomes in the majority of studies published to date used basic measures such as mRS. This neglects patient-orientated factors such as neuropsychological outcomes, quality of life, and financial burden. The decision to proceed with decompression should remain a multidisciplinary team decision made jointly with the patient's family.

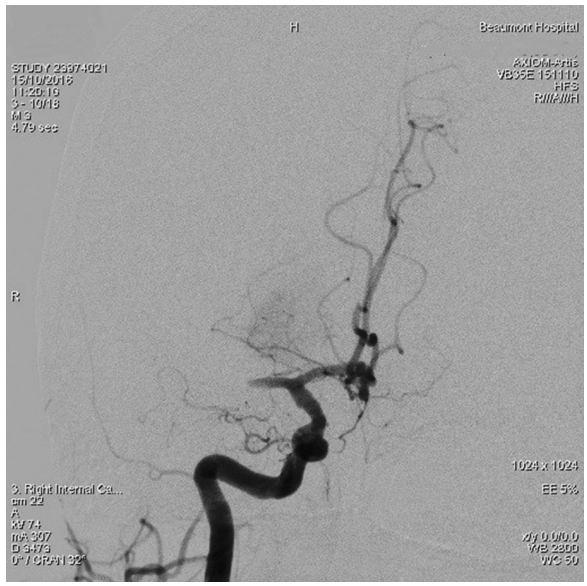

Fig. 51.5 Digital subtraction angiogram with a right internal carotid injection demonstrating a filling defect in the right MCA.

Procedure

This involves a standard question mark or T-incision. The frontotemporoparietal craniectomy should extend to a minimum 12 cm anteroposteriorly. In the coronal plane, the craniectomy should reach the mid-pupillary line superiorly, and should come down inferiorly to the floor of the anterior and middle cranial fossa, a minimum of 10 cm. The dura is opened widely and may be augmented with a graft.

Infratentorial

Unlike decompressive craniectomy for supratentorial stroke, there have been no RCTs for infratentorial decompression and current

recommendations are based on case series, observational, and retrospective studies. This is probably due to the fact that most published series have reported significant reduction in mortality with good functional outcomes. Signs and symptoms of posterior circulation stroke are discussed earlier. It is important, as ever, that a through neurological exam is performed on presentation to establish if the ischaemic territory involves the cerebellum only or brainstem and cerebellum. The mass effect from cytotoxic oedema of the infarcted cerebellum can efface the fourth ventricle, causing obstructive hydrocephalus and/or brainstem compression. This process can evolve over 1–7 days with peak at 72 hrs. The possibility of deterioration has been reported to range from 7% to 32% of cases. Current recommendations are that if a patient's deterioration is due to mass effect, then surgical intervention is appropriate. Two surgical strategies have been proposed (i) external ventricular drain (EVD) first and if patient fails to improve then suboccipital decompression; (ii) suboccipital decompression with preoperative right frontal EVD or intraoperative posterior parietal EVD. The EVD is usually set at 15–20 cm H_2O to prevent upward herniation. Published series of patients who were initially treated for clinical deterioration and radiological evidence of hydrocephalus with an EVD, demonstrate that between 20% and 30% went on to require a suboccipital craniectomy (Amar, 2012; Wijdicks et al., 2014).

Procedure

This involves a standard midline incision and exposure of the external occipital protuberance to C1, wide craniectomy with removal of the posterior arch of C1, and a Y-shaped durotomy with duroplasty. Some authors recommend resection of the infarct tissue.

Neuroprotective medical and anaesthetic strategies

These are similar to those of traumatic brain injury (TBI) protocols. See Chapter 41.

Transient ischaemic attacks (TIAs) and carotid endarterectomy

Preoperative

Atherosclerosis

Atherosclerosis is a chronic condition of the tunica intima of arteries. It is principally driven by three interdependent mechanisms; namely inflammation, oxidative stress, and dysfunction of the renin angiotensin system which leads to endothelial dysfunction. This in turn leads to subendothelial accumulation of lipids, fibronectin, and calcium, producing an atheromatous plaque, which causes gradual stenosis of the vessel. As the plaque progresses, the overlying endothelium may ulcerate, leading to activation of platelets and the clotting cascade with resultant thrombus formation. Depending on the calibre of the vessel and the degree of stenosis, this could result in occlusion at the site of the plaque or detach to cause thromboembolism distally (Tousoulis et al., 2011; Husain et al., 2015).

The risk factors associated with atherosclerosis are encompassed in metabolic syndrome or Syndrome X. There are various definitions of metabolic syndrome. However, they all share common processes such as (i) hyperglycaemia due to either insulin resistance, glucose intolerance, or type 2 diabetes; (ii) weight measurements such as increased BMI, central obesity, or race and gender waist measurements; (iii) dyslipidaemia with raised triglycerides and reduced high-density lipoproteins; and (IV) hypertension, defined as BP exceeding 140/90 (or 130/85 for the International Diabetes Federation). Other criteria include microalbuminaemia, disorders of uric acid metabolism, and serum markers of inflammation (ESR, CRP). Central to the definition is disorders of glucose regulation (van Rooy and Pretorius, 2015).

TIAs present as temporary neurological deficits that resolve fully without evidence of infarction. The signs and symptoms are discussed earlier for the various arterial territories and resolve due to collateral supply to the area of ischaemia. As most TIAs last less than 5 minutes, the patient may have recovered by the time they are reviewed. The patient may report symptoms of weakness in the arm, leg or face, unsteadiness, nausea, vertigo or dizziness, confusion, or amnesia (Markus et al., 2013). The 90-day risk of developing an ischaemic stroke after a TIA is approximately 17% with the majority occurring within 48 hrs making it imperative to diagnose and treat urgently (Giles and Rothwell, 2007; Gupta et al., 2014). The use of scoring systems such as $ABCD^2$ help predict the likelihood of subsequent stroke (see **Table 51.4**:>=4 high risk, =<3 low risk).

Investigation of TIAs usually begins with the non-contrast CT. This helps exclude TIA mimics. MRI with DWI with in 24 hrs helps establish that the presentation was due to ischaemia with 97% of diffusion restricted lesions corresponding to infarction (Souillard-Scemama et al., 2015). Vascular imaging should include the Aortic arch and neck vessels as well as the intracranial vessels assessing for evidence of atherosclerotic stenosis or occlusion. MRA, CTA, ultrasound (US), and catheter angiography all have high sensitivity and specificity in detecting carotid artery disease and estimating severity of stenosis. MRA may provide additional information regarding plaque characteristics which may predict future risk of events (Mono et al., 2012; Zhao et al., 2013). ECG and cardiac echo are used to assess for cardiogenic causes of emboli. The remaining investigations centre on the metabolic syndrome and include fasting glucose, glucose tolerance test, HbA1C, BP measurements, weight measurements, and lipid prolife.

Management depends on aetiology and modifying risk factors. If the source is cardiogenic due to atrial fibrillation (continuous or paroxysmal) the patient is commenced on long-term anticoagulation, otherwise the patient is commenced on antiplatelet therapy such as dipyridamole with aspirin. Target BP <=140/90 mmHg or 130/85 for diabetics. Dyslipidaemia is treated with a statin with goal low-density lipoprotein (LDL) less than 2.59 mmol/litre. Hyperglycaemia is treated with dietary modification or oral hypoglycaemic agents. Smoking cessation and exercise are encouraged. Current recommendations for carotid revascularization include symptomatic stenosis more than 50% or asymptomatic stenosis more than 70%. Whether to perform a carotid endarterectomy (CEA) or carotid angioplasty and stenting (CAS) depends factors such vascular and plaque anatomy as well as patient comorbidities.

Operative

Carotid endarterectomy

The evidence behind carotid endarterectomy is based on several well-designed international RCTs for both symptomatic

Table 51.4 ABCD[2]

Risk factor	Score
Age >= 60 y	 1
Blood pressure Systolic >=140 mmHg or diastolic >=90 mmHg	 1
Clinical features of TIA Unilateral weakness with or without speech impairment Speech impairment without unilateral weakness	 2 1
Duration TIA duration >= 60 minutes TIA duration 10–59 minutes	 2 1
Diabetes	1

Reprinted from *The Lancet*, Volume 366, Issue 9479, PM Rothwell, MF Giles, E Flossmann, CE Lovelock, JNE Redgrave, CP Warlow, Z Mehta, A simple score (ABCD) to identify individuals at high early risk of stroke after transient ischaemic attack, pp. 29–36, Copyright (2005), with permission from Elsevier.

and asymptomatic carotid artery disease. The North American Symptomatic Carotid Endarterectomy Trial (NASCET 1991 and 1998) and the European Carotid Surgery Trial (ECST 2003) enrolled 659 and 1807 patients, respectively. Not only did each trial established the efficacy of CEA over best medical management (antiplatelet therapy and risk factor reduction) in secondary prevention of ischaemic events, pooled analysis helped formulate current treatment recommendations. In symptomatic patients (TIA, amaurosis fugax, or non-disabling stroke) with above 70% stenosis of the ipsilateral carotid artery CEA should be performed within 2 weeks. In patients with 50–69% stenosis, CEA is only recommended in high volume centres with a complication rate less than 6%. For stenosis less than 50%, CEA is not recommended. In patients with ipsilateral stenosis more than 70% and near-total or a total occluded contralateral carotid artery, CEA on the ipsilateral side is still recommended, despite the higher risk of operative morbidity.

The Asymptomatic Carotid Artery Study (ACAS 1995) and the Asymptomatic Carotid Surgery Trial (2004) compared the efficacy of best medical management (antiplatelet therapy and risk factor reduction) to best medical management and CEA in asymptomatic patients with carotid artery disease. The benefit of CEA was less apparent and the degree of stenosis less influential. The numbers needed to treat in asymptomatic patients to achieve a 5-year risk reduction were significantly higher when compared to symptomatic patients and the influence of perioperative morbidity and mortality becomes more influential. Therefore, selection of asymptomatic patients for CEA should be based on the patient's comorbidities and complication rates of the centre (Brott et al., 2011).

Technique

The procedure can be performed under local (LA) or general (GA) anaesthesia (Link et al., 2014). An intravascular shunt can be used to maintain cerebral blood flow during the procedure. Alternatively, one of several methods (awake patient under LA, EEG, SSEP, TCD, or stump pressures), can be used for monitoring during carotid clamping, with selective shunting if there is an indication of hypoperfusion.

Position: Supine with ipsilateral shoulder roll with neck extended and head turned to contralateral side.

Incision: Curvilinear just behind the anterior border of sternocleidomastoid, extending from 1 cm below the mastoid tip to 1 cm below angle of mandible (avoiding the parotid) to 1 cm above the sternoclavicular joint.

Approach: Platysma is divided, exposing the cervical fascia, external jugular vein and the greater auricular nerve as it exits lateral border of sternocleidomastoid to supply sensation to the earlobe. The sternocleidomastoid muscle (SCM) is mobilized and retracted laterally to expose the carotid sheath which is then entered. The common facial vein serves as a landmark to the carotid bifurcation and is ligated. The vagus and hypoglossal nerves are identified and protected. Ansa cervicalis is also identified and may be sacrificed if necessary.

Endarterectomy: Intravenous heparin is administered. Careful exposure of the common carotid and ICA follows (see **Fig. 51.6**). The superior thyroid artery, ICA, and common carotid artery (CCA) are controlled in that order. A shunt should be used if there is ipsilateral change in the EEG, SSEP, or TCD. An arteriotomy is made in the mid-portion of the CC and continued cranially with Potts scissors. Normal tuncia intima is identified from CC to ICA. The plaque is dissected distally up the ICA from the intima with gentle dissection. The external carotid artery (ECA) is everted allowing dissection of the plaque. After removal of any loose debris the site is irrigated with heparinized saline. Any intimal flap is secured to the surgical bed with 7-0 prolene in an inside to outside fashion. The arteriotomy is closed either primarily or with a patch (either autologous vein, PTFE, or woven polyester) with 5-0 prolene. Antegrade and retrograde flushing manoeuvres are performed to remove debris before final sutures are placed. The ICA is back-bled to purge any remaining air or debris and then reclamped while the ICA and CCA are released to direct any debris up the ECA.

Closure: Patency of the vessels can be assessed with intraoperative doppler. A wound drain maybe placed. The wound is closed in layers.

Endovascular management of carotid disease

Endovascular options include CAS with embolic protection device. The Stenting and Angioplasty with Protection in Patients with High Risk for Endarterectomy (SAPHIRE) trial randomized high-risk symptomatic and asymptomatic patients into CEA and CAS groups. High risk patients were defined based on a combination of comorbidities and surgical anatomical factors and was defined as having one or more of the following: NYHA III or IV heart failure; COPD; more than 50% contralateral stenosis; contralateral recurrent laryngeal nerve palsy; prior carotid revascularization; previous radical neck surgery or radiotherapy; and prior carcinoma of the gall bladder (CAGB). In this study, there was better outcomes in asymptomatic patients with high surgical risk in the CAS group when compared to the CEA group. There has been no demonstration of superior efficacy of CAS over CEA in all other groups based on symptoms and risk (Ooi and Gonzalez, 2015). With improvement in endovascular techniques this may change.

Complication management

Postoperatively, blood pressure control is necessary to prevent hyperperfusion injury. Any new postoperative deficit requires emergent stroke workup to exclude ICA acute occlusion or embolic phenomenon. Lastly, the development of a neck haematoma is an emergency requiring prompt securing of the airway and evacuation

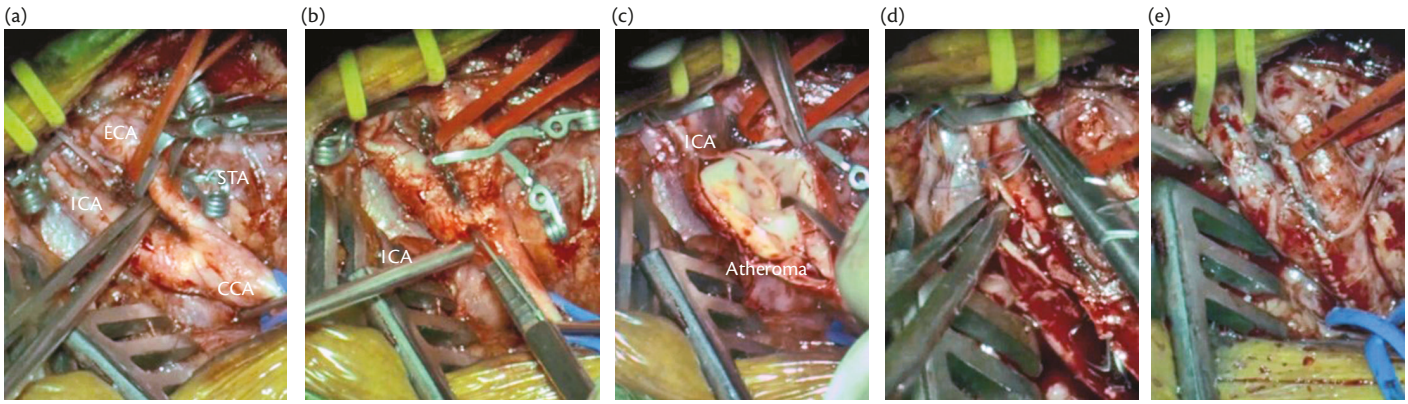

Fig. 51.6 Carotid endarterectomy. The intraoperative pictures illustrate the steps in a carotid endarterectomy. (A) The carotid bifurcation is widely exposed and slings are placed around the internal carotid artery (ICA), external carotid artery (ECA), and common carotid artery (CCA). Following the administration of intravenous heparin, vascular clips are placed on the ICA, CCA, ECA and the first ECA branch: superior thyroid artery (STA). (B) A knife is used to incise the midpoint of the ICA, over the carotid bulb into the CCA exposing the full extent of the atheromatous plaque. (C) A dissector is used to identify the plane between the atheromatous plaque and the vessel media. The atheroma is circumferentially dissected from the ICA and CCA, and a stump is followed into the ECA and amputated. Any intimal flaps (particularly distally into the ICA) are tacked down with a fine suture. (D) The vessel is closed with a continuous prolene suture from distal to proximal ensuring there is no kinking or narrowing of vessel calibre. (E) Unclamping of the STA can be used to back bleed into the endarterectomy site and exclude air before the final suture is tied. Vascular clamps are opened in a specific order in order to avoid embolic material from entering the intracranial circulation: ECA, CCA, ICA.

of the clot. Ear, nose, and throat (ENT) colleagues should be notified immediately in case endotracheal intubation fails and a tracheostomy is necessary.

Controversy

Decompressive hemicraniectomy for malignant MCA infarction

Decompression for malignant MCA infarction (MMCAI) unequivocally reduces mortality. By reducing mortality, it not only increases the number of patients with good outcome (mRS 1–3) but also those with poor outcome (mRS>3). We shall try to explore some of the controversy surrounding this topic with respect to age and functional outcomes.

Age and survival

It is well established that decompressive hemicraniectomy increases survival in patients younger than 60 years. Recently with DESTINY II, this trend has been confirmed in patients 61–80 years.

Age and functional outcome

Functional outcome appears to be on the most contentious issue surrounding DHC for MMCAI. Using a broad, non-specific metric such as the modified Rankin Scale, has led to significant criticism for two main reasons. Firstly, the mRS is a seven-point scale measuring motor function and the survivor's ability to look after their bodily needs. It neglects other factors such as neuropsychological, quality of life, burden on caregivers, and healthcare systems. Secondly, what constitutes a good or bad outcome using this scale. This is an important issue as all primary and secondary outcome measures dichotomize at this point. Studies demonstrating an increase in good outcomes from DHC have used a mRS of 0–4 as a good outcome and mRS 5–6 as poor outcome. If an MRS of 0–3 is used as a good outcome, then there appears to be no significant difference between treatment and control groups. This is due to the fact that there is an increase in survivors with major disability in the surgical group (mRS of 4) (Yang et al., 2015). mRS of 4 is defined as unable to attend to own bodily needs without assistance, and being unable to walk unassisted.

What is suggested by recent meta-analysis and RCTs is that there may be a direct relationship between age and survivors with major and severe disability—and that using chronological age alone, which neglects patient biological factors and comorbidities, may be as contentious as the mRS (Juttler et al., 2014).

Extracranial-intracranial bypass for cerebral ischaemia

Mathew R. Guilfoyle and Peter J. Kirkpatrick

Introduction

Symptomatic stenosis or occlusion of the cervical (C1) internal carotid artery (ICA) is best addressed surgically with direct endarterectomy or thrombectomy procedures. This strategy is not usually possible for more distal lesions, and restoring brain perfusion requires diversion of blood from the extracranial to intracranial circulation with a variety of indirect and direct bypass techniques. However, despite five decades of experience and technical refinement, extracranial-intracranial (EC-IC) bypass for cerebral ischaemia remains contentious and there are conflicting bodies of evidence and opinion regarding how best to select patients for surgery, and whether there is meaningful clinical benefit.

Types of EC-IC bypass

Direct bypass

In contrast to the high-flow bypasses that permit the ICA (or vertebral artery) to be sacrificed to exclude complex aneurysms or excise tumours, revascularization for ischaemia is intended to supplement rather than replace the native circulation. Flow rates of the order of 30–50 ml/min are sufficient to augment perfusion above ischaemic thresholds and into the autoregulatory range. By far the most common direct 'low-flow' EC-IC bypass involves anastomosis of either the posterior (parietal) or anterior (frontal) branch of the superficial temporal artery (STA) to a cortical (M3 or M4) branch of the ipsilateral middle cerebral artery (MCA). The surgical technique is described in detail later. Direct bypass to the posterior circulation using the STA or occipital artery in situations of vertebrobasilar insufficiency is possible, but very rarely indicated.

Indirect bypass

Several related techniques have been advanced that essentially facilitate collateralization of cerebral blood flow from the external carotid circulation. The ischaemic brain strongly expresses angiogenic growth factors (Lanfranconi et al., 2011) and the aim of indirect bypass is to remove physical barriers to encourage neovascularization that bridges the extracranial and intracranial circulations. These procedures are most common in children, or adults where donor and recipient vessels are too small to fashion a direct anastomosis.

Pial synangiosis involves dissecting several centimetres of one or both STA branches and then suturing the adventitial cuff of the artery to the pia, such that it is in direct contact with the cortical surface. Alternatively, the STA can be sutured to the free edges of the durotomy and laid over the brain surface (encephaloduroarteri osynangiosis, EDAS), or the richly vascular temporalis muscle can be dissected on its vascular pedicle and flapped on to the cortical surface (encephalomyosynangiosis, EMS); these options are often combined as an encephalomyoarteriosynangiosis (EMAS). To encourage collateralization of larger areas of cortex, including posterior and anterior cerebral territories, drilling multiple burr holes and opening of the dura can be a simple but effective procedure.

The maximal benefit of an indirect bypass may not be apparent for up to a year following surgery and therefore patients with a relatively acute presentation or progressive symptomatology are not suitable for solely indirect revascularization. A combined procedure fashioning a STA-MCA anastomosis together with some form of indirect bypass is advocated by many surgeons.

Indications and patient selection

In the majority of patients, stenosis or occlusion of the distal ICA, or its terminal divisions, is either a consequence of atherosclerosis or moyamoya disease (MMD); rarer aetiologies include chronic dissections, penetrating trauma, or iatrogenic injury.

Crucial to determining the need for EC-IC bypass is an understanding of the natural history of the underlying disease process and the estimated future risk of stroke. Irrespective of aetiology, truly asymptomatic patients in whom vascular changes are discovered incidentally have a low risk of ischaemic events and, as a general rule, prophylactic surgery is not indicated. This group of patients should have vascular risk factors addressed and be monitored for the development of symptoms, at which time intervention may become necessary. At the contrasting end of the spectrum, patients who present with large established strokes involving entire vascular territories, without significant remaining tissue at risk, are also not appropriate for revascularization.

Atherosclerotic steno-occlusive disease

Following the initial introduction of the STA-MCA bypass procedure by Yasargil in the late 1960s (Yasargil et al., 1970), the technique rapidly gained widespread popularity for the treatment of patients at high risk of stroke from severe atherosclerotic stenosis or occlusion of the ICA or MCA. Series of several hundreds of patients suggested the procedure was both durable and safe: five-year graft patency was reported to be more than 95% and the incidence of perioperative death or major disability under 5% (Chater, 1983; Sundt et al., 1985).

To rigorously address the question of whether revascularization reduced the risk of future stroke compared to medical treatment alone, the EC-IC Bypass Study Group undertook a multicentre randomized controlled trial involving 71 North American, European, and Japanese centres (Group, 1985). Eligible patients had occlusion or severe stenosis of the distal ICA or M1-MCA segment, with clinical evidence of a transient ischaemic attack (including amaurosis fugax) or minor stroke within the preceding three months. A total of 1377 patients were recruited, all received aspirin and aggressive hypertension control, and 663 were randomly allocated to receive a STA-MCA bypass. Methodologically the study was well conducted and the surgery was technically very successful with a high graft patency rate of around 96% achieved both at high and low volume units. The principal finding of the trial striking: there was significantly higher incidence of stroke in patients who received a bypass compared with those who had medical treatment alone. On average the excesses risk was estimated at 14%, although most of the events occurred early following surgery and the cumulative number of strokes at five-years following randomization was similar between the two groups. Multiple subgroup analyses failed to identify any patients with specific clinical features that fared better with revascularization. Although critics of the trial questioned the generalizability of the study to the wider population as large numbers of patients at participating centres were treated outside the study, the number of EC-IC bypass procedures sharply declined following its publication in 1985.

In response to the EC-IC bypass trial there was renewed focus on improving patient selection for surgery by quantifying cerebrovascular reserve and reactivity using techniques including single photon emission computed tomography, positron emission tomography (PET), magnetic resonance perfusion, Xenon CT, and contrast-enhanced CT perfusion (Schmiedek et al., 1994; Grubb et al., 1998a; Patel et al., 2010). In essence, all these modalities involve measuring basal cerebral perfusion and then repeated following a vasodilatory challenge such as hypercapnia or intravenous acetazolamide. In patients with a critical stenosis, the autoregulatory capacity of the distal vascular bed is already exhausted at baseline as vessels maximally dilate to expand cerebral blood volume, preserve flow, and maintain tissue oxygenation. In response to the vasodilatory challenge the relative blood flow decreases in the affected territory as it is either unable to vasodilate further, in contrast to the hyperaemia in surrounding regions, or the increased flow into the adjacent brain induces a 'steal' effect from the ischaemic territory and the blood flow and transit times deteriorate further (**Fig. 52.1**). Using PET, the oxygen extraction fraction (OEF) of the tissue can also be quantified and as this increases it implies increasingly severe steal effect and ischaemia. A loosely defined grading system has been proposed progressing from Grade I, in which there is loss of vasodilatory capacity but no significant steal, 'severe' Grade I and Grade II where there is significant steal effect and/or increased OEF, and Grade III where there is frank ischaemia that cannot be compensated by increased OEF (Grubb et al., 1998a).

Collective analysis of perfusion imaging studies suggested that for patients with evidence of significant steal effect in response to a vasodilatory challenge the annual risk of stroke is in the region of 10–20% (Grubb et al., 1998b; Garrett et al., 2009). Moreover, STA-MCA bypass measurably improved cerebrovascular reserve and reactivity, and reduced the risk of stroke by around two-thirds (Garrett et al., 2009).

These promising findings suggested a subgroup of patients who might benefit from revascularization could reliably be identified. The Carotid Occlusion Surgery Study (COSS) was a randomized controlled trial comparing STA-MCA bypass with best medical management alone in patients with atherosclerotic ICA occlusion, an ischaemic event within the preceding 120 days, and increased OEF in the ipsilateral hemisphere on PET imaging following acetazolamide (Powers et al., 2011). Of 194 patients randomized, 97 were allocated to receive a bypass and 93 ultimately had surgery. COSS was terminated early due to futility and the results closely correspond to those of the earlier EC-IC bypass trial, again demonstrating that despite excellent graft patency rates (>96%) there was significantly increased risk of ipsilateral stroke within 30 days in the surgical arm (14.4% vs. 2.0%); the cumulative stroke risk at two years postoperatively was no different between groups (21.0% vs. 22.7%) (Powers et al., 2011; Grubb et al., 2013).

The Japanese EC-IC Bypass Trial (JET) was a study with similar methodology to COSS randomizing 196 patients with steno-occlusive disease and impaired reactivity to best medical management with or without EC-IC bypass. At an interim analysis there was a suggestion of a marginally significant reduction in further strokes among the 98 patients who received a bypass, but the full outcomes and details of the trial have never been published (JET Study Group, 2002).

It is useful to note that a randomized trial of endovascular stenting for patients similar to those enrolled to the original EC-IC bypass trial (i.e. angiographic intracranial arterial stenosis with an ischaemic attack within the previous 120 days) also failed to show a benefit of the intervention over best medical therapy (Chimowitz et al., 2011). Among a total of 451 patients the 30-day risk of stroke was 14.7% in those who received a stent, compared with 5.8% without.

Collectively, these trials clearly indicate that the majority of patients with atherosclerotic intracranial arterial stenosis are best managed medically. Nonetheless, there exists a minority of patients who fail to develop adequate collaterals and continue to have transient ischaemic events, or remain symptomatic with disabling physical and cognitive deficits as a consequence of cerebral hypoperfusion, despite optimal medical therapy. This group of patients should be carefully assessed for potential EC-IC bypass to prevent further stroke and provide symptomatic relief.

Moyamoya disease

MMD patients presenting with ischaemic events have a risk of the order of 15–50% of further stroke within 12 months; the clinical course of patients presenting with haemorrhage is more aggressive still. For symptomatic MMD patients, current opinion thus favours surgical intervention to reduce the risk of further stroke or

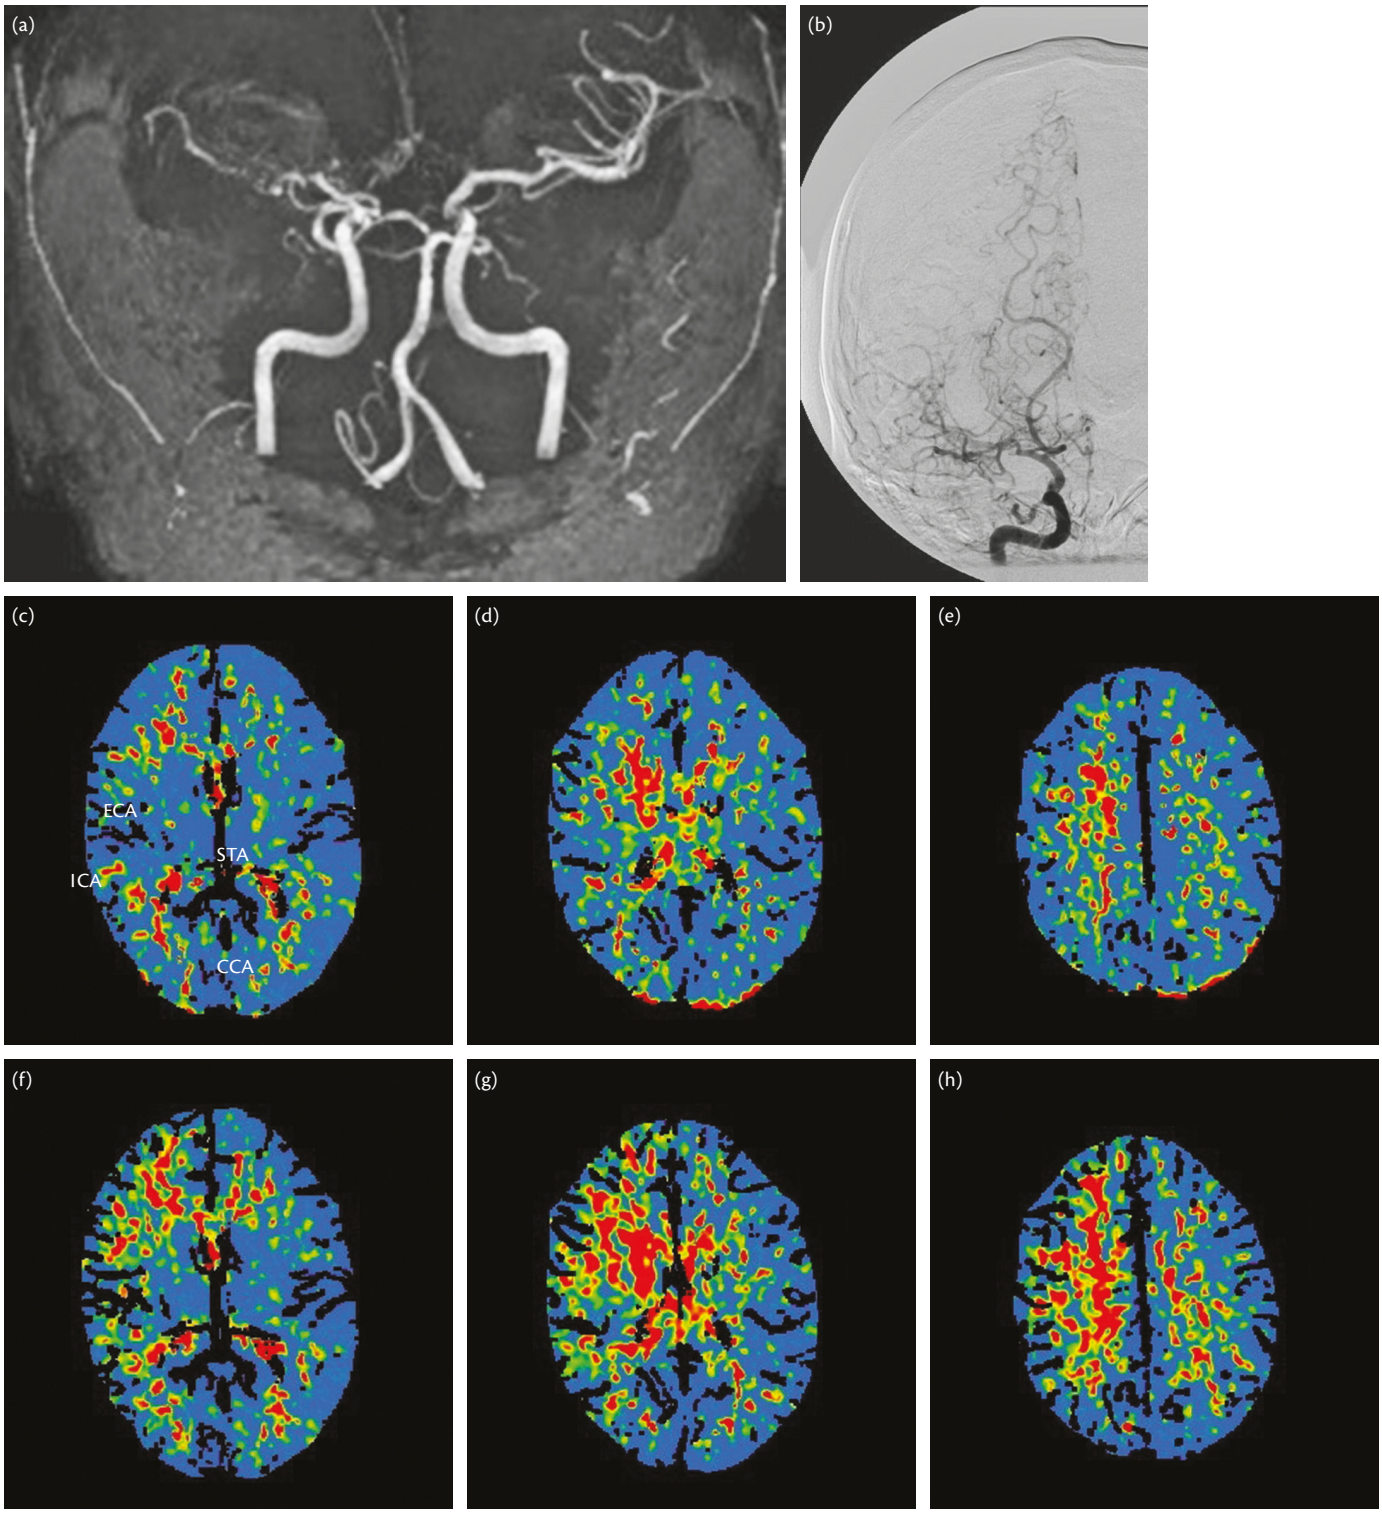

Fig. 52.1 Imaging of intracranial stenosis and cerebrovascular reserve. (A and B) Magnetic resonance angiogram and digital subtraction angiogram showing stenosis of the M1 segment of the right middle cerebral artery (arrow). (C–E) Baseline mean transit time (MTT) parameter maps of contrast-enhanced CT-perfusion imaging; minor degree of delayed perfusion within right MCA territory. (F–H) Corresponding MTT maps following administration of acetazolamide showing worsening delayed perfusion throughout the right MCA territory, indicative of exhausted cerebrovascular reserve and steal phenomenon.

haemorrhage. There are no randomized controlled trials comparing the effect of direct or indirect EC-IC bypass on further ischaemic events in MMD patients and the preferred revascularization technique remains unclear. Indirect bypass has been presumed to be the safer option but published case series suggest that the combined risk of ischaemic or haemorrhagic stroke is equivalent for both direct and indirect techniques at around 5.5%; perioperative mortality is under 1% (Kazumata et al., 2014). In contrast, the STA-MCA procedure

has superior results to indirect bypass in terms of angiographic outcomes, assessed as the extent of MCA territory that is revascularized, and is more effective at reducing the risk of recurrent stroke over the medium-term (3.5% vs. 11.2%) (Kazumata et al., 2014).

A recent small randomized controlled trial examined the efficacy of direct EC-IC bypass for the prevention of recurrent haemorrhagic events in MMD disease (Miyamoto et al., 2014). Eighty patients who had suffered a bleed within the preceding year were randomized to medical management or bilateral STA-MCA bypass. The annual risk of rebleed episodes was lower in the surgical arm (2.7% vs. 7.6%), in accordance with the findings of larger prospective observational series (Jiang et al., 2014; Miyamoto et al., 2014).

STA-MCA bypass technique

Preoperative workup

All patients should be thoroughly evaluated by a stroke physician or neurologist to confirm the diagnosis and ensure that medical management has been optimized. CT or MRI is required to establish the extent of established infarction, together with perfusion imaging sequences and acetazolamide challenge to confirm dynamic vascular steal. Catheter angiography is performed to localize the location of the stenosis/occlusion, or the grade the severity of MMD. Identifying concomitant aneurysms and other vascular malformations is imperative prior to any consideration of revascularization. It is mandatory to obtain selective external carotid injections, to assess both the degree of existing collateralization to the intracranial circulation and the patency and calibre of the STA; a minimum diameter of 1 mm is generally required. The suitability of donor and recipient arteries seen on the angiogram will influence whether a direct or indirect bypass is attempted, although the final decision is usually left until the vessels are directly inspected intraoperatively. Patients are in general recommended to continue their antiplatelet therapy perioperatively to reduce the risk of early graft occlusion.

Operative procedure

During induction of general anaesthesia there should be continuous intra-arterial monitoring to ensure a normal blood pressure is maintained; even mild hypotension may result in critical cerebral ischaemia in these vulnerable patients.

The patient is placed supine on the operating table with the head on a horseshoe head rest; a three-pin fixator can be used if preferred but is not obligatory. The course of the STA branches should be palpated or identified with a Doppler probe to plan the skin incision. A linear incision beginning in front of the tragus in the line of the main STA vessel can be used but our preference is for a Y-shaped incision with each limb following the approximate course of the STA and its terminal branches (Fig. 52.2A). It is imperative to avoid adrenaline infiltration of the planned incision as this will constrict the donor vessel; plain local anaesthetic should be carefully injected within the subcutaneous layer only.

The skin is incised and the subgaleal plane in which the STA courses is developed. The vessel is most superficial proximally at the zygoma, but it is usually preferable to identify a branch more distally in the first instance. Once the artery is identified it is dissected proximally, retaining a cuff of connective tissue, and dividing minor branches several millimetres from the vessel (Fig. 52.2B). The anterior or posterior division is chosen as the donor based on calibre and length of vessel available, and the other branch is then divided as distally as possible to allow the STA to be mobilized, retracted to one side, and protected. The intended donor vessel is maintained in continuity until the anastomosis is performed.

The temporalis is then incised and reflected, and a small craniotomy performed over the distal sylvian fissure. Under the operating microscope the cortical vessels are inspected and an appropriate recipient selected—generally the largest calibre vessel with fewest branches that affords sufficient length to allow temporary clips to be applied. The arachnoid is incised with a diamond knife and branches from the intended recipient vessel are coagulated and divided such that a segment of around 15 mm is prepared.

A contrasting piece of card is passed beneath the cortical vessel to facilitate suturing (Fig. 52.2C). Intravenous heparin (5000 IU) is administered and then the donor STA branch is divided. Good flow is confirmed and the artery is skeletonized for a few millimetres and its end and brought to the recipient vessel, ensuring it has been well mobilized to avoid tension. The STA is temporarily clipped and the anastomotic site is trapped with microclips on the recipient vessel (Fig. 52.2D). An arteriotomy is performed with the diamond knife, approximating the calibre of the STA. The end to side anastomosis is then fashioned with interrupted 10-0 nylon sutures, first inserting anchoring sutures at each corner of the arteriotomy and then completing both sides in turn with three to five sutures (**Fig. 52.2**E–H). Patency of the recipient vessel is confirmed periodically with a blunt probe. A continuous suture can be used but interrupted provides greater precision, is more easily revised if necessary, and it is better suited to adjusting for a degree of mismatch in calibre of the donor and recipient vessel.

Once the anastomosis is complete the temporary clips are sequentially removed from the cortical vessel and STA and the anastomosis is inspected. A small amount of bleeding is controlled with a haemostatic agent and gentle pressure, or if required an additional 10-0 suture can be placed. Patency and antegrade flow are confirmed with the Doppler probe and intraoperative indocyanine green angiography. A bolus of 200 ml 20% mannitol is administered to improve blood flow while the graft establishes and is monitored for 10–15 minutes prior to closure. If there is concern that either vessel or the anastomosis is occluded the unused STA branch can be employed as a vent to assess antegrade flow from the STA and retrograde flow from the cortical vessel.

The dura is approximated and the bone flap carefully replaced, ensuring the STA is not compressed as it passes over the edge of the craniotomy. Temporalis fascia, skin, and galea are closed in routine fashion.

Postoperative care

Close monitoring and control of fluid balance and blood pressure is recommended over the first 12–24 hours following surgery to avoid postoperative hypotension and ischaemia, and to try and minimize the risk of hyperaemia and brain swelling. Graft patency can be checked at regular intervals with Doppler ultrasound. Additional instructions should include strict avoidance of any pressure over the graft from, for example, elastic face masks.

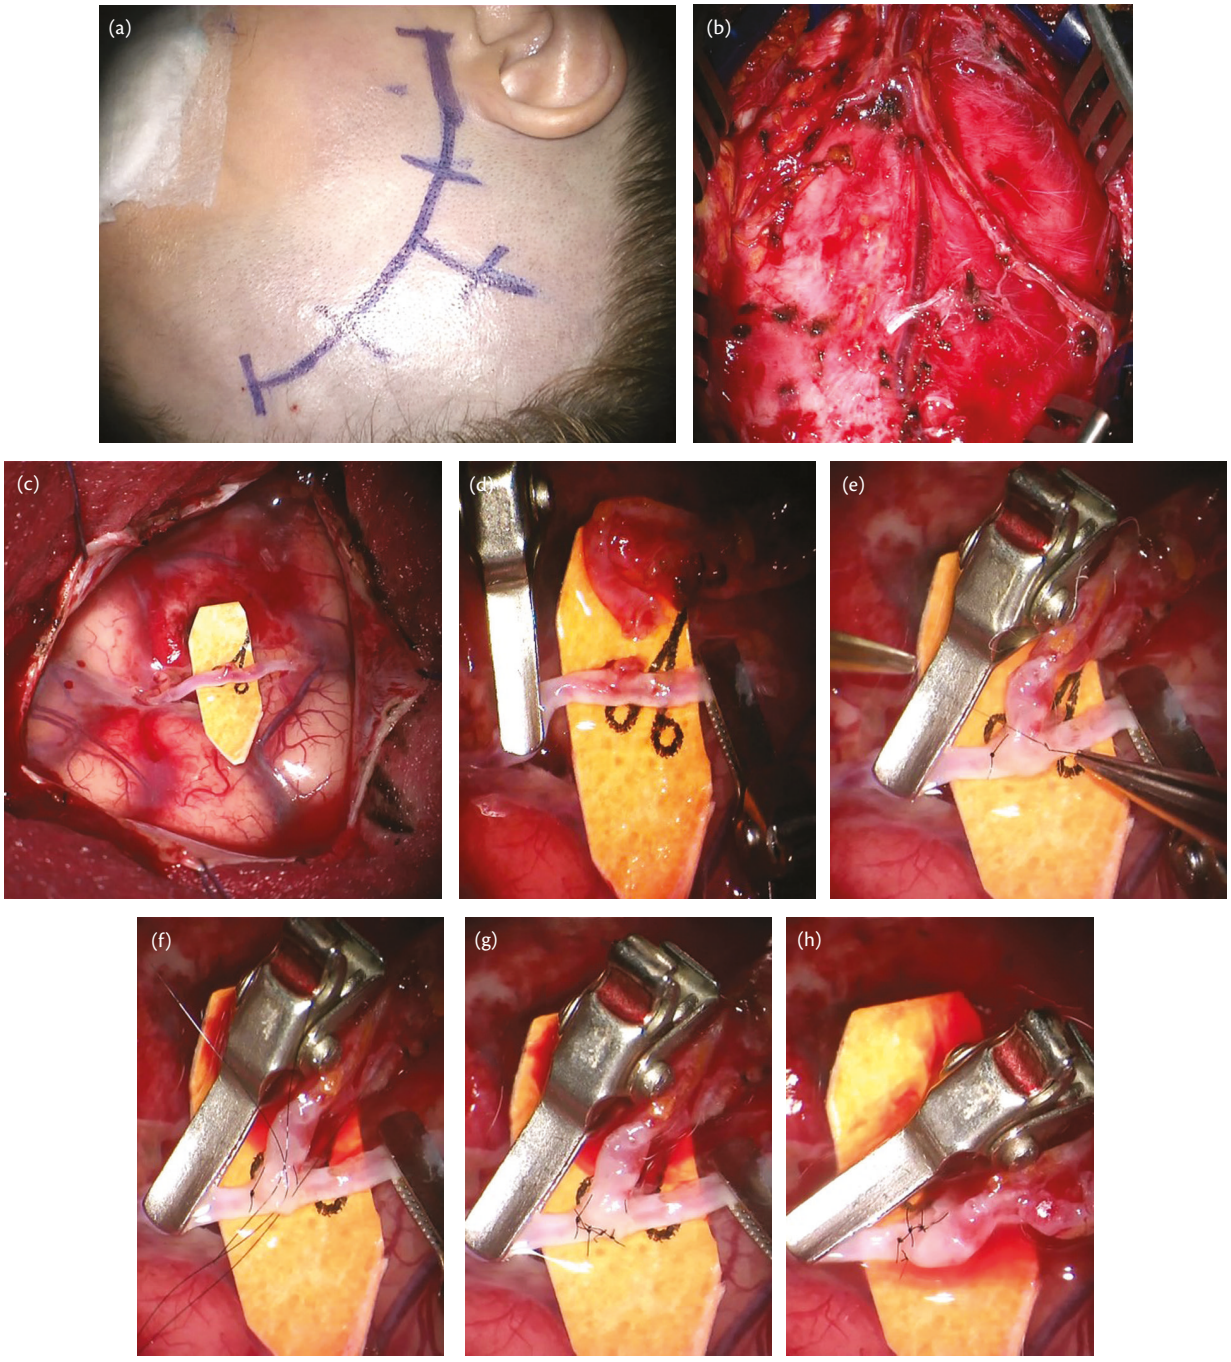

Fig. 52.2 STA-MCA anastomosis technique. (A) Skin incision along course of superficial temporal artery (STA). (B) STA branches dissected, posterior (parietal) division labelled. (C) Following craniotomy a recipient vessel is dissected and prepared. (D) Skeletonized end of STA brought alongside cortical artery and clips applied. Arteriotomy marked with dashed line. (E) Anchoring sutures at each end of the anastomosis with 10-0 nylon. (F–G) interrupted sutures placed along one side and then tied. (H) Same procedure repeated on the back wall of the anastomosis.

Conclusion

The majority of patients with atherosclerotic intracranial arterial stenosis are best managed medically but for selected patients with refractory symptoms, and demonstrable hypoperfusion on imaging, revascularization with a direct EC-IC bypass remains an important treatment option. For patients with symptomatic MMD, direct or indirect bypass effects a significant reduction in the risk of recurrent ischaemic attacks and haemorrhage. Surgery is not indicated for patients with asymptomatic stenosis due to atherosclerosis or MMD.

Giant aneurysms and bypass surgery

Mario Teo, Omar Choudhri, and Michael Lawton

Introduction

Giant intracranial aneurysms are defined as lesions with the largest diameter of 2.5 cm or more, according the Cooperative Study of Intracranial Aneurysms and Subarachnoid Haemorrhage, and constitute 2–5% of all cerebral aneurysms (Locksley, 1966; Sughrue et al., 2011). They remain among the most difficult cerebrovascular lesions to treat.

The natural history of giant aneurysms is universally poor. Drake reported a mortality of 68% at 2 years and 80% mortality at 5 years in his series of giant aneurysms treated conservatively (Drake, 1979). Therefore, a conservative strategy is not appropriate in the majority of cases, particularly in the younger age group. In older series, direct surgical clipping or clip reconstruction was favourable in up to 30% and 50% of patients with posterior and anterior circulation giant aneurysms, respectively. With improvement in skull base approaches, microsurgical techniques, and neuroanaesthesia, contemporary series showed that up to two third of giant aneurysms can be directly clipped or clip reconstructed (Darsaut et al., 2011; Sughrue et al., 2011). Furthermore, steady advances in endovascular techniques have allowed endovascular treatment of giant aneurysms, with or without adjunctive techniques such as stents or balloon assistance, and more recently with flow diversion devices.

Despite significant progress, currently the best data and reported outcomes for the safe and complete obliteration of giant aneurysms remain those from surgical series (**Table 53.1**, from Sughrue et al., 2011).

Pathology and pathophysiology

Saccular aneurysms are the most common subtype of giant aneurysm, with approximately 60–70% in the anterior circulation (in the cavernous, paraclinoid, and carotid bifurcation regions of the internal carotid artery (ICA), the proximal MCA portion, the anterior cerebral artery (ACA)/anterior communicating artery (ACoA), in decreasing frequency.) Posterior circulation aneurysms are located at the basilar apex, midbasilar artery, vertebral artery, vertebrobasilar junction, and rarely on the posterior inferior cerebellar artery (PICA) and anterior inferior cerebellar artery (AICA). Other types of giant aneurysms include fusiform or serpentine subtype, with dissection as the postulated aetiology, and infectious subtype. The rupture rate for fusiform aneurysms is believed to be low and their angiographic progression is unpredictable.

The pathological basis for intracranial aneurysm formation is poorly understood, and is covered elsewhere. After giant aneurysm formation, pulsatile and irregular blood flow within the aneurysm exerts force on the diseased wall, causing the aneurysmal sac to distend, thin out, and grow. Thrombus formation and remodelling of the luminal surface of the endothelium occurs in an attempt to repair the aneurysm. However, ongoing chronic, irregular, pulsatile flow impairs the healing process and results in disorganized collagen deposition, atherosclerotic degeneration of the wall, thrombus formation of varying ages, and dystrophic calcification. Consequently, giant aneurysms are dynamic lesions with cyclical cascades of thrombus formation and resolution.

Clinical presentation

Unlike small cerebral aneurysms, patients with giant aneurysms frequently (60–80%) present with thromboembolic events or symptoms related to neurovascular compression caused by mass effect, which is especially true of posterior circulation aneurysms that occupy the small volume of the posterior fossa. Aneurysmal rupture causing subarachnoid or intraparenchymal haemorrhage is a less likely presentation (20–30% of cases), with a worse outcome than mass effect (Hamburger et al., 1992). Rapid aneurysmal growth (frequently caused by acute thrombosis) can present with severe headaches resembling an acute bleed. Other presentations that occur more rarely include seizures (usually caused by MCA aneurysm) and hemiparesis.

Table 53.2 correlates the symptoms of mass effect with giant aneurysm location.

Investigations and pretreatment workup

Historically, plain skull radiography was used to diagnose giant aneurysms as they are calcified (20% of cases), and can remodel the skull base including the sella (Pia and Zierski, 1982). Computed tomography (CT) and CT angiography allowed for measurement of aneurysm size, parent vessel calibre, assessment of its relation with skull base anatomy, and visualization of thrombosed and calcified aneurysmal contents.

Table 53.2 Aneurysm location and symptoms caused by mass effect

Aneurysm location	Presenting mass-effect symptoms and signs
Anterior circulation	Visual deficits
Cavernous ICA	Retro-orbital headache
	Diplopia
	Facial sensory loss
	Hypopituitarism (occasional)
	Epistaxis (rarely)
Ophthalmic or paraclinoid ICA	Ipsilateral retro-orbital headache
	Decreased visual acuity
	Asymmetric visual field defects
Carotid bifurcation	Visual field defects (Homonymous hemianopia)
	Hemiparesis
	Seizures
	Hypopituitarism (rarely)
MCA	Seizures
	Hemiparesis
ACA-ACoA	Visual field defects (bitemporal hemianopia)
	Decreased visual acuity
	Hormonal changes (hypothalamic compression)
	Personality changes
Basilar trunk	Diplopia
Vertebrobasilar junction	Facial sensory loss
PICA	Speech, swallowing difficulty
	Lower cranial nerve deficit
	Gait instability
	Cerebellar symptoms
	Long tract signs

MRI on the other hand, visualizes the giant aneurysm and its relationship with brain parenchyma and associated perilesional oedema that can be caused by rapid aneurysmal growth or acute thrombosis. The characteristic onion-ring appearance of laminated, intervening layers of hemosiderin and methaemoglobin can also be appreciated within the thrombus of a giant aneurysm.

Six vessel digital subtraction angiography is the gold standard for obtaining anatomical information including parent vessel anatomy, aneurysm morphology, associated perforating vessels, feasibility of vessel occlusion, evaluation of bypass options, and both intracranial—intracranial and extracranial—intracranial collaterals. To assess for vascular reserve, balloon test occlusion (BTO), including Allcock's test (ipsilateral carotid compression during vertebral artery injection) and hypotensive challenge, can be incorporated as required. Hypotensive challenge consists of lowering mean arterial pressure with nitroprusside drip by 20 mmHg, or 25% of mean arterial pressure, whichever is greater.

Taking into account of all these informative radiological studies and including the patient's neurological condition, medical comorbidities, predicted treatment risks, local expertise, and preferences of the patient and family, the best treatment strategy can be made on an individual basis in conjunction with the multidisciplinary team, which includes endovascular surgeons, interventional neuroradiologists, and neurovascular neurologists.

Surgical strategies

For surgical patients not suitable for direct clipping of the aneurysm neck, it is necessary to use other techniques to exclude the aneurysm. A good strategy is to induce flow reversal by sacrificing the diseased vessel either proximal or distal to the aneurysm, while providing a bypass graft to revascularize the distal territory (**Figs. 53.1** and **53.2**). In general, high-flow bypass is used in patients who fail BTO, and low-flow bypass for patients who fail BTO after hypotensive challenge. *In situ* bypass strategies are used for aneurysms in specific locations without the need to redirect flow from the extracranial circulation. Such techniques have been reported in the paired ACA and PICA vessels, as well as the *in situ* temporal artery to M2 bypasses for treatment of giant aneurysms in the corresponding locations (Bederson and Spetzler, 1992; Sanai et al., 2009).

Procedures such as deep hypothermic circulatory arrest for clipping of giant basilar apex and MCA aneurysms are associated with high risk and have given way to safer alternative approaches such as adenosine arrest (transient AV blockade), rapid ventricular pacing and proximal occlusion with bypass (Sughrue et al., 2011). Both adenosine and rapid ventricular pacing cause transient hypotension that decreases the tension in the aneurysm allowing safe manipulation and clipping.

Extracranial-intracranial bypass surgery

Choosing the type of graft

In general, when major parent vessel occlusion is anticipated, 'low-flow' vessels (which typically provide flows of 25–30 ml/min) such as the superficial temporal artery (STA) or occipital artery (OA) are not sufficient to revascularize a whole hemisphere. In this situation, 'higher flow' vessels such as radial artery (50–150 ml/min) or saphenous vein (100–200 ml/min) are required. Apart from flow requirement, the graft selection also depends on graft availability, size of the recipient vessels, and the preference of the surgical team.

Radial artery grafts are prone to severe vasospasm, but this problem can be overcome by the judicious use of pressure distention and soaking in papaverine (Mohit et al., 2007). The advantages of the radial artery graft include less of a size mismatch between the graft and the recipient vessel, and therefore it is an easier anastomosis technically and causes less turbulent flow at the anastomotic site (Houkin et al., 1999; Mohit et al., 2007; Kocaeli et al., 2008).

Saphenous vein graft (SVG), on the other hand is easier to harvest, supports greater flow, and is not prone to significant spasm. However, the size mismatch and the fragile endothelium could cause a more challenging distal anastomosis. Reversal of the vein graft with disruption of the venous valvar system can mitigate against size mismatch however it risks thrombosis secondary to endothelial disruption.

Choice of donor vessel

Generally, in high-flow bypass, the external carotid artery (ECA) distal to the carotid bifurcation is the preferred donor vessel.

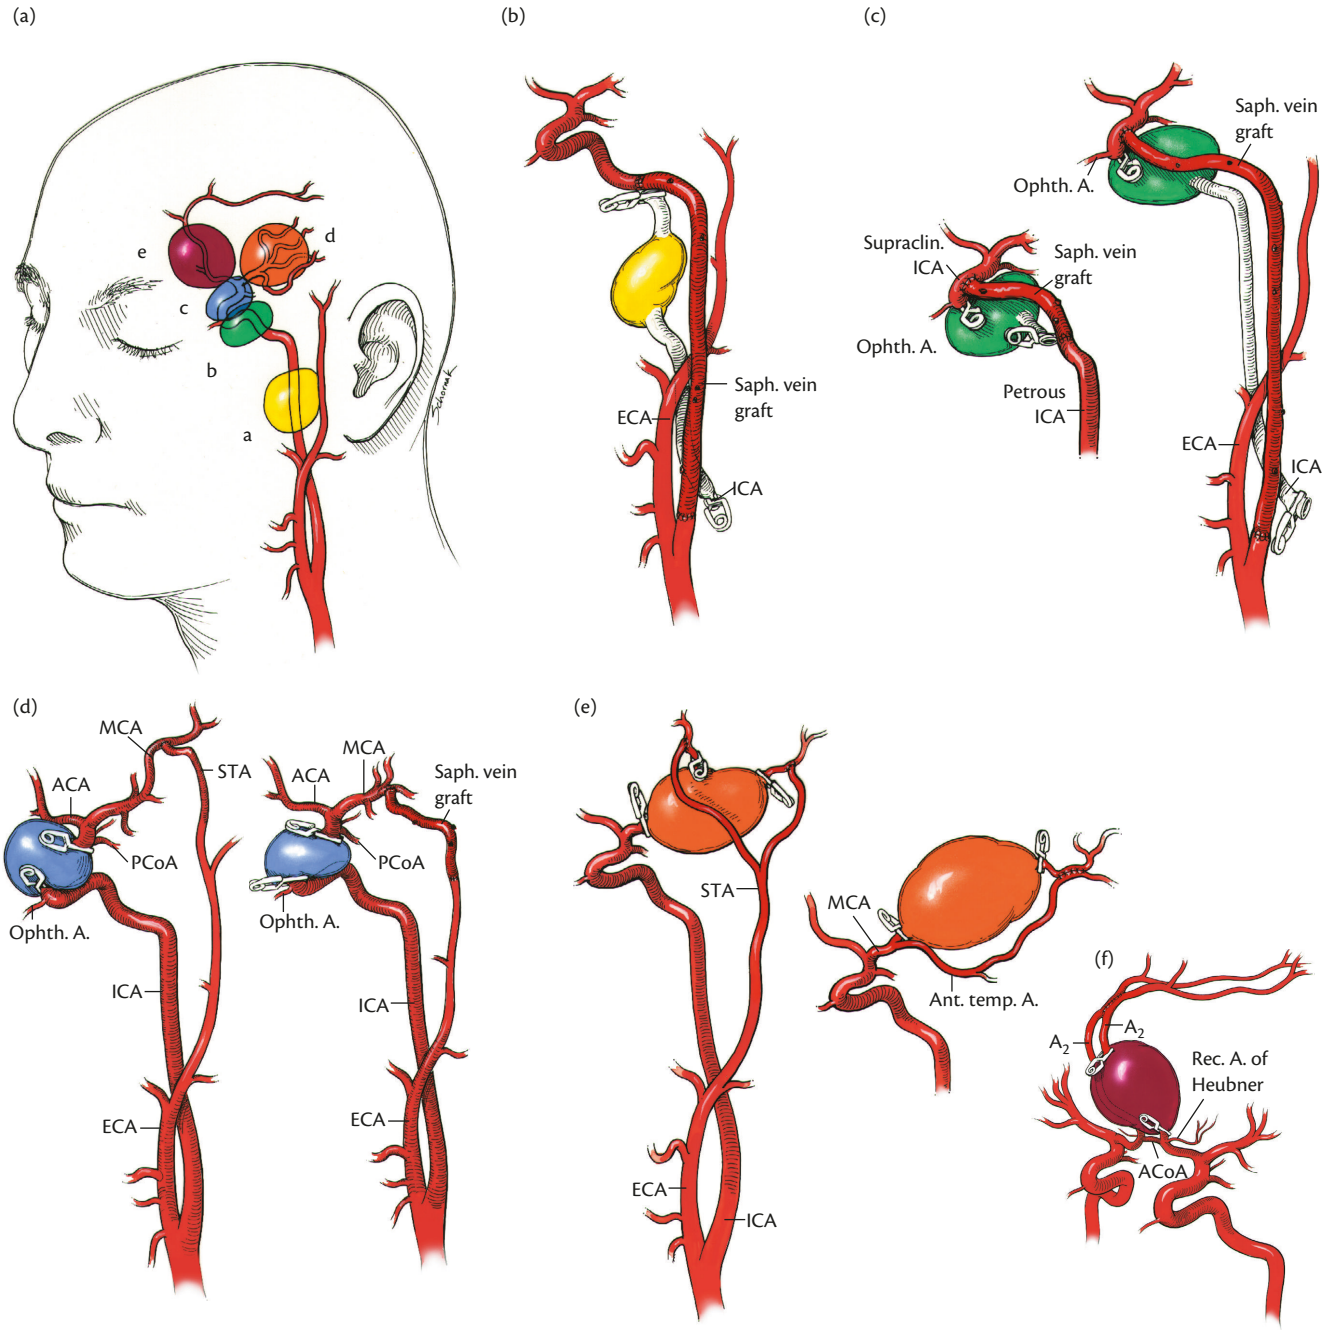

Fig. 53.1 (A) Schematic drawings of techniques for revascularization of the anterior circulation. (B) Internal carotid artery (ICA) aneurysms at the cranial base can be trapped and revascularized with a cervical-to-petrous carotid bypass using a saphenous vein graft. (C) Cavernous ICA aneurysms can be trapped with a petrous-to-supraclinoid (C3-C5) carotid bypass using a saphenous vein graft or, alternatively, a cervical-to-supraclinoid carotid bypass. (D) Supraclinoid ICA aneurysms can be trapped with a superficial temporal artery-to-middle cerebral artery (STA-MCA) bypass. An alternative strategy is to use an STA-MCA bypass with a saphenous vein interposition graft. (E) MCA aneurysms can be trapped and revascularized with a double-barrel STA-MCA bypass. Alternatively, an anterior temporal artery-to-MCA *in situ* bypass may be used for select aneurysms. (F) Anterior cerebral artery aneurysms can be trapped and revascularized with an A2-A2 *in situ* bypass. ACA, anterior cerebral artery; ACoA, anterior communicating artery; Ant. temp. A., anterior temporal artery; ECA, external carotid artery; MCA, middle cerebral artery; Ophth. A., ophthalmic artery; PCoA, posterior communicating artery; Rec. A. of Heubner, recurrent artery of Heubner; Saph., saphenous; supraclin., supraclinoid.

Avoiding the ICA is important because clamping the ICA during anastomosis can cause cerebral ischaemia, particularly in patients who have already failed BTO and therefore do not tolerate ICA occlusion. If the ECA cannot be used due to anatomical variations or inaccessibility, a common carotid artery anastomosis might be necessary that permits ECA-to-ICA collateral flow during the anastomosis.

In low-flow bypass, depending on the proximity of the recipient vessels, the choices include STA vessel (frontal or parietal branch), OA, and posterior auricular artery (PAA).

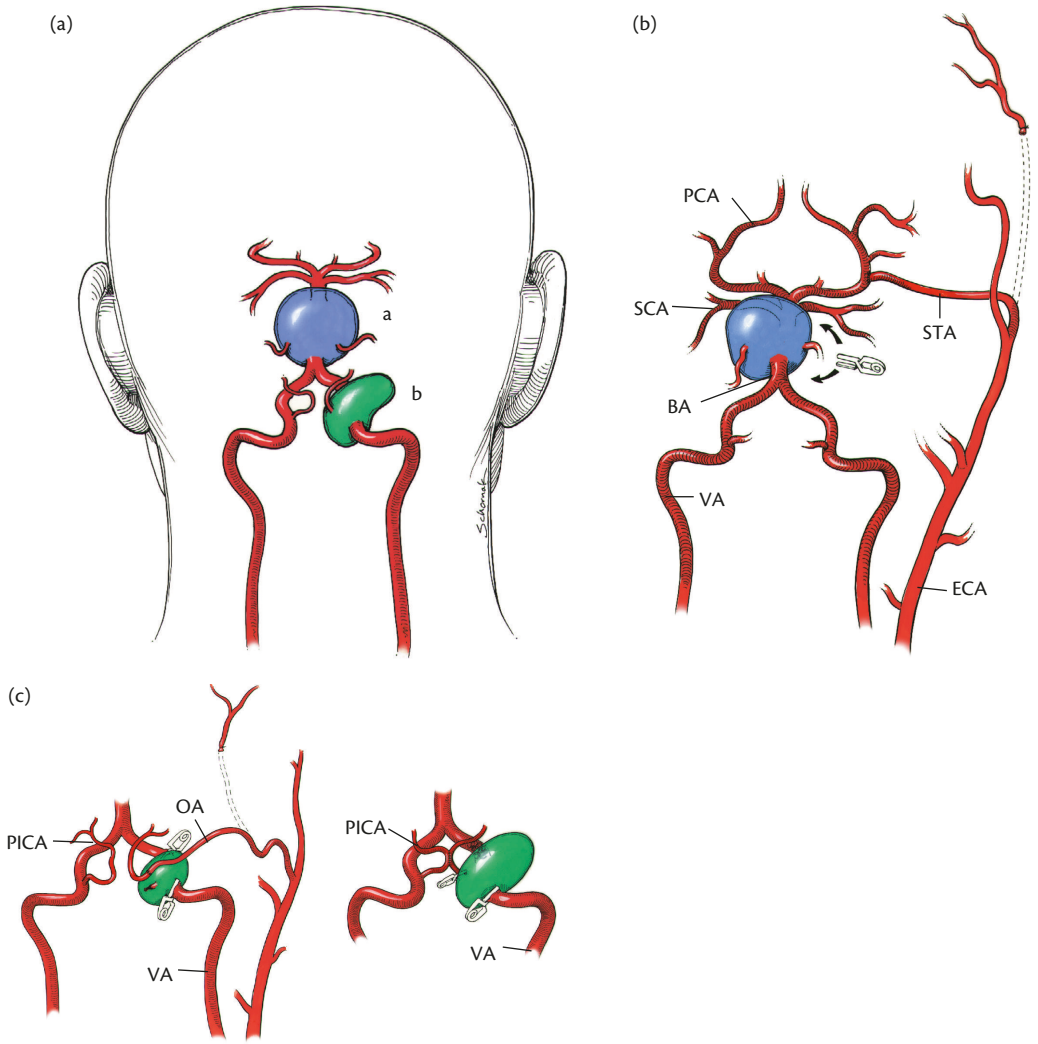

Fig. 53.2 (A) Schematic drawings of techniques for revascularization of the posterior circulation. (B) The midbasilar artery can be occluded proximally or distally to the aneurysm and revascularized with a superficial temporal artery (STA)-to-posterior cerebral artery (PCA) bypass or an STA-to-superior cerebellar artery (SCA) bypass. We prefer to occlude the basilar artery in the perforator-free zone below the SCAs. In select cases a double-barrel bypass using the STA as a donor to PCA and SCA may be used to revascularize the brainstem. (C) Vertebral artery aneurysms can be trapped by placing clips on the proximal vertebral artery and at the origin of the posterior inferior cerebellar artery (PICA). Endovascular coils can be placed distally in the vertebral artery. A PICA-PICA *in situ* bypass is used for revascularization of the distal territories. Alternatively, an occipital artery (OA)-to-PICA bypass can be performed. High-flow extracranial-intracranial bypass for the anterior circulation

The technical aspects of low-flow bypass are covered elsewhere, therefore we will concentrate on high-flow bypass in this section, and illustrate the surgical steps with a case example (Fig. 53.3).

The operation is performed under general anaesthesia with neuromonitoring, mild hypothermia (33–34°C), urinary catherization, central and arterial line (to ensure optimal fluid management).

The patient is supine, head fixed in Mayfield head holder, shoulder roll placed under the ipsilateral shoulder, and head rotated to the contralateral side to ensure the cranial operative field lies parallel to the floor.

Cranial exposure

A pterional craniotomy is fashioned after curved hairline incision with myocutaneous scalp flap, and flattening of the sphenoid wing. The dura is then tacked up and opened based on the sphenoid wing. Under microscopic guidance, the Sylvian fissure is split widely to identify an M2 branch of the MCA, as the M1 branch is generally avoided to minimize injury to lenticulostriate perforating arteries. The appropriately sized M2 segment is chosen as the recipient vessel, and the vessel dissected free of arachnoid adhesions. A piece of high-visibility background material is passed beneath the recipient vessel. We typically utilize suction microtubing under the background material to keep the field clear of irrigation and bleeding (Fig. 53.3A).

Cervical exposure

A transverse neck crease incision at the level of the hyoid bone is made to expose the carotid bifurcation. Alternatively, a longitudinal incision along the anterior border of sternocleidomastoid can be used, especially where the carotid bifurcation is difficult to expose. Medial to the sternocleidomastoid, the deep cervical fascia and carotid

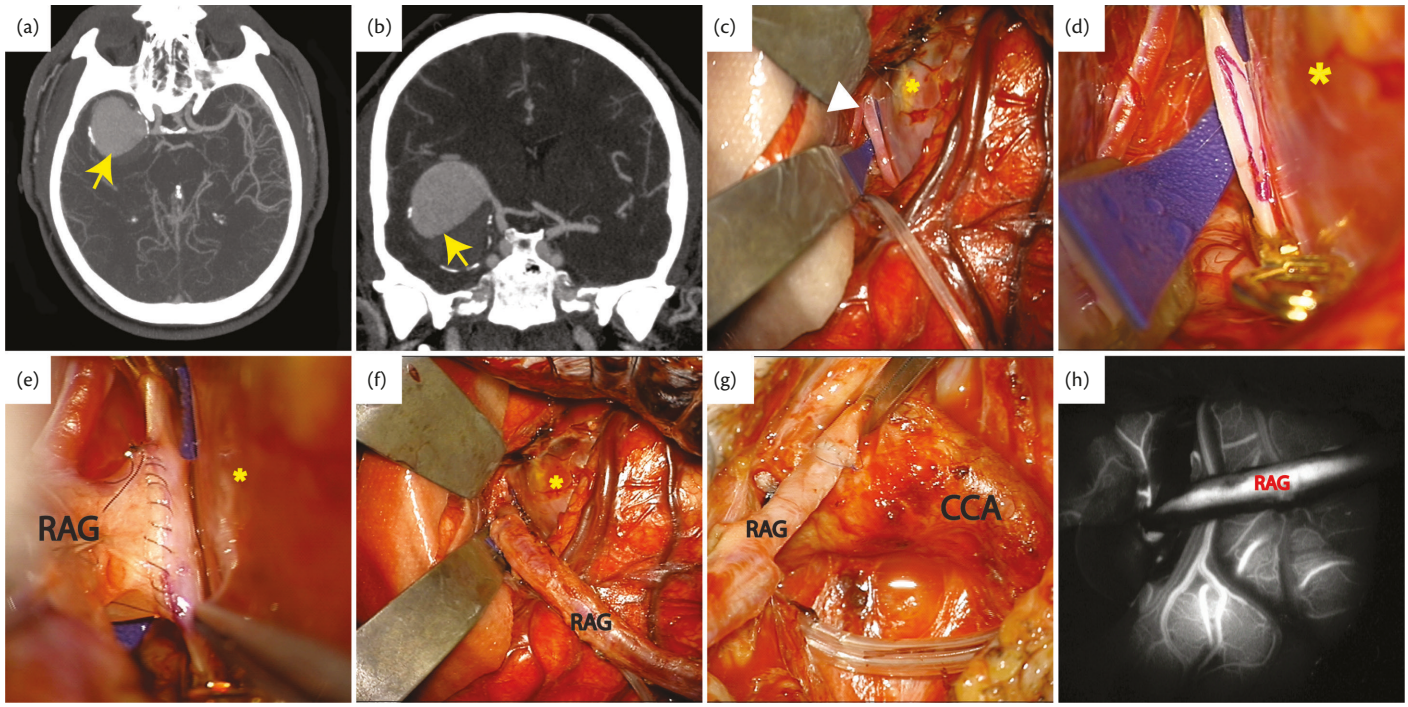

Fig. 53.3 Anterior circulation high-flow ECA-RAG-MCA bypass. A 36-year-old male presented with subarachnoid haemorrhage from a giant partially thrombosed right MCA aneurysm as seen on axial and coronal computed tomography angiography (CTA) reconstructions (yellow arrow in image A and B). (C) A right pterional craniotomy was completed followed by a trans-Sylvian approach to expose the M2 branch outflow vessel (white arrowhead) and the aneurysm dome (yellow asterisk). (D) Magnified right trans-Sylvian view showing the M2 branch arteriotomy being prepared as recipient vessel for radial artery graft (RAG). (E) Anastomosis suture line between RAG and M2 within the Sylvian fissure. (F) Trans-Sylvian dissection showing the RAG in relation to aneurysm dome (yellow asterisk). (G) Proximal anastomosis suture line in the neck between external carotid artery and RAG. Common carotid artery (CCA) is seen proximal to the bifurcation. (H) Intraoperative Indocyanine Green Angiography (ICG) following completion of bypass demonstrates filling of RAG and MCA territory. The aneurysm was subsequently trapped and dome thrombectomy completed.

sheath are opened to expose the carotid artery, and up to 2 cm of the ECA beyond the carotid bifurcation to prepare for an end to side anastomosis of donor graft to ECA. This allows for enough room to create the bypass after the application of temporary vascular clamps.

Donor graft harvest

In harvesting the SVG, we routinely check that the patient does not have varicosities or previous surgery that have compromised the saphenous vein. At the time of surgery, the vein is dissected from the ankle (medial malleolus) to the knee for 20–25 cm. Alternatively, the femoral artery is identified in the groin and the femoral vein is found medial to it, from which the saphenous vein is located. It can then be dissected distally towards the knee to harvest a long interposition graft. During the mobilization procedure all side branches are ligated or clipped, ensuring that this does not stenose or compromise the lumen. After the cranial and cervical sites are fully exposed, prepared, and haemostasis ensured, the SVG is ligated, divided, and flushed with heparinized saline. This serves to clear the lumen of blood clots and serves as a pressure test for the ligated side branches. The adventitia and connective tissue are cleaned for approximately 1–2 cm on either end of the SVG to facilitate for anastomosis. The valves in the graft are broken down by passing a series of disc dissectors, and the patency of SVG confirmed by heparinized saline flush in both directions. Alternatively, the direction of the graft can be reversed (ankle or knee end for proximal cervical anastomosis) to ensure that flow courses in the direction of the valves, which eliminates the need for valvulotomies that might damage the intimal lining and are thrombogenic.

Radial artery harvest

Radial artery graft (RAG) is an excellent option as an interposition graft given good size match with the donor and recipient vessels. While an endoscopic technique has been described, we prefer an open approach. An important prerequisite before proceeding to use a RAG, is to complete a modified Allen's test to assess ulnar collateral circulation in the hand. A curvilinear skin incision 1 cm proximal to wrist crease and 1 cm distal to elbow crease is used, centred over the radial pulse by palpation or hand-held Doppler. Brachioradialis and flexor carpi radialis muscles with their fascia form the space for the radial artery. The fascia is divided to expose the radial artery in loose areolar tissue. Once the fascial plane of the radial artery is entered, the dissection is carried proximal to distal. The artery is dissected as a pedicle along with its venae comitans. A sponge soaked in papaverine is laid over the segment of the radial artery (RA) not being addressed. The radial artery is harvested below the take off for the recurrent radial artery and proximal to the take off for the superficial palmer artery distally. The side branches encountered are managed with Weck clips and electrocautery and handling of the RA is minimized. The graft is marked with blue ink to indicate the proximal and distal ends. Once dissected the radial artery is ligated proximally and distally with a heavy silk tie and transected. The proximal radial artery is then flushed with heparinized solution (2500 U of heparin in 250 cc saline and 60 mg papaverine) using an olive tipped syringe cannula as a pressure test.

Pre- or postauricular tunnel

This should be created early on to allow subcutaneous ooze to settle, by passing a pair of Roberts forceps in the pre- or postauricular tunnel.

We routinely use a chest tube passed with a Kelly clamp from the craniotomy opening to the cervical opening. The graft is then passed through the chest tube to protect it from stretching or kinking. The chest tube conduit is then removed once the graft is passed. Enough subcutaneous dissection is required to avoid graft compression. The bypass graft is delivered after cranial anastomosis, but prior to temporary clip removal. The deflated graft is delivered with enough tension to ensure no redundant intracranial loop, and no graft kinking or twisting.

Anastomoses

Prior to applying the temporary clips to the MCA vessel, MAP is raised slightly to 90 mmHg (to optimize flow in the collateral circulation), hypothermia of 33–34°C is maintained, and propofol is titrated to achieve burst suppression. Arteriotomy is made in the recipient MCA (Fig. 53.3B), and the lumen is flushed with heparinized saline. The graft and recipient vessels are tinted with indigo-carmine or a sterile marking pen to better visualize the arteries during the microanastomosis. Monofilament sutures (10-0 or 9-0) are used to anchor the apices of the incision, heel stitch first, followed by the toe stitch. The side walls of the anastomosis are sutured in a continuous or an interrupted fashion, also using 10-0 monofilament sutures (Fig. 53.3C). We prefer a continuous technique to allow improved apposition and size match corrections.

Sutures should be passed from outside the donor to inside the recipient or outside the recipient to inside the donor, and then tied on the outer surface of the anastomosis. Great care must be taken not to catch the back wall of the vessel while suturing the anastomosis. The clamp time for the creation of microanastomosis should be as short as possible. Once the anastomosis is complete, the temporary clips on the recipient artery are released, with expected minor blood leakage around the anastomotic site.

Back bleeding of the graft is important to perfuse the graft endothelium to minimize the effects of ischaemia. After this, heparinized saline is introduced into the free end of the graft and irrigation provided while an aneurysm temporary clip is applied close to the MCA anastomosis site.

Following that, the ECA anastomosis is performed with continuous or interrupted (9-0 prolene) suture in an end to side fashion on the ECA (Fig. 53.3D). Artery slings can be used to present the ECA more favourably into the wound as the depth of the vessels increases the surgical challenge for anastomosis. After applying temporary clips on the proximal and distal ECA, an oval arteriotomy is created. The SVG is cut to size (to minimize excessive kinks and redundant loops), fish mouthed, and the anastomosis proceeds as described for the intracranial stage.

After completion of the bypass, the temporary clip on the distal graft is released to reconfirm back filling, followed by ECA clamps removed to establish anterograde flow in the graft. Adequacy of treatment and patency of parent vessels is analysed intraoperatively using intraoperative angiography, indocyanine green fluorescence videoangiography, Charbel Transonics flow probe, and/or Doppler flow measurements (Fig. 53.3E).

Closure and postoperative care

Multilayer wound closure of both cranial and neck wound proceeds with meticulous attention to haemostasis, and graft patency is monitored during bone flap replacement, temporalis opposition, and final skin closure. Postoperatively external bypass graft compressions from facemask elastic need to be avoided, and the patient managed in the ICU with strict instructions for euvolaemia and normotension. The graft is monitored regularly with hand-held Doppler.

The patient would then have occlusion of the ipsilateral parent vessel endovascularly either under the same anaesthesia, with angiographic confirmation of bypass graft patency or in a delayed manner within a few days. Long-term surveillance of bypass graft and the underlying giant aneurysm should follow a local management guideline.

High-flow extracranial to intracranial bypass in the posterior circulation

Posterior circulation giant aneurysms can be particularly challenging given their difficult access. While clip reconstruction can be used in some selected giant posterior circulation aneurysms, surgical revascularization with trapping may often be needed (Patel and Kirkpatrick, 2009). The posterior cerebral artery (PCA), superior cerebellar artery (SCA), and PICA are the usual recipient vessels, and STA or OA is used as a donor for many of these bypasses. While the OA is a robust donor vessel, it may not have sufficient flow to supply the entire posterior circulation. In addition, the length afforded by the OA may not be enough to reach the depths of the posterior fossa. Pisapia et al. examined the contemporary literature on posterior circulation bypasses and found 34 cases of high-flow bypasses for posterior circulation complex aneurysms. Twelve of these cases were done using RAG while the remaining 22 using SVG (Pisapia et al., 2011). Vertebral artery V3 segment and ECA were the most common donor vessels and over the long term, the reported graft patency rate was 95%. For some of the giant dolichoectatic posterior circulation aneurysms, flow reversal or flow reduction therapies with EC-IC and IC-IC bypasses may provide the best therapy, with the MCA-PCA bypass with a RAG being the preferred technique for revascularizing the distal basilar circulation (Lawton et al., 2016) (Fig. 53.4).

Outcome of surgical treatment

Comparing the outcome of surgical series for the treatment of giant intracranial aneurysms, the most recent literature have reported improved patient outcomes (Table 53.1), and an increasing use of bypass techniques plus indirect giant aneurysm occlusion. In the senior author's own experience, during a 13-year period, 140 patients with 141 giant aneurysms were treated surgically. One hundred aneurysms (71%) were located in the anterior circulation, and 41 aneurysms were located in the posterior circulation. 46% of the aneurysms were treated directly with neck clipping, and 51% were treated indirectly with parent artery occlusion, and bypass was used in 38% of cases. 108 aneurysms (77%) were completely occluded, 14 aneurysms (10%) had minimal residual aneurysm, and 16 aneurysms (11%) were incompletely occluded with reversed or diminished flow. Surgical mortality was 13%, and 9% permanent neurological morbidity. Bypass-related complications resulted from bypass occlusion (7 patients), aneurysm haemorrhage due to incomplete aneurysm occlusion (4 patients), or aneurysm thrombosis with perforator or branch artery occlusion (4 patients). Overall, with a mean follow-up of 2 years, good outcomes were observed in 114 patients (81%), and 109 patients (78%) were improved or unchanged after therapy (Sughrue et al., 2011).

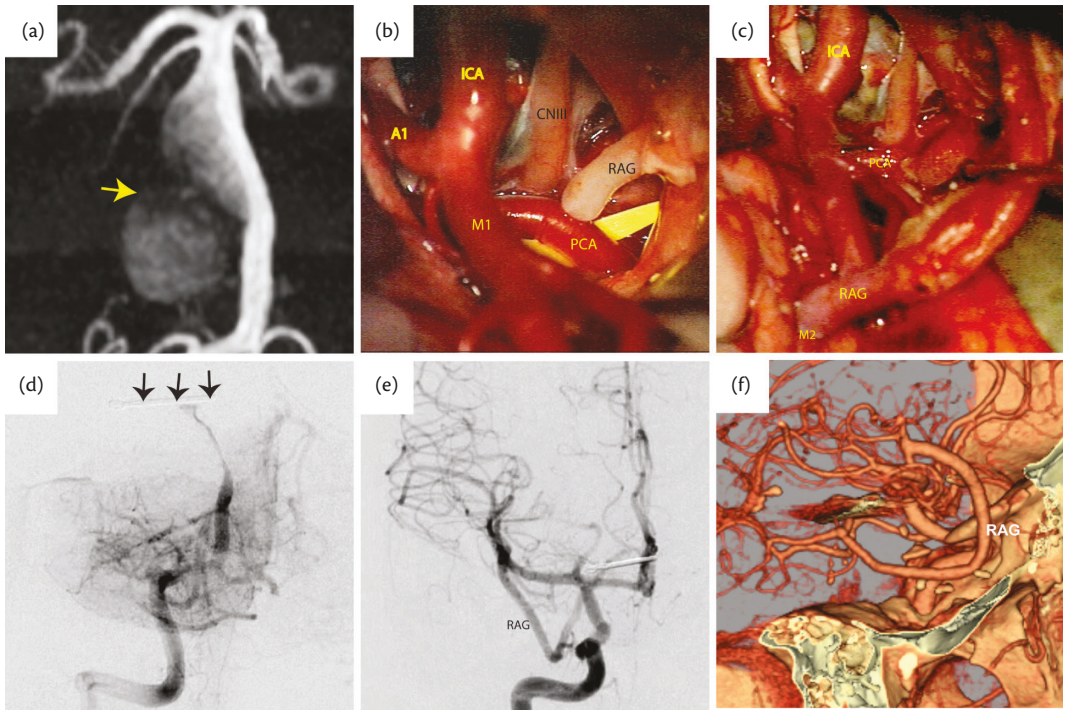

Fig. 53.4 Posterior circulation high-flow MCA-RAG-PCA bypass. A 44-year-old male presented with a giant partially thrombosed basilar trunk aneurysm (arrow in A). The patient was treated with a right orbitozygomatic craniotomy followed by an MCA to PCA bypass using a radial artery interposition graft (RAG) and aneurysm outflow occlusion proximal to SCA origin. (B) A right trans-Sylvian exposure with expansion of the carotid oculomotor triangle and anastomosis between PCA and RAG completed. Structures in the surrounding such as ICA, A1, M1 and oculomotor nerve (CNIII) can be identified. (C) Another view of the right Sylvian fissure showing RAG anastomosis with M2 and PCA. (D) An anteroposterior (AP) view of the right vertebral artery angiogram postoperatively showing filling of proximal vertebrobasilar circulation, clip occlusion of aneurysm outflow and no filling of aneurysm secondary to thrombosis from flow redirection. (E) An AP view of the right carotid circulation showing patency of the MCA-RAG-PCA bypass feeding the posterior circulation. (F) An oblique lateral postoperative 3D reconstruction CT Angiogram demonstrating filing of the radial artery bypass and obliteration of the giant basilar aneurysm.

Outcome of bypass treatment

As shown in Table 53.3, high-flow EC-IC bypass can be performed safely and successfully to allow for parent vessel occlusion in patients with complex giant intracranial aneurysms, resulting in good patient outcome and aneurysm obliteration in a large proportion of patients. Bypass graft patency rate is 90% or higher, with 5–20% of surgical morbidity reported, which included postop ischaemic stroke or haemorrhage, graft occlusion, or infectious complications. In the earlier series, 30-day surgical mortality was higher, but remained low at 1% or less in the more contemporary surgical series. In one of the largest bypass surgical series that included 93 patients with giant intracranial aneurysm (46% involving ICA, 32% MCA, 18% posterior circulation), the bypass patency rate was 96%, and long-term excellent or good outcome was observed in 94% of patients at a mean follow-up of 3 years (Shi et al., 2015).

Outcome of endovascular treatment

Giant aneurysms have not been favourable lesions for endovascular therapy (Table 53.1), as they are frequently wide-necked with intraluminal thrombosis, and the anatomy of parent and branch arteries at the base are distorted. These anatomical factors make giant aneurysms unfavourable for coiling to achieve complete obliteration. Furthermore, there is a very high likelihood of aneurysm recurrence needing multiple retreatments, and occasional rehaemorrhages, and neurological deterioration from progressive aneurysm enlargement. Techniques like stent or balloon assistance, which are frequently employed for GIA, increases intraprocedural risks (Lylyk et al., 2009). In one of the largest endovascular experiences with 39 giant aneurysms, Jahromi et al. (2008) reported a complete occlusion rate of 36%, stent assistance in 66%, and an average of two sessions to treat each aneurysm. Cumulative treatment morbidity occurred in 12 patients (32%), and treatment mortality occurred in 6 patients (16%). Overall, 11 patients died at late follow-up (29%). Despite advancement in endovascular techniques, the same group published their subsequent result from 2007 to 2012, and showed 31% procedure related mortalities, and 46% permanent neurological morbidity or death at last follow-up (Dumont et al., 2014).

Flow diverting stents have recently gained approval for treatment of proximal ICA aneurysms (from the petrous to superior hypophyseal segment) (Lylyk et al., 2009; Nelson et al., 2011; Fischer et al., 2012). They enable blood flow diversion into the native direction of blood flow, and over time neoendothelialization of the diseased vessel and exclusion of the aneurysm, thereby inducing thrombosis within the aneurysmal sac. Flow diverters have been shown to preserve flow to covered perforators in some cases, but complications including late in-stent thromboses, delayed haemorrhage and perianeurysmal oedema were not infrequent (Alderazi et al., 2014). The results of the Pipeline for Intracranial Treatment of Aneurysms (PITA) and Pipeline for

Abbreviations: ACA, anterior cerebral artery; ACoA, anterior communicating artery; AICA, anterior inferior cerebellar artery; BA, basilar artery; CCA, common carotid artery; ECA, external carotid artery; GIA, giant intracranial aneurysm; ICA, internal carotid artery; MCA, middle cerebral artery; OA, occipital artery; PC, posterior circulation; PCA, posterior cerebral artery; PCoA, posterior communicating artery; PICA, posterior inferior cerebellar artery; RAG, radial artery graft; STA, superficial temporal artery; SVG, saphenous vein graft; VA, vertebral artery; N/A, not available.

Uncoilable or Failed Aneurysms (PUFS) trials for the use of these devices in the proximal anterior circulation have been promising (Nelson et al., 2011). However, the results of their use in posterior circulation are less promising (Siddiqui et al., 2012). This is particularly true for giant holobasilar fusiform dolichoectatic basilar aneurysms having layered thrombus, where multiple overlapping short flow diverters were employed. This led to high morbidity from perforator occlusion and delayed ruptures. Furthermore, the added risk of dual antiplatelet with flow diverters make them less ideal in the setting of SAH.

Nevertheless, the currently approved flow diversion devices are not designed for use at arterial bifurcations, or for fusiform aneurysms involving the MCA and basilar artery (BA) with perforating vessels, which could lead to devastating complications from perforator infarcts.

Conclusion

Giant aneurysms are uncommon but highly challenging lesions with a poor natural history. Therefore, treatment to minimize morbidity and mortality is paramount. A proportion of giant aneurysms can be treated with primary clipping, clip reconstruction, or coiling, however, some patients still need the use of complex revascularization and flow reversal techniques. With the ongoing development in endovascular techniques, an increasing number of these lesions may be treated successfully without open surgery in the future. In the meantime, ongoing problems with endovascular reconstruction, aneurysm recurrence after coiling, and uncertain outcomes with the use of flow diverters outside of the cavernous and paraclinoid carotid artery segments make surgical treatment the preferred treatment for patients with giant aneurysms.

Spontaneous intracranial haematoma

Berk Orakcioglu and Andreas W. Unterberg

Pathophysiology, epidemiology, incidence, and risk factors for spontaneous ICH

Epidemiology/incidence

Spontaneous intracerebral haematoma (ICH) accounts for up to 20% of all strokes with a slight predominance in males. Incidence increases with increasing age and anticoagulant or antithrombotic treatment. Due to demographic changes, the incidence is likely to increase by 35% by 2050 (Stein et al., 2012). There is an association with ethnic origin: among Caucasians it is 20/100 000 compared to 60/100 000 in Japan. Mortality rates in the first week and first year after ictus range from 31% to 34% and 53% to 59%, respectively (Flaherty et al., 2006).

Classification

ICH can be classified in various means: bleeding source, anatomical localization of the clot, presence of haematoma components in other compartments (i.e. ventricle). A descriptive anatomical classification allows the main haematoma localization to be defined as lobar, basal ganglia, thalamic, brain stem, or cerebellar, with or without extension into the subarachnoid space or ventricle. An ICH necessarily involves brain parenchyma, however with respect to these locations typical or atypical haematoma can be diagnosed. Typical ICH can be found in the basal ganglia or thalamus in younger patients. Lenticulostriate or thalamic arterioles are the putative rupture site and are closely related to episodes of acute or chronic arterial hypertension. In elderly patients, lobar haematomas are termed atypical and are often related to amyloid angiopathy. In younger patients atypically located haematomas raise the suspicion of a vascular malformation or tumour as a bleeding source that requires extended vascular workup.

Risk factors

The main risk factors for ICH are arterial hypertension in basal ganglia haematoma and amyloid angiopathy in the elderly population with cortical bleeds. Between 5% and 10% of ICH occur during heparin or vitamin K-antagonist (most commonly warfarin) administration. Anticoagulation with vitamin K-antagonists is associated with a 0.5–1% cerebral haemorrhage risk per year and in only half of these patients is overdosage present. Patients with oral anticoagulant (OAC) treatment are exposed to a higher risk for spontaneous ICH and mortality is higher if reversal of OAC medication is not undertaken (Kuramatsu et al., 2015).

Other known risk factors are cardiac diseases, diseases related to the haematopoietic system, coagulopathies (haemophilia, von Willebrand syndrome), thrombocytopenia, leukaemia, and disseminated intravascular coagulopathy.

Unlike ischaemic stroke, diabetes, hypercholesterinaemia, and smoking are not risk factors for ICH, whereas low level of cholesterol may double the risk of ICH. Cerebral vein thrombosis furthermore may induce ICH in various localizations.

Pathophysiology

One of the most important characteristics of ICH is that early progression of haematoma size or oedema (**Fig. 54.1**) can lead to secondary neurological worsening of patients.

Whereas haematoma enlargement is likely to occur in the first 24 h after onset, inflammatory processes begin soon after onset and oedema development may last up to weeks after ICH (**Fig. 54.2**) (Xue and Del Bigio, 2000).

Analyses of serial CT-angiography in ICH patients have found that the early 'spot-sign' (within 6 hours) is a strong predictor for bad outcome (Mayer et al., 2009; Demchuk et al., 2012). 'Spot sign' refers to contrast extravasation within the haematoma in the early phase after onset of the disease. In theory, with increasing haematoma volumes there is an increased risk of increased intracranial pressure (ICP) and consequent decrease in CBF and $P_{br}O_2$ leading to local or global ischaemia. Whether cytotoxic and/or vasogenic oedema plays a key role in perihaemorrhagic pathophysiology remains a question of debate (Butcher et al., 2004). These secondary brain tissue changes could be the most important factors that impact on patient outcome. The role of the pathophysiological factors during the first hours after the initial event, is not well understood (Kirkman and Smith, 2013).

Haematoma degradation products and coagulation factors initiate a secondary neuronal damage cascade which are mainly based on thrombin and iron toxicity. Alongside inflammatory processes and disturbance of the blood brain barrier promote oedema formation in the perihaemorrhagic tissue (Nakamura et al., 2006; Xi et al., 2006).

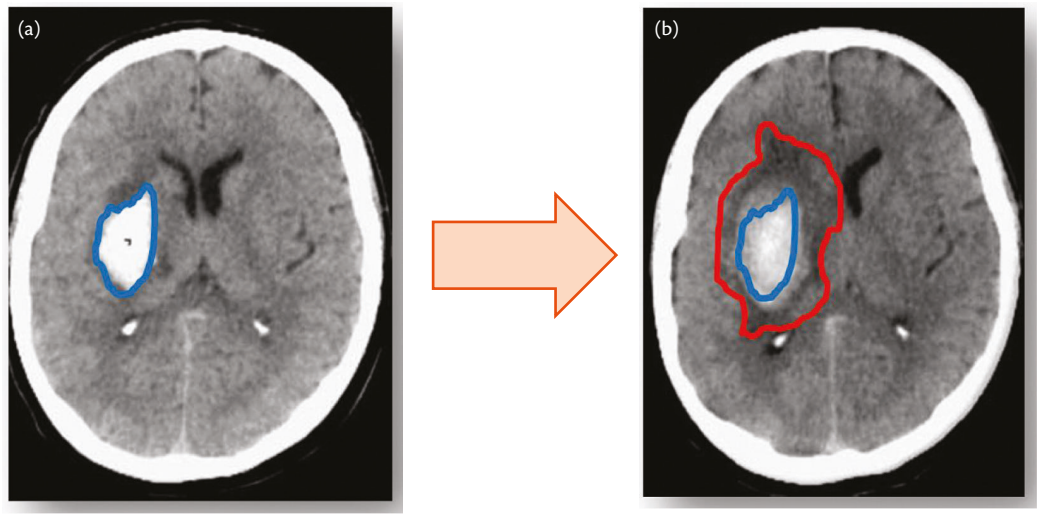

Fig. 54.1 Putaminal haemorrhage with mild space occupying effect (A); subsequent oedema development around the primary lesion leads to compression of midline structures (B).

As well as these vasogenic oedema promoting factors, metabolic contributors are discussed as a cause of late deterioration. Mechanical compression of surrounding vessels by haematoma was thought to induce ischaemia with cytotoxic oedema. However, most authors have found reduced perfusion, but no frank ischaemia in the perihaemorrhagic zone. Mitochondrial dysfunction seems to play a role, though its origin is still unclear (Kim-Han et al., 2006). New experimental data suggests that mitochondrial dysfunction induced ischaemia is more likely to occur in larger haematomas (Orakcioglu et al., 2015).

The other leading cause of ICH (15%, with an increasing tendency due to demographic changes) is cerebral amyloid angiopathy (CAA). In these patients, amyloid can be found within the medial and adventitial layers of cerebral arteries located in the cortex. These changes predispose for lobar haematomas and amyloid deposition increases with older age.

The Boston criteria summarize the diagnostic criteria for CAA. For definite diagnosis histopathological examinations are mandatory. However, the Boston criteria help to clinically classify lobar haematomas in the absence of histological correlates (see **Box 54.1**).

Clinical presentation and workup

Depending on the location, size, and dynamics of the haematoma patients clinically present in various ways. **Box 54.2** summarizes symptoms going along with certain locations. However, with increasing size of the haematoma clinical deterioration is probable and stroke unit or neurointensive care should be available in the early phases after the ictus.

Generally, ICH should be regarded as an acute life-threatening event. Even if presenting symptoms appear mild at onset, haematoma progression may lead to rapid neurological deterioration. The key aspects of acute management of ICH are: (1) identifying and treating an underlying source of bleeding (e.g. AVM);

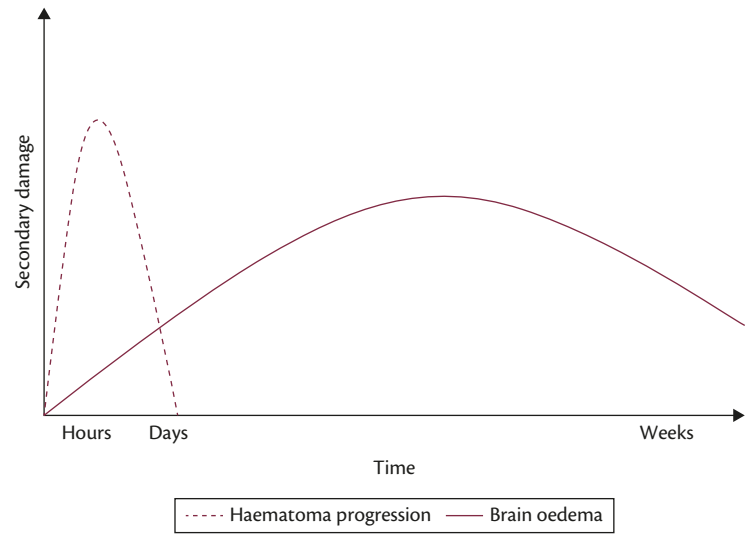

Fig. 54.2 Timeline of haematoma progression and oedema development after primary ICH.

Box 54.1 Boston criteria for cerebral amyloid angiopathy (CAA)

Certain CAA

Post-mortem histological findings showing

- lobar, cortical, or corticosubcortical haematoma
- severe CAA with associated vasculopathy
- missing other causes

Probable CAA with supporting pathology

Clinical data and pathological findings show

- lobar, cortical, or corticosubcortical haematoma
- a certain degree of CAA in histology
- missing other causes

Probable CAA

Clinical and radiological findings show

- multiple haematomas mainly lobar, cortical, or corticosubcortical (incl. cerebellum)
- age ≥55 years
- missing other causes

Possible CAA

Clinical and radiological findings show

- singular lobar, cortical, or corticosubcortical haematoma
- age ≥55 years
- missing other causes

Box 54.2 Typical symptoms of ICH in relation to localization

Putamen

- contralateral hemiparesis
- conjugate gaze deviation to lesion side
- homonymous hemianopia
- aphasia if ICH on the dominant side

Thalamus

- contralateral sensory symptoms
- initial reduced conscious state progressing to coma
- hemiparesis
- hemiataxia (up to 20%)
- oculomotor symptoms caused by pressure to the midbrain (i.e. Parinaud's syndrome)
- neuropsychological deficits

Caudate nucleus

- hemiparesis
- often intraventricular involvement with meningism

Pons

- initial reduced conscious state progressing to coma
- tetraparesis
- abnormal flexion- or extension
- bilateral cranial nerve deficits in medial lesions
- tegmental localization: internuclear ophthalmoplegia, dilated pupil, and contralateral hemiparesis

Midbrain

- initial reduced conscious state progressing to coma
- Parinaud's syndrome

Cerebellum

- initial reduced conscious state progressing to coma
- ataxia
- dizziness
- gaze palsies
- signs of elevated ICP

(2) general intensive care to secure vital functions; (3) specific neurointensive measures to control elevated ICP; (4) specific treatments to limit haematoma progression; and (5) evaluation whether operative treatment options exist (i.e. EVD, operative removal of large clots).

Investigation

Computed tomography (CT) remains the gold standard for diagnostic imaging in ICH as it is widely available, cheap, and can be performed quickly on admission. Sensitivity and specificity in detecting a clinically significant ICH is close to 100% and once an ICH has been found additional contrast-enhanced sequences (CT angiography, CT venography) may add valuable information on the underlying aetiology. In atypical haematomas in young patients these additional methods are essential to exclude underlying vascular abnormalities such as aneurysms. Haematomas are classified as atypical if subarachnoid haematoma (aneurysmal SAH) or intraventricular rupture of a periventricular haematoma (AVM) are seen. Underlying calcifications and clot components in different stages (cavernous haemangioma) also lead to the suspicion of an atypical clot that requires further workup.

Gradient echo- and T2*-susceptibility-weighed magnetic-resonance imaging (MRI) are comparable to CT in terms of sensitivity and specificity in diagnosing ICH (Masdeu et al., 2006). MRI including MR-angiography can also be used to detect ICH in the early phase. However, there is a lower availability of scanners, higher technical complexity, and cost, as well as longer examination times. Sedated and ventilated patients should be managed by specialized neurointensive care units and physicians in the MRI scanner. One advantage of MRI is its sensitivity to detect cerebral microbleeds that hint towards the diagnosis of CAA.

The clot volume should be determined once ICH is seen with regard to prognosis. A well-established method to estimate ICH volume is the a*b*c/2 formula (Kothari, 1996). Clot volumes of 30 cc and below are likely to go along with an acceptable functional outcome, whereas clot volumes larger than 60 cc are often associated with a poor functional prognosis and dependency.

Recent reports have highlighted the importance of the previously defined 'spot-sign'. Patients showing a positive spot sign in early CT-A are likely to have haematoma expansion and subsequently worse prognosis. However, lobar haematomas in CAA patients rarely have a positive spot sign. Whether or not the presence of this sign will influence therapeutic stratification remains a matter of debate (Evans et al., 2010).

Typical hypertensive haematomas are not routinely investigated with contrast-enhanced CT. However, if there is sufficient clinical suspicion of an atypical haematoma at least CT-A is advocated to rule out true vascular pathologies such as aneurysms or arteriovenous malformations.

Digital subtraction angiography is indicated in selected cases in which neither CT nor MR-based imaging has demonstrated the

bleeding source in atypical cases. It is also used if vasculitis is suspected or if there is the suspicion of an underlying AVM, where it is superior to non-invasive angiography.

Medical management

The key goals of a conservative treatment regimen are maintenance of vital functions, optimization of cerebral perfusion and oxygenation, and control of the main risk factors for subsequent haematoma progression. In larger haematomas ICP-control measures may be necessary to achieve these goals.

Blood pressure management

Studies on the prognostic value of elevated blood pressure following spontaneous ICH have shown inconclusive results. Most of the studies indicate that a markedly elevated blood pressure is associated with poor clinical outcome. Most patients with acute ICH present with highly elevated blood pressure and in a high percentage these have a positive history of arterial hypertension. As a physiological reaction to elevated ICP, blood pressure may be increased, even in patients without positive history of arterial hypertension. Theoretically, elevated blood pressure may drive haematoma expansion and progressive oedema development and thereby cause worse results. Therefore, specific and aggressive blood pressure lowering measures should be undertaken in the acute management of ICH. The results of the INTERACT II Study confirm it is safe to lower systolic blood pressure to a target of less than 140 mmHg. Although the study authors could demonstrate that haematoma progression could be lowered significantly, a relevant effect on outcome was not be observed (Anderson et al., 2013). Taking into account these findings the new guidelines for the management of ICH of the European Stroke Organisation (ESO) recommend high normal to mild hypertensive systolic blood pressure levels in the acute setting (Steiner et al., 2014).

Seizure treatment

With an incidence rate of 7.5% epileptic fits are seen more often in ICH than in other stroke subtypes (Passero et al., 2002) and seizures in ICH are negative predictors for good outcome. In most cases seizures are seen within the first 3 days and in association with lobar bleeds and may be the presenting symptom. Importantly, non-convulsive seizures are a cause of unexplained deterioration in ICH patients. EEG or continuous EEG-monitoring should be used promptly if there is a suspicion of seizure. Late onset seizures are also described and are related to lobar haematoma, microbleeds and alcohol abuse trigger (Rossi et al., 2013; Madžar et al., 2014).

For the acute management of epileptic seizures benzodiazepines are favoured and for ongoing treatment in the acute setting, phenytoin, levetiracetam, and valproic acid are commonly used antiepileptics.

Treatment of anticoagulation, antiplatelet therapy, and coagulopathies

In almost 40% of all patients with ICH progressive haematoma expansion is seen within 24 hours (Box 54.3). The above-mentioned

Box 54.3 Info box 1

Correction of anticoagulation and aggressive blood pressure control constitute the basis for any intensive care or operative treatment of acute ICH.

Surgical management

The key factors in selecting appropriate surgical candidates are haematoma size, patient age, comorbidity, location (lobar vs. deep), and the clinical course of the patient.

Rationale for surgical treatments

As mentioned earlier, ICH is a volume related primary space occupying lesion. With subsequent toxic and metabolic processes perihaemorrhagic oedema is likely to occur in the border between the solid clot and brain parenchyma (Butcher et al., 2004). Experimental data suggest that local mechanical effects of the clot restrict perihaemorrhagic perfusion and thereby promote secondary neuronal injury (Orakcioglu et al., 2014). These secondary changes and concomitant tissue swelling may continue over several days and often lead to neurological deterioration. Once secondary deterioration occurs late surgical measures for haematoma reduction may miss the therapeutic window for achieving a better prognosis. In the STICH II trial 21% of initially conservatively treated patients developed oedema related deterioration and crossed-over to surgical treatment. Compared to initially surgical patients this subgroup had a worse final outcome. Subgroup analysis of STICH II suggests that patients with a GCS of 9–12 without clinical signs of cerebral herniation should be evaluated for surgical treatment.

The theoretical considerations related to the haemorrhage and pathophysiological mechanisms already mentioned here suggest early surgical removal of intracerebral clots. However, despite impressive postoperative radiological results, two large randomized controlled multicentre studies (STICH I and II) have not delivered evidence that an early policy of haematoma removal is clinically beneficial (Mendelow et al., 2005; Mendelow et al., 2013).

Individualized surgical treatments have not been studied in both STICH I and II and because of that modern operative minimally invasive techniques remain a promising treatment option. In the randomized controlled MISTIE II study, evidence could be found that the stereotactic placement of catheters into the clot with consecutive rt-PA facilitated clot reduction significantly reduced perihaemorrhagic oedema (Mould et al., 2013). MISTIE III comparing endoscopic clot reduction and lysis versus "standard medical care" did not reveal significant beneficial effects on outcome either (Hanley et al., 2019).

Other minimally invasive options comprise endoscopic treatments using navigated burr hole approaches. Experienced Asian centres have recently reported a retrospective study that found minimally invasive endoscopic haematoma evacuation can be associated with reduced early mortality thus enabling functional improvement in patients with medium- to large-sized haematomas. This may be mainly attributed to the sophisticated surgical approach including neuronavigation and modern endoscopic equipment. Prospective randomized controlled clinical trials comparing this treatment modality with conventional hematoma evacuation through craniotomy and with conservative treatment alone are needed to investigate effects on long-term mortality and functional outcome.

ICH in the posterior fossa have not been studied in randomized controlled studies comparing conservative and operative management. Only one study compared two surgical techniques in infratentorial haematoma removal, showing that a mini-craniectomy is beneficial over large decompressive surgery (Tamaki et al., 2004). From retrospective case series it is apparent that the pathophysiology is different to supratentorial ICH and surgery is more likely to be utilized in large haematomas due to the limited space in the posterior fossa. The indications for surgery are obliteration of the fourth ventricle regardless of clinical symptoms or ICH size,

GCS score is less than 14, haematoma diameter above 30 mm and not less than 7 mm (Da Pian et al., 1984; Mathew et al., 1995; Kirollos et al., 2001). However, the ESO guidelines from 2014 conclude that there is insufficient evidence from RCTs to make definitive recommendations about how, when, and for whom surgical evacuation should be performed in adults with infratentorial ICH.

Controversy section

ICH patients should be transferred to specialized neuro-ICU or stroke units whenever possible. Careful evaluation of patient-specific characteristics (i.e. age, risk factors, haematoma location and size, and so on), neurological and premorbid condition, coagulation disorders, and diagnostic workup including vascular protocols are mandatory to individually decide for best possible treatments. Whether or not to perform surgery not only depends on these factors, but also on the availability of specific techniques such as endoscopic removal and other minimally invasive procedures. Once an operative approach to remove the clot is favoured after careful discussion neuronavigation or stereotactic methods should be used to limit approach related morbidity and thereby help improving outcome. The following surgical measures exist to treat ICH patients:

- ventriculostomy and external drainage (EVD) in cases of suspected elevated intracranial pressure (ICP) or intraventricular involvement;
- navigated/stereotactic burr hole trephination and catheter placement along the long axis of the clot with consecutive and repetitive rt-PA clot lysis and aspiration (MISTIE procedure);
- navigated/stereotactic burr hole trephination and endoscopic clot removal along the long axis;
- navigation assisted small craniotomy and microneurosurgical clot removal;
- decompressive hemicraniectomy in selected cases (i.e. ICH in sinus-vein thrombosis).

Most controversy exists in younger patients with relatively large haematomas in the deep basal ganglia. As valuable indicators for secondary neurological deterioration are still missing uncertainty remains to whether surgery should be undertaken or not. If surgery is not favoured in the first instance secondary brain swelling and oedema can progress, and delayed surgery may become the only option. In STICH II 21% of conservative patients received delayed surgery of which most had a secondary deterioration. Ideally these patients could have undergone surgery before neurological and radiological worsening, but selection criteria remain unclear:

Box 54.4 Case presentation

A 35-year-old Asian female suffered sudden headaches with consecutive right-sided hemiplegia and facial paralysis. CT revealed a large basal ganglia ICH secondary to severe hypertension (Fig. 54.3A). There was an initial GCS of 14 but early deterioration to GCS of 8 followed, with significant haematoma progression that indicated an endoscopic approach for haematoma removal. Postoperatively the patients recovered quickly to a moderate hemiparesis, and early GCS of 15 before rehabilitation. Postoperative MRI on day 3 (Fig. 54.3B) showed haematoma removal and limited oedema development going along with normal ICP during the early postoperative course.

The case in Box 54.4 illustrates the need for interdisciplinary decision-making between neuro-intensivists, neurologists, and neurosurgeons. Even if optimal medical treatment was initially favoured due to the patients' early good clinical condition, the GCS of 14 at presentation may have increased the likelihood of subsequent deterioration. For this reason even mild changes in the clinical status of the patients should lead to re-evaluation of the above-mentioned surgical options.

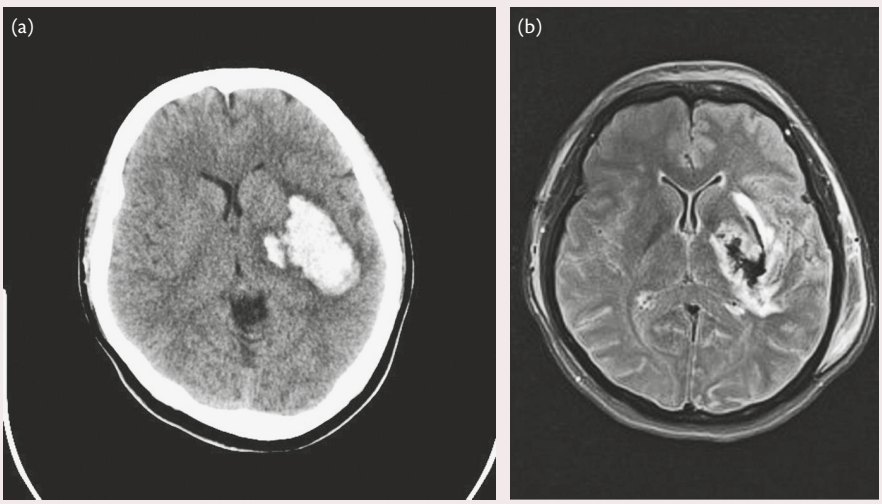

Fig. 54.3 (A) CT showing a large basal ganglia ICH secondary to severe hypertension. (B) Postoperative MRI showed haematoma removal and limited oedema development continuing with normal ICP during the early postoperative course.

medical measures (i.e. blood pressure lowering) to reduce haematoma expansion are necessary to limit secondary neurological deterioration. Point of care diagnostics are now widely available in order to rapidly assess coagulopathies, antiplatelet drug degree of efficiency, and help to accelerate coagulation management (Beynon et al., 2013; Beynon et al., 2014). If thrombolytic dysfunction is proven, then administration of tranexamic acid, desmopressin, or fresh-frozen plasma should be considered, although, there is no evidence-based data to support this practical treatment recommendation (Campbell et al., 2010; Sprigg et al., 2014).

Following the guidelines in traumatic brain injury new data have shown that OAC or NOAC (new oral anticoagulant) associated ICH should be treated by stopping anticoagulation, administering vitamin K, and considering specific reversal (e.g. prothrombin complex concentrates, PCC) to limit haematoma expansion (Le Roux et al., 2014). Among patients with OAC-associated ICH, reversal of INR less than 1.3 within 4 hours and systolic BP under 160 mmHg at 4 hours were associated with lower rates of haematoma enlargement, better outcome, and resumption of OAC therapy was associated with lower risk of ischaemic events (Kuramatsu et al., 2015).

Cavernomata and angiographically occult lesions

Janneke van Beijnum and Hiren Patel

Introduction

Cerebral cavernous malformations (CCMs), known in addition as cavernomata or cavernous (haem)angiomata, are vascular malformations consisting of abnormally enlarged capillary cavities without intervening parenchyma (see section on capillary telangiectasia, this chapter) or arterial feeders with venous drainage (see arteriovenous malformations, Chapter 50). About 10–20% of CCMs are associated with a developmental venous anomaly (DVA, see later in this chapter), which is an extreme variation of the normal venous anatomy. CCMs can occur as result of an underlying genetic disorder, and genetic analysis is recommended in patients with a positive family history or multiple lesions. A conservative approach for asymptomatic CCMs seems justified in the large majority of cases and follow-up imaging is only needed if patients become symptomatic. Indications for surgical treatment are multiples haemorrhages, CCMs with mass effect causing symptoms, and patients with intractable epilepsy with an identified epileptogenic focus. Stereotactic radiosurgery can be considered in exceptional cases with a very high surgical risk.

Pathology

Histological description

On macroscopic examination, CCMs appear as mulberry-like malformations which can vary in size from just a few millimetres to several centimetres. Evidence of haemorrhage in different stages within the CCM and haemosiderin staining of surrounding brain are visible. At a microscopic level, they consist of tightly packed single layer endothelial-lined caverns. The cavern walls are composed of connective tissue lacking organized collagen and a distinct muscular layer which is present in normal vessels and arteriovenous malformations. Additionally, tight junctions between the endothelial cells lining the caverns are missing. This may contribute to the small, repetitive bleeds which are typical for CCMs. Characteristic haemosiderin depositions are present in the basal lamina and intervening neural tissue is absent, which differentiates them from capillary telangiectasia (Wong et al., 2000; Haasdijk et al., 2012).

Theories of pathogenesis, genetics, and familial syndromes

The pathogenesis of CCMs has been partly unravelled by studying the genes implicated in familial CCMs. Familial occurrence of CCMs has been reported in nearly 20% of patients although some of the sporadic cases may represent autosomal dominant inheritance with variable expression and incomplete penetrance. In Hispanic-American patients of Mexican descent, the proportion of familial cases may be as high as 50% due to a shared mutation in the KRIT1 (k-rev interaction trapped protein 1) gene (Q455X) (Haasdijk et al., 2012).

Mutations in three known genes have been associated with CCMs which are outlined in **Table 55.1**. Proteins encoded by these CCM genes are implicated in junction formation between endothelial cells in vessels. Therefore, loss-of-function mutations may result in abnormal blood vessels with gaps between these endothelial subunits.

Although CCMs are vascular lesions, in-situ hybridization studies have demonstrated expression of KRIT-1, MGC4607, and PDCD10 in astrocytes, neurons, and various epithelial cells. Therefore, CCMs could also be the consequence of faulty signalling between endothelial and neural cells and raises the question whether the primary defect in CCMs is of vascular or neuronal origin (Haasdijk et al., 2012).

Furthermore, familial CCMs are less likely to be associated with DVAs than sporadic CCMs, which are associated with a DVA in almost half of the cases. This suggests that a different underlying pathogenic mechanism exist for CCM development (Petersen et al., 2010).

Mutations associated with CCM1 are most common, followed by CCM2, and CCM3 being much more rare. Almost all CCM patients with at least one affected relative will have a mutation in one of the CCM genes, whereas this is the case in 60–80% of patients with multiple lesions, but without affected relatives (Denier et al., 2006; Haasdijk et al., 2012) Although the number of affected relatives is generally lower in CCM3 families, the clinical course appears to be more aggressive in comparison to the CCM1 and CCM2 phenotypes, in both familial and sporadic cases with a greater number of lesions, more frequent haemorrhage and presentation in childhood (Denier et al., 2006; Shenkar et al., 2015).

Table 55.1 Genetics of CCMs

	Chromosome	Possible function(s)
CCM1 KRIT1	7q11.2-21	Cell adhesion (ICAPα), cell spreading (malcavernin), direction of endothelial cell migration (HEG1), tumour suppressor gene (RAP1a)
CCM2 MGC4607 malcavernin	7p13	Lumen formation (PDCD10), vascular permeability (Rac1), migration (kinases in p38 MAPK signalling cascade)
CCM3 PDCD10	3q26.1	Apoptosis (malcavernin), direction of endothelial cell migration (SSTK24)
Unspecified gene	3q26.3-27.2	

Abbreviations: HEG1, heart of glass 1 receptor; ICAP1α, α isoform of the β1-integrin regulator integrin cytoplasmic adaptor protein 1; KRIT1, k-rev interaction trapped protein 1; PDCD10, programmed cell death 10; STK24/25, serine/threonine protein kinase.

Recommendation

- Genetic analysis is advised in patients with a family history of CCMs or multiple lesions.

Clinical presentation and radiological investigation

Clinical presentation

The incidence of CCMs varies between 0.17 and 0.56 per 100 000 population per year (Brown et al., 1996; Al-Shahi et al., 2003). In the latter prospective population-based study more than half of the CCMs were incidental findings at either autopsy (11%) or imaging (46%; see Al-Shahi et al., 2003). The lower incidence is reported from a retrospective study performed between 1965 and 1992 (Brown et al., 1996) and could therefore be hypothesized as a direct result of the increasing availability of MRI scanners since the 1980s.

CCMs most frequently present in the fourth and fifth decade, and there may be small preponderance in women (58%). Roughly half of patients with CCMs are asymptomatic whereas about a quarter of patients present with either single or multiple epileptiform phenomena. Patients who have experienced a first seizure are extremely likely to develop long-term epilepsy, as only 6% will be isolated. Almost half of the CCM patients become two years seizure-free within 5 years following the diagnosis of epilepsy (Josephson et al., 2011). Additionally, patients can present with either haemorrhage (~12%) or focal deficits (~15%) (Al-Shahi Salman et al., 2012).

Radiological investigation

CCMs are not visible on an angiogram, and therefore can be referred to as angiographically occult lesions, or cryptic vascular malformations. Although a CCM can be diagnosed on a CT-scan by virtue of brain haemorrhage or calcifications, the diagnosis is usually made on MRI imaging (see **Figs. 55.1–55.5**). CCMs can exhibit a heterogeneity in signal characteristics on MR scan, and classically they appear as 'popcorn'-like lesions surrounded by a low-signal rim due to haemosiderin deposition after repeated micro-haemorrhages (on T2(*)-weighted sequences, see **Figs. 55.1–55.3**). Radiologically, CCMs can be categorized into four types (**Table 55.2**), with gradient-echo sequence (GRE) (see **Figs. 55.4** and **55.5** compared to **Figs. 55.2** and **55.3**, respectively) demonstrating CCMs far better than T2, on account of haem causing a susceptibility artefact (Zabramski et al., 1994; Lanzino and Spetzler, 2007).

The most common location for CCMS to occur is lobar (67%), followed by infratentorial (brainstem 14% and cerebellum 13%). Deeply located cavernomata are relatively rare (6%) (Al-Shahi Salman et al., 2012).

Recommendation

- Haem-sensitive MRI sequences such as GRE or susceptibility-weighted sequences should be used in the detection of multiple CCMs.

Natural history of cavernomata

As with arteriovenous malformations, reliable data regarding the natural history of CCMs is scarce. The majority of natural history studies are biased because they describe either selected patients who did not receive treatment for some reason and a short untreated follow-up of those who did receive treatment. Moreover, the large majority of those studies are hospital-based and have not looked at the population in general.

It is generally accepted that the overall annual risk of first-ever CCM-related haemorrhage is low (0.4–0.6% per year) and that the risk of a subsequent haemorrhage is much higher (3.8–23% per year), although this risk decreases over time (Al-Shahi Salman

Table 55.2 Radiological classification of CCMs

Type		T1	T2
I	Signs of (sub)acute haemorrhage with extralesional extension	Hyperintense haemorrhage focus	Hyper- or hypointense bleeding focus which extends through hypointense rim in *type IA* CCMs and without extension in *type IB* CCMs
II	Subacute haemorrhage	Reticulated mixed core	Reticulated mixed core with hypointense rim (typical 'popcorn' lesion)
III	Chronic resolved haemorrhage Usually seen in familial CCMs	Iso- or hypointense lesions	*Standard T2*—hypointense lesions with hypointense rim *GRE*—greater magnification in comparison to T2
IV	Typically seen in familial occurrence of CCMs	Usually not visible	*Standard T2*—usually not visible *GRE*—small punctate hypointense lesions

et al., 2012; Flemming et al., 2012). Data from a large retrospective hospital-based study reported a variable annual haemorrhage rate of 6.2% in patients who presented with a bleed, 2.2% in patients presenting with non-haemorrhage related symptoms and 0.33% in patients with incidental CCMs. A prospective population-based study showed that the cumulative 5-year re-bleeding risk is almost 30% in patients who initially presented with haemorrhage, whereas the 5-year risk of a first-ever haemorrhage was only 2.4% (Al-Shahi Salman et al., 2012). Presentation with haemorrhage, male sex and multiplicity of lesions can increase the haemorrhage risk (Flemming et al., 2012).

When interpreting the data about CCMs and haemorrhage rate, it is important to note that CCMs can cause symptoms without a recent overt haemorrhage. Moreover, there is a tendency of microscopic leaking of blood resulting in the typical radiological MR appearances of CCMs. This necessitates the need for a clear definition

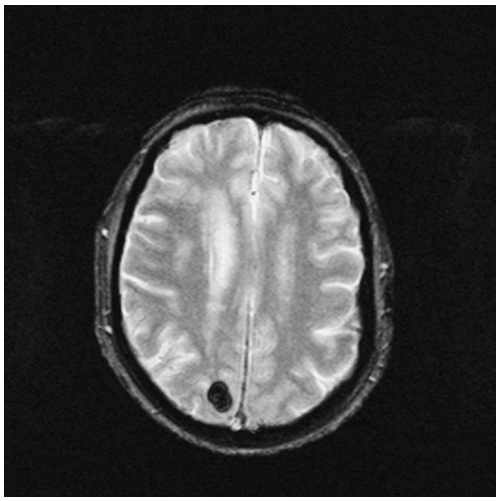

Fig. 55.5 Axial T2 GRE MR image demonstrating cavernoma more clearly compared to Figure 55.3.

of CCM-related haemorrhage. Currently, the definition stands as thus: a clinical event with acute/subacute onset of symptoms with radiological, pathological, surgical or CSF evidence of either recent extralesional or intralesional haemorrhage (Al-Shahi Salman et al., 2008).

Management strategies and outcomes

There are currently no randomized control trials comparing treatment modalities either against each other, or with conservative management. Moreover, there are no observational studies comparing microsurgical resection with radiosurgery (Samarasekera et al., 2012). One population-based cohort study compared surgical and conservative management and concluded that surgery is associated with a worse short-term functional outcome due to early complications after CMM resection. Other predictors of poor outcome following surgery are location of CCM in the brainstem, increasing age, and male sex. Additionally, the risk of symptomatic haemorrhage or new focal neurological deficit was higher after resection in comparison to conservative management. Mortality was comparable; one patient (4.0%) in the surgical group died after a seizure whereas in the conservative group four patients (3.7%) experienced CCM-related deaths (Moultrie et al., 2014).

Conservative management

In all patients, the balance between risk and benefit has to be carefully assessed before considering any intervention. Recent studies show that risks of CCM treatment cannot be disregarded and CCM resection can be associated with a poor short-term outcome when compared to conservative management (Moultrie et al., 2014; Poorthuis et al., 2014). A systematic review showed that the overall incidence of death, haemorrhage or new/worsened permanent deficit after resection or stereotactic radiosurgery (SRS), is approximately 6 per 100 person-years. The surgical risks were lower if patients presented with haemorrhage or in patients with CCMs outside the brainstem (Poorthuis et al., 2014). This suggests that for incidentally discovered CCMs strong consideration should be given to conservative treatment unless a clinical haemorrhage or symptomatic growth occurs during follow-up. Additionally, conservative management should be considered in patients with symptomatic CCMs that are associated with high treatment risks, such as those in eloquent locations (e.g. brainstem).

Surgical resection

Indications for resection are generally previous haemorrhage and/or growth with associated symptoms and signs.

Surgical risks should be weighed against the natural history in every patient, on a case-by-case basis. In general, the threshold for resection should be higher for patients with CCMs in eloquent or surgically inaccessible areas in comparison to patients with CCMs in non-eloquent areas. Surgical experience is key to this decision-making, especially for brainstem CCMs. When considering resection of brainstem CCMs, the cavernoma should reach the pial or ependymal surface, in order to minimize operative neurological deficits. Relatively safe entry zones in the brainstem are summarized in the following paragraph (Giliberto et al., 2010). However, the use of intraoperative electrophysiological monitoring is recommended given the grave consequences if critical structures are damaged.

Safe entry zones in the dorsal midbrain are located just above and below the lamina quadrigemina, and in the lateral mesencephalic sulcus. In the floor of the fourth ventricle, safe entry zones include the median sulcus, the suprafacial triangle (just above the facial colliculus), the infrafacial triangles (just below the facial colliculus). Specifically, with regards to the medial sulcal approach, care must be taken at or above the level of the facial colliculus as the medial longitudinal fasciculus may be encountered resulting in internuclear ophthalmoplegia. In this case an anterolateral approach is more appropriate. In the medulla, the posterior median fissure, posterior intermediate sulcus, and posterior lateral sulcus can be used for relatively safe access. Ventral entry zones include the corridor between SCA and PCA, the 'peritrigeminal area' between the fifth and seventh nerve, the retro-olivary sulcus, and the anterolateral sulcus (Giliberto et al., 2010).

This decision-making process approach is demonstrated by Kivelev et al., who reported outcomes according to a grading scale that their group had developed. In this scale, points are allocated for location (supratentorial 1 point; 2 points if infratentorial, basal ganglia, or spinal) and pre-existing neurological deficit (1 point if present). A good functional outcome (Glasgow outcome score 5: normal activities, minor neurological deficits) was achieved in 87%, 79%, and 46% of patients with grades 1, 2, and 3, respectively (Kivelev et al., 2011).

Most studies looking at resection of CCMs associated with seizures are also limited and lack rigorous definition criteria for epilepsy and subsequent outcome measures (von der Brelie and Schramm, 2011). Seizure freedom in CCM patients with medically refractory epilepsy can be allegedly achieved approximately 88%. Surgery may require more extensive resections in order to accomplish better seizure control. In this series, seizure freedom was achieved in 80% of patients with chronic epilepsy due to CCMs and 91% CCM patients with sporadic seizures (von der Brelie et al., 2013). The surgical procedure will undoubtedly vary with both CCM location and preferred approach.

Preoperative counselling is extremely important in order to inform patients about natural history, benefits (preventing future haemorrhage with related morbidity and mortality) and risks of surgery (including postoperative haemorrhage, infection, focal neurological deficits, CSF leak, epilepsy, and risk to life). The postoperative course after brainstem CCMs resection is likely to be associated with at least a degree of temporary neurologic deterioration, prolonged admission to intensive care with even the possibility of tracheostomy and/or percutaneous endoscopic gastrostomy (PEG) along with subsequent requirements for rehabilitation.

In pooled analyses, the risk of postoperative complications (composite of death within 30 days, symptomatic haemorrhage, new or worsened focal neurological deficit) was estimated at 7.7% (95% CI 5.2–11) for studies looking at resection of predominantly supratentorial CCMs and at 50% (95% CI 37–64%) for resection of brainstem CCMs (Moultrie et al., 2014).

In selecting the appropriate operative approach, preprocedural tri-plane MRI can be helpful. A key principle in approaching a CCM is to find the shortest trajectory which minimizes neural injury, (particularly in spinal cord or brainstem CCMs) and avoiding 'blind-spots' along the surgical corridor. The two-point method can

help to select a surgical approach, utilizing an extended line to the skull that incorporates one point in the centre of the CCM and a second point at where the CCM manifests at the pial surface (or alternatively, at a safe entry point into the brain/spinal cord).

Although intraoperative surgical landmarks such as yellow discoloration can guide the surgeon to the pial or subependymal entry point to identify the CCM, frameless navigation can be of great benefit. Intraoperative monitoring may also be useful, particularly when resecting CCMs in eloquent locations (Lanzino and Spetzler, 2007; Nader et al., 2014).

The general technique of CCM resection involves circumferential dissection of the glial plane in non-eloquent CCMs, emptying of the caverns to achieve internal debulking with subsequent facilitation of resection, by rolling it away from the glial plane. Ideally, an *en-bloc* resection should be attempted, since this minimizes the risk of incomplete resection.

Removal of eloquent CCMs requires an entirely different approach. Essentially, an 'inside-out' dissection is preferable, which is done by entering and emptying the CCM to make it collapse on itself. This is followed by careful dissection of the plan between capsule and eloquent brain tissue to minimize surrounding brain injury.

If the CCM is associated with a DVA, the latter should be preserved during resection as it represents part of the normal venous system. Only small branches of the DVA can be cauterized but sacrifice of the main trunk(s) may lead to venous infarction with potentially disastrous consequences (Lanzino and Spetzler, 2007; Nader et al., 2014).

Stereotactic radiosurgery

The aim of SRS of CCMs is the prevention of haemorrhage by inducing thrombosis-obliteration in the cavernoma. As CCMs are angiographically occult lesions, the effectiveness of SRS cannot be assessed by imaging as in AVMs, but relies solely on the basis of occurrence of haemorrhage during follow-up period (Nagy and Kemeny, 2013). As the risk of recurrent intracranial haemorrhage declines over time (Al-Shahi Salman et al., 2012; Flemming et al., 2012) it is questionable if the reduced haemorrhage risk after SRS that some studies have described can be attributed to this treatment. Therefore, SRS should be restricted to either highly eloquently or surgically inaccessibly areas, such as basal ganglia and brainstem (where the cavernoma does not present at the surface).

Morbidity related to SRS includes both post-treatment haemorrhages and adverse radiation effect. Around 7% of patients were found to have persisting neurological decline resulting from post-SRS haemorrhages. With treatment doses between 12 and 15 Gy and defining the CMS target within the haemosiderin ring, the radiation-related complications are generally between 1% and 7%. A number of SRS studies treating CCM patients with medical refractory epilepsy reported that about 40–50% of patients were seizure-free at follow-up (Nagy and Kemeny, 2013). A comparative study including patients with epileptogenic cavernomata demonstrated 87% of patients were without seizures after surgery compared to 64% after SRS (Hsu et al., 2007).

Recommendations

- Given the major limitations with respect to the evidence guiding management of CCMs only limited recommendations can be made.
- Decision-making regarding patients with CCMs should be done on a case-by-case basis (Samarasekera et al., 2012).
- A conservative approach for asymptomatic CCMs seems justified in the large majority of cases.
- Follow-up imaging is only indicated when patients develop symptoms.
- Resection of CCMs can be considered after recurrent haemorrhage, in patients with CCMs causing mass effect that results in either (progressive) neurological signs or symptoms and in CCM patients with intractable epilepsy. In the latter group, patients should undergo preprocedural evaluation, in order to identify the epileptogenic focus.
- In cases of eloquently located CCMs, the threshold for surgery is raised given the considerably higher morbidity and mortality, but may be considered after repeated extralesional haemorrhages and neurological decline.
- SRS can be considered in exceptional cases, for example recurrent haemorrhages in brainstem cavernomata which do not reach the pial surface and are therefore associated with very high surgical risk.

Other angiographically occult malformations

Developmental venous anomalies

DVA are extreme variations of the normal venous system. They are usually asymptomatic although DVAs may give symptoms due to increased inflow, compromised venous outflow, or remote arteriovenous shunt with increased venous pressure. Haemorrhage may occur but this is usually due to an associated CCM (Osborn, 1994; Pereira et al., 2008). DVAs are thought to develop in compensatory response to incidents during embryogenesis, thereby recruiting and dilating pre-existing transmedullary veins (Pereira et al., 2008).

DVAs can be diagnosed on both CT and MRI as either a curvilinear enhancing structure or flow void with enhancement of the dilated medullary veins ('caput medusae'). Their detection rate is approximately 0.43 (0.31–0.61) per 100 000 patients per year and includes a combined CCM/DVA in at least one-fifth of cases (Al-Shahi et al., 2003; Meng et al., 2014). Additionally, DVAs with three or more medullary veins in the same MRI section, infratentorial lesions, and multiple DVAs were more likely to be associated with a CCM (Meng et al., 2014). The venous phase of angiogram demonstrates the caput medusae aspect of transmedullary veins draining into the venous collector vein, which in turn drains into either the superficial or deep venous system (Osborn, 1994).

Recommendation

- In most patients, DVAs are normal variants that do not require treatment. If a DVA diagnosed during investigation of intracerebral haemorrhage (ICH), one should exclude an associated CCM.

Capillary telangiectasia

A capillary telangiectasia consists of nests of dilated capillaries without smooth muscle or elastic fibres in their walls. The presence of intervening brain parenchyma distinguishes a capillary telangiectasia from a CCM. The most frequent location is the Pons.

Multiplicity is common and they are usually incidental findings on MR or at autopsy. Often they can be found in conjunction with CCMs. Akin to CCMs, capillary telangiectasias are usually not visible on angiogram, but racemose type lesions may show a faint blush and can manifest as a curvilinear area of enhancement on MRI. On T2 or GRE sequences they can be seen as multiple hypointense foci.

It is important to realize that *brain* capillary telangiectasia is *not* a part of hereditary haemorrhagic telangiectasia (HHT). HHT is an autosomal dominant neurocutaneous disorder characterized by *mucocutaneous* capillary telangiectasia and arteriovenous malformations and fistulae in lungs, liver, brain, and spine (Osborn, 1994).

Controversy

The role of SRS in the management of CCMs is debatable. The literature is limited to single centre case series, and expert opinions vary greatly.

Some regard SRS in CCMs as effective as that for AVMs, whereas others consider it only as salvage treatment, or even not at all (Lanzino and Spetzler, 2007; Lunsford and Sheehan, 2009; Nagy and Kemeny, 2013; Lu et al., 2014; Nader et al., 2014; Mouchtouris et al., 2015). As the effect of SRS on CCMs can only be assessed by comparing the incidence of haemorrhage, current publications have therefore been limited to comparing pre- and post-SRS bleeding rates (Samarasekera et al., 2012). A meta-analysis of five retrospective Class III studies, reported a reduced haemorrhage rate after SRS of brainstem CCMs in four of these but a non-significant, slightly increased haemorrhage rate in one. Twelve per cent (12%) of patients experienced new neurological deficits after SRS and 2.2.% died after CCM haemorrhage. Unfortunately, no attempts to assess any kind of bias were made (Lu et al., 2014).

Moreover, as the risk of recurrent intracranial haemorrhage declines over time (Al-Shahi Salman et al., 2012; Flemming et al., 2012), it is questionable as to whether or not the reduced haemorrhage risk after SRS seen in some studies can be attributed to SRS, or may merely represent the natural history of CCMs.

In one handbook on intracranial stereotactic radiosurgery, a conclusion is proffered that the decrease in haemorrhage risk following SRS is limited, whereas the risk of complications is high. The use of SRS for CCMs should thus be limited until a class I randomized controlled trial provides evidence to the contrary (Lunsford and Sheehan, 2009).

Surgical principles in spinal surgery

Simon Thomson, Chris Derham, and Senthil Selvanathan

Preoperative considerations

Patient selection

There are many spinal conditions where the outcomes from surgical and non-surgical management are similar and it is critically important to appreciate the multifactorial nature of back and neck pain. Surgery is effective at dealing with some tissue derived pain inducers, but it has no effect on factors related to secondary gains and can often make these worse. As surgery is frequently only one of many options for a patient, factors such as comorbidities, outstanding litigation, or personality type can significantly change whether surgery is the best way forward. Conversely, in some patients, where for example, there is progressive myelopathy with tight stenosis then even quite severe comorbidities should be tolerated in the decision to treat surgically.

Some patients may choose not to have surgery despite strong indications, this is a legal right and has to be respected. Other patients, however, may want surgery where there is very little indication for it, this may need to be challenged, the surgeon is not obliged to perform surgery in this situation but a second opinion should usually be offered. The assessment of risk versus benefit in spinal patients can be marginal and very challenging, to do it well requires considerable experience, but it is a skill that is as important as any technical skill relating to how a procedure is performed.

Consent and preoperative education

Consent, at least in United Kingdom, is too often thought of as a purely legal process but it should not just be reduced to a discussion of the risks, benefits, and alternatives. Patients need information about many other things including length of stay, post-op activity, and the expected time to return to work. Managing expectations is important, for example, a patient who expects their neck pain to be resolved by an anterior cervical discectomy is highly likely to be disappointed and a patient who expects to stay for 5 days postoperatively will not be keen to mobilize early. However, it should be noted that while informing and educating patients has been extensively studied, mostly in hip and knee surgery, somewhat surprisingly, it has not been shown to improve postoperative anxiety or surgical outcome (McDonald et al., 2014).

Anticoagulation medication

Most medication will continue unchanged during a spinal procedure but anticoagulation and antiplatelet therapy may need to be addressed.

Warfarin should be stopped and anticoagulation will usually reverse in up to five days. Bridging therapy with high dose low molecular weight heparin can be considered depending on the indication for warfarin therapy. High dose low molecular weight heparins will also need to be stopped and the anticoagulation effect will reverse over 24 hours. Rivaroxaban is a newer factor Xa inhibitor, used in place of warfarin. For the surgeon it is important to note that unlike warfarin, the anticoagulant effect is not immediately reversible, but it wears off faster in around 2 days. This is covered further in Chapter 5.

Whether to stop antiplatelet drugs before elective spinal surgery is controversial. Antiplatelet drugs include aspirin, the phosphodiesterase inhibitor dipyridamole, and the adenosine diphosphate (ADP) receptor inhibitors clopidogrel (irreversible) and tricagrelor (reversible). Non-steroidal anti-inflammatory drugs also inhibit platelets but unlike aspirin this effect is only while they are in the circulation and the antiplatelet activity therefore rapidly wears off when the drugs are stopped.

Aspirin works by irreversibly blocking cyclo-oxygenase enzymes. Platelets have no nucleus and cannot replace enzymes. Platelets survive for an average of 10 days, thus if aspirin is stopped it takes 10 days for the entire platelet population to be renewed. However, normal haemostasis can be demonstrated with as few as 20% normal platelets and studies show that reversing the effects of aspirin may take as little as 2–4 days. Furthermore, there is now increasing evidence for a platelet rebound phenomenon with a relative prothrombotic state when aspirin is stopped (Gerstein et al., 2012).

In a large study published in 2011, patients taking antiplatelet drugs for any indication and having elective, non-cardiac surgery were randomized to placebo or aspirin from 10 days preoperatively. There was no difference in major thrombotic or bleeding events (Mantz et al., 2011). With regards to spinal surgery, a non-randomized study was published in 2015 in patients with cardiac stents, having orthopaedic spinal surgery. Those continuing aspirin where compared with those stopping aspirin at least 5 days preoperatively. There was no difference in bleeding related complications between the groups (Cuellar et al., 2015).

Some patients with cardiac stents, especially drug eluting stents are at high risk if their antiplatelet drugs are stopped within a year of the stent being inserted. Discussion with cardiologists before stopping antiplatelet drugs is advised in these cases. Conversely intradural spinal procedures carry a high risk of adverse events if haemorrhage occurs and, in these cases, antiplatelet drugs would normally be stopped.

Operative considerations

Patient positioning

Spinal procedures are performed prone, supine, lateral, or occasionally in a lithotomy position. Correct patient positioning is critically important.

Prone positioning is used for all posterior spinal approaches. When operating on the posterior cervical spine, patients will usually be placed in head pins (Mayfield or Sugita). The chin is flexed down and the head lifted up to maximize the space between the back of the shoulders and the occiput. It is important to ensure that the chin is not resting on the operating table and is clear of the head frame. The operating table will normally be placed in a head-up position. The arms are usually beside the patient. Placing the patient head up improves venous return and therefore helps to reduce intraoperative bleeding.

Prone positioning for lumbar or thoracic spine procedures may be on a frame or spinal operating table that flexes the patient's lumbar spine. It is important to get the width of the supports correct—too close together and the abdomen will be compressed, raising venous pressure; too far apart and the patient will be inadequately supported. Alternatively, the knee elbow position is used by some surgeons which does drop venous pressure very effectively, but care needs to be taken to avoid nerve palsies.

When positioning prone ensure the neck is not overextended, especially if the knee elbow position is used. The axillae should not be compressed, the shoulders must be in a comfortable position and male external genitalia must not be compressed. The eyes are the organs most at risk, the corneas should be protected from pressure and skin prep running round from the back of the neck. Pressure on the eyes can cause blindness and extreme care should be taken to check the eyes in every case.

Supine positioning is used for anterior cervical spine surgery. The head will usually be held on a ring or horseshoe. A rolled towel or other support behind the shoulders helps in getting the right degree of neck extension. Some surgeons will elect to use traction but extreme care should be taken with patients with large cervical disc prolapses where neck extension and traction can cause spinal cord injury. The eyes should be padded to reduce the risk of an inadvertent injury.

Lateral positioning is used for extreme lateral interbody fusion (XLIF) procedures. The positioning of the patient is one of the most fundamental parts of performing safe and effective surgery. It is vital that true lateral and antero-posterior views are obtained using fluoroscopy once the patient is positioned and secured, thus minimizing the risk of parallax errors and reducing the risk of placing the cage obliquely. Depending on the level of surgery being undertaken, the operating table is sometimes 'broken' to allow lateral bending, hence opening up the disc space, particularly at the L4/5 level. The surgical working plane is perpendicular to the sagittal plane allowing the visceral contents to fall forwards upon entering the peritoneal cavity and reducing the risk of injuring its contents. Neuromonitoring assessment is recommended for the XLIF approach especially when approaching the L4/5-disc space in a transpsoas fashion due to the risk of injuring the lumbar plexus. Contra-indications to performing the XLIF approach include anomalous vascular anatomy, peritoneal scarring on both sides and spondylolisthesis greater than grade II.

The anterior lumbar interbody fusion technique (ALIF) allows better surgical access to the L5/S1 disc segments as the iliac crest does not interfere with access to this region as would occur with an XLIF approach. Positioning for the ALIF approach is more straightforward than that for the XLIF, and can be undertaken in a simple supine position with the hips and knees partially flexed and the surgeon approaching from the lateral or lithotomy position. The L5/S1 disc segment is approached as compared to the L4/5 segment due to the configuration of the vascular anatomy. Complications that may arise during the ALIF approach, other than obvious vascular injury, include visceral damage, retrograde ejaculation, and sympathetic dysfunction.

The use of X-rays and checking levels

X-rays are used extensively in spinal surgery to assess bone positions, screw trajectories, and to count levels. X-rays are ionizing radiation and their use is controlled to protect both the public and staff. Nevertheless, failing to use X-rays sufficiently is also a risk.

When using X-rays there is a risk of parallax errors. This occurs, for example if a marking needle is too far from the bones and the X-ray machine is not square to the patient. The risk can be minimized by keeping needles close to the structure that is being marked and ensuring that the X-ray machine is correctly positioned. Images can usually be checked by looking at the end plates or on anteroposterior (AP) views at the pedicles.

Performing surgery at the wrong level is a constant risk in spinal surgery. There are many pitfalls to be cautious of including lumbarization of S1, sacralization of L5, klippel-feil anomalies in the cervical spine, congenital fusion of C2 and C3, and abnormal numbers of vertebrae. The highest risk area is probably the thoracic spine. Various techniques are used to check levels including counting up from the sacrum, counting down from C2, and counting from T12 on the AP view. It is advised that counting is done by two people independently to minimize risk. Preoperative skin marking has been used but it is not very accurate. If this method is used the patient should be X-rayed with the arms in the same position as they will be on the operating table. A preoperative injection of methylene blue dye has also been used successfully to mark levels.

Intraoperative X-rays once the pathology has been reached will help confirm the level. In obese patients, even in experienced hands, it is relatively easy to go up or down a level between the skin incision and reaching bony landmarks.

Operating microscopes and image guidance

Operating microscopes are now widely available in neurosurgical theatres. The lighting and magnification of these instruments allows for smaller wounds and more precise surgery.

Image guidance is also widely available in neurosurgical departments because of its applications in cranial neurosurgery. When

used in the spine it confers some benefits over multiple X-rays. The radiation dose for the patient and theatre staff is reduced and visualization in any plane is possible with image guidance. This is particularly useful when the anatomy is not quite typical.

Image guidance registration in the spine relies on a reference being anchored to an adjacent vertebra. The vertebra of interest is then registered from multiple points on the spinous process and lamina or by using X-ray. Screw trajectories can then be assessed based on the preoperative computed tomography (CT) scan images.

Intraoperative neurophysiology in spinal surgery

Somatosensory evoked potentials (SSEPs) are measured percutaneously from the scalp over the sensory cortex. A stimulus is applied, usually using bipolar electrical stimulation over a peripheral nerve such as the median nerve at the wrist or the posterior tibial nerve at the ankle. The signal is carried in the dorsal columns.

The signal from a single stimulus is too small to be detected and gets lost in the background brain electrical activity. A technique called signal averaging is used where between 100 and 1000 signals are averaged, this results in a better signal to noise ratio. Averaging this number of signals, however, takes several minutes so SSEPs do not give immediate feedback on spinal cord function.

Motor-evoked potentials (MEPs) are measured from a muscle after a stimulus is given to the motor cortex. Signal averaging is not required for MEPs but the patient may 'jump' so surgery should be stopped briefly when the stimulus is applied, for this reason MEPs cannot be run continuously like SSEPs. The motor signal is carried in the corticospinal tracts which are more anterior in the cord. The anaesthetist should not use paralysing anaesthetic agents and total intravenous anaesthesia is usually required. Thus, SSEP and MEPs are complementary tests and will frequently be used together.

During SSEP monitoring, a 10% increase in latency from baseline, or a 50% reduction in amplitude are suggestive of a dorsal column insult in the spinal cord and this can be used to prevent further cord injury during surgery. The situation is different for the MEP response. Any significant change in morphology, amplitude or a disappearance would suggest pathological disruption to the anterior cortico-spinal tracts and some neurophysiologists may view this an all or nothing response (i.e. a non-reversible insult to the cord has occurred when this is registered). It is important to recognize that although the aforementioned changes are sensitive, they are not specific for cord injury and not uncommonly there can be false positives. Other factors such as change in temperature, blood pressure, use of volatile anaesthetics, and muscle relaxants can also affect the readings.

Neurophysiology is now routinely used in scoliosis surgery as an alternative to the 'wake up test'. It has become more commonly used in other areas of spinal surgery especially in intramedullary tumour surgery. In some countries neurophysiology is a routine part of monitoring the patient for all spinal procedures, but this is not standard practice in all parts of the world.

Fusion in spinal surgery

All metal work will eventually fail if bony fusion does not occur. In patients with malignant spinal cord compression the construct has to be longer than in patients with a traumatic spinal injury because the former is not likely to fuse while the latter usually will.

Fusion rates in the cervical spine are over 90% for anterior cervical discectomy procedures but the lumbar spine does not fuse as readily (Fraser and Härtl, 2007). Although failure of fusion can occur at either site, it is much more common in the lumbar spine. Fusion failure most commonly presents as spinal pain, especially on movement. It is best confirmed with dynamic X-rays or a CT scan.

Fusion can be promoted during an operation by decorticating bone surfaces, by adding autograft, usually taken from the iliac crest or by using several different surgical products including allogeneic cancellous or cortical bone, demineralized bone matrix, or synthetic calcium phosphate-based bone-graft substitutes. All of these provide a scaffold along which osteoblasts can migrate (**Fig. 56.1**).

Recombinant bone morphogenetic protein 2 (rhBMP-2) promotes osteoblast differentiation and is effective in promoting spinal fusion. Recent data has raised significant safety concerns with BMP2 including life-threatening events. Complications include implant displacement, subsidence, infection, urogenital events, retrograde ejaculation, radiculitis, ectopic bone formation, osteolysis, and poorer global outcomes (Carragee et al., 2011).

A review examining whether non-steroidal anti-inflammatory drugs inhibit bone fusion concluded that there is a pooled odds ratio of 3.0 for non-union in patients taking NSAIDs but that this becomes non-significant when only high-quality studies are used (Dodwell et al., 2010). Smoking also inhibits spinal fusion (Bydon et al., 2014).

Spinal surgery implants

The use of internal fixation started in the appendicular skeleton (limbs) before being used in the axial skeleton (spine). These implants can be utilized in the correction of deformity (scoliosis and kyphosis) and stabilization (fracture, dislocations, malignant, infective, and degenerative pathologies). Various implants have been used over the decades including hooks and wire-rod constructs but these relied on the presence of a lamina and are now little used. The major advance in spinal instrumentation came about following the introduction of the screw-rod fixation systems. These systems utilize pedicles and lateral masses as fixation points, the advantage being that these structures are strong fixation points in the spine. Furthermore, the screw-rod system allows instrumentation of the sacrum and can be combined with a laminectomy. Modern systems are non-ferrous to permit MRI scanning.

Screws consists of two parts (i.e. the section that contains the thread (shaft) and the head which consists of the housing where the rod sits). The variation of the different types of screws is based on the type of head, the type of interface between the screw head and shaft, whether the shaft is fully threaded/partially threaded and finally if the shaft is fenestrated.

An important aspect of screw design is the interface between the screw head and shaft. This interface provides freedom between the screw head and shaft, there are two main types; monoaxial and polyaxial screws.

Monoaxial screws (**Fig. 56.2**) do not allow movement between the screw head and the shaft. This is ideal for deformity correction however rod contouring can be difficult. Polyaxial screws on the other hand have a joint with a spherical head enclosed in a housing which allows the screw head to move in relation to the shaft. The advantage of polyaxial screws is that they allow the surgeon some flexibility in connecting screws to the rods. Polyaxial screws also have a safety

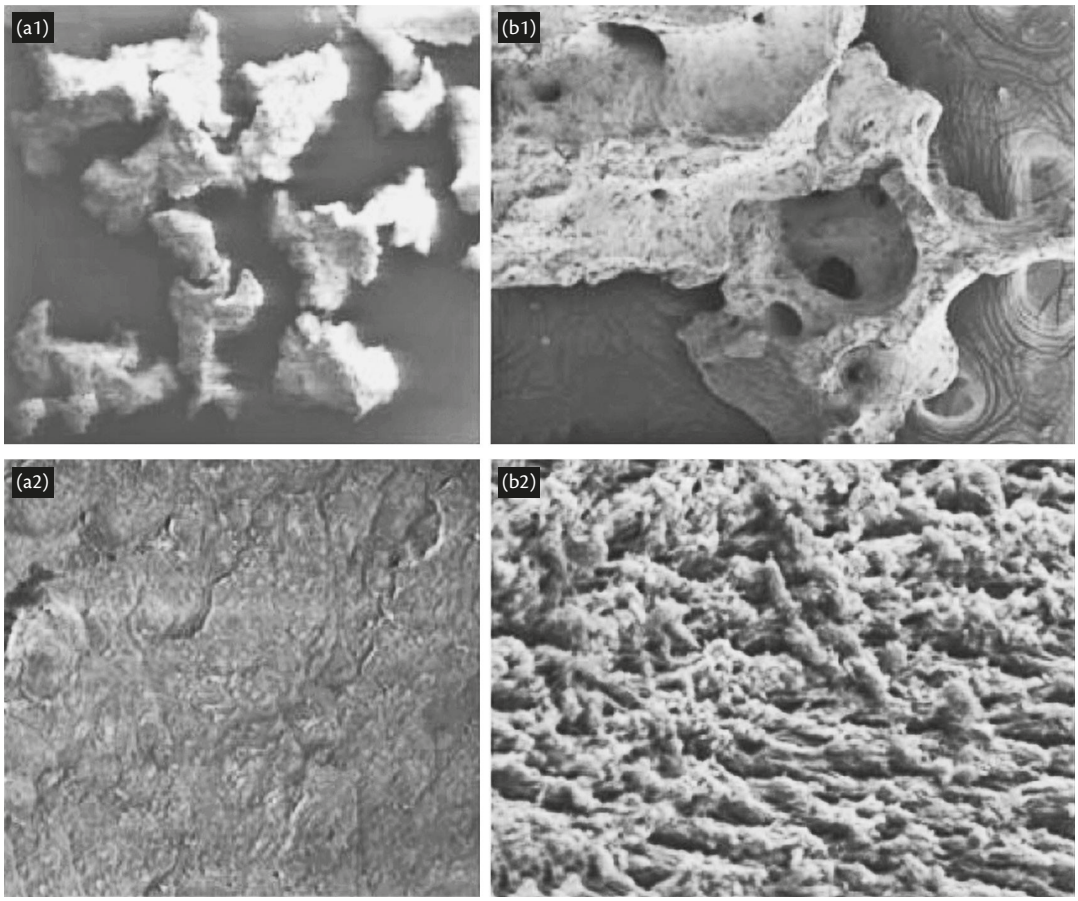

Fig. 56.1 Scanning electron microscope images of the synthetic bone substitute NanoBone® (a1, a2), whereas b1 and b2 show the characteristics for xenogenic material Bio-Oss®. (upper row: ×25 magnification, scale bar = 1 mm; lower row: ×2000 magnification, scale bar = 20 μm) (see Ghanaati et al., 2013).

benefit of failing at the head–shaft interface rather than along the screw shaft or rod.

Polyaxial screws (Fig. 56.3) can be further divided into uniplanar and multiplanar types. Uniplanar or uniaxial screws allow movement in the cranial/caudal plane only. This is useful in scoliosis cases where the polyaxial element helps in the siting of the rods and the absence of medial/lateral movement enables rotation of the vertebra.

Multiplanar polyaxial screws may be non-biased or have a biased or favoured angle. The non-biased angled polyaxial screw offers up to 30° of angulation in each direction (i.e. 60° conical movement). In biased angle polyaxial screws the offset angle of the screw head, will allow angulation of up to 55° in one direction. This high degree of angulation enables the screws to be placed in their best anatomical position at the same time avoiding the need for difficult rod contouring.

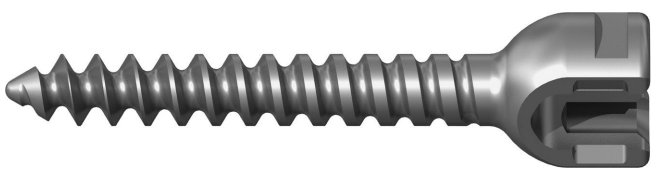

Fig. 56.2 Monoaxial screw with a fixed head.

There are also variations in the shaft designs. There are fully threaded or smooth shank screws. Smooth shank screws have a 10 mm unthreaded segment and are used in the C1 lateral mass where the smooth shank is designed to prevent the thread irritating the C2 nerve root. Another type of smooth shank screw is a lag screw which also has an unthreaded segment and a distal half that is threaded. This is used in fixation of peg fractures where the thread is in the odontoid peg and the smooth shaft in the C2 vertebral body, tightening the screw compresses the fracture and therefore enhances bony fusion. A major difference between the lag screw and the smooth shank screw is that the screw head in the lag screw is flat to enable it to sit flush with the prevertebral fascia, while the smooth shanked C2 screw has a head that can accommodate a rod.

Some screws are fenestrated with a hole down the middle of the screw. This enables K-wires to guide placement of the screw or insertion of cement into the vertebral bodies through the screws.

The pitch of the screw is the distance travelled by the screw in one 360 degree turn. A fine pitched screw travels a short distance in one turn, is used in cortical bone and generally has a higher pull out strength, while a course pitch screw travels further with each turn requires less force to insert and is used in cancellous bone. There is an outside or nominal diameter and a core diameter. The length is measured from the base of the head to the tip. Where a screw has a poor hold a rescue screw may be used—it will usually have a wider

Fig. 56.3 Polyaxial screw showing how the head can move on the shaft.

diameter and coarser pitch than the conventional screw it is used to replace.

Screw tips may be rounded requiring the drilling of a pilot hole and the hole will need tapping to start the screw off. A second type of screw tip is self-tapping—it has cutting flutes at the tip but still requires a pilot hole. Finally, self drilling screws are sharp and do not require a pilot hole at all.

Anterior vertebral constructs frequently utilize plates. These may be either locking or non-locking/dynamic plates. In locked plates the screw is held in the plate so that the angle of the screw to the plate is fixed. Conversely, dynamic plates allow some movement as the fracture 'settles'. Most plate/screw systems also have a method of stopping the screws from backing out of the plate over time. It is important to appreciate that the screw/plate and screw/rod constructs primarily resist distraction forces, while a cage primarily resists compression forces hence combining the two systems is likely to give the best stability.

Artificial disc replacement was first tried in 1966 (Fenstrom) and then abandoned in the cervical spine. Subsequently especially in the last 20 years, however, it has been developed further both in the lumbar and the cervical spine. There is now 10 year follow up data on lumbar disc arthroplasty showing an improvement in Oswestry Disability Index (ODI) (Le et al., 2004). Several different disc designs are available made of metal, polyurethane, or ultra-high-molecular-weight polyethylene (UHMWPE) (Fig. 56.4). The spine is expected to flex approximately 100 million times in a lifetime, and this puts high demands on artificial disc replacements. Surgical precision in placing these exactly in the midline is important. Problems that have been noted with these discs include implant movement, joint fusion, dysphagia (in the cervical spine) and implant fracture.

Fig. 56.4 ActivC cervical arthroplasty made from cobalt-chrome-molybdenum and high molecular polyethylene.

Minimally invasive spine

Spinal surgery frequently involves large incisions and extensive muscle dissection, consequently postoperative pain, infection, and wound problems are sometimes problematic. Minimal access surgery is a collection of techniques designed to minimize the size of the incision and muscle injury but permit the surgeon to perform the same decompression and/or fusion. The specific techniques are covered elsewhere, the general principles are explained here.

Open minimal access surgery requires that the wound is correctly positioned, and that appropriate retractors and long-handled instruments are used. The operating microscope is essential, not just for its optical magnification but also for the lighting that is designed to run parallel with the line of vision. Tubes have been developed that can act as access ports and are inserted over a series of dilators. Tubes provide excellent access for decompression procedures such as lumbar discectomy, laminectomy, and cervical foraminotomy. The extreme lateral interbody fusion technique provides a good example of how it is possible to perform extensive surgery through a 2 cm incision.

Instrumentation can also be inserted using minimal access techniques, pedicle screws are inserted through stab incisions then a rod can be rotated down into the screw heads. The main problem with this approach is that bony fusion is more difficult to promote. The technique is therefore probably best suited to malignant spinal cord compression cases.

The benefits of minimal access surgery are less pain, less analgesia requirements, and shorter lengths of stay. The disadvantages are that these operations may be more difficult than the open alternatives, risks of incorrect port placement, more X-ray exposure, inability to fuse bones, and the equipment is often expensive.

Infection prevention

Neurosurgical perioperative infection prevention, including the use of systemic antibiotics is covered in Chapter 95. Only factors specific to spinal surgery will be considered here.

Skin hair removal is usually unnecessary in the spine and there is no evidence that it reduces infection rates. If hair has to be removed then using razors as opposed to clippers has been found to increase the risk of surgical site infections (NICE, 2008).

In a large but unrandomized study, topical gentamicin applied on a collagen sponge reduced postoperative discitis. In this study

neither the treatment or placebo group had systemic antibiotics (Rohde et al., 1998).

Lamina flow theatres have been recommended for use in all orthopaedic implant surgery, however, the evidence for this comes from joint replacement surgery, there are no randomized studies in spinal surgery and recent work has suggested that lamina flow may even be a risk factor for surgical site infection as a result of patient hypothermia or poorly positioned theatre staff (Gastmeier et al., 2012).

Preoperative showering, double gloving and maintaining normothermia are also factors relevant to spinal surgery recommended by the UK National Institute for Clinical Excellence (NICE, 2008).

Postoperative considerations

Analgesia

Posterior spinal, transthoracic, and transabdominal approaches can cause significant postoperative pain. Analgesics like paracetamol, opioids, and non-steroidal anti-inflammatory drugs are widely used. The non-steroidal anti-inflammatory drugs may prevent fusion and can cause gastric problems, asthma, cardiac, and renal impairment. Local anaesthetic in the wound may help as part of a balanced analgesic regime and is often used with adrenalin before the skin incision is made to reduce bleeding from the skin edges. Paravertebral blocks are sometimes used in transthoracic surgery and there is randomized evidence to show benefit from perioperative single dose epidural fentanyl in lumbar surgery (Guilfoyle et al., 2012).

Venous thromboembolism (VTE)

Early mobilization, good hydration, and compression stockings and/or boots should be standard practice to minimize the risk of venous thromboembolism.

Low molecular weight heparins are widely used but there is little agreement on whether they should be started preoperatively or how long postoperatively (Bono et al., 2009). The incidence of deep vein thrombosis in spinal surgery is estimated as anywhere between 0.29% and 31% and is very dependent on the screening method used. There is evidence that low molecular weight heparins reduce the risk of VTE in spinal surgery but there is also evidence that they are underutilized because of concern about postoperative compressive extradural haematomas even though the reported incidence of this complication is only between 0% and 1% (Hamidi and Riazi, 2015).

Physiotherapy

Physiotherapy is widely utilized following spinal surgery—it has five main themes as follows; mobilizing patients; spinal range of motion exercises; stability exercises; neural mobility exercises; and advice and education.

In a recent review there is some low-quality evidence that physiotherapy improves outcome after surgery (Gillmore et al., 2015). Which of the physiotherapy themes is most important, the role of preoperative physiotherapy, and whether inpatient or outpatient physiotherapy should be used is not clear, however. There is considerable variability in referral to outpatient physiotherapy and in the degree of physiotherapy intervention that is provided.

Spinal stability

Peter R. Loughenbury and Richard M. Hall

Anatomy of the vertebral column

The vertebral column is a series of bones that connect the head to the pelvis. In humans, this has become highly specialized to allow for an upright posture and bipedal gait, so that the column stands as a vertical rod held in position by ligaments and muscles. There is a unique mechanical arrangement of structures within the spine and a complex relationship between the vertebral column and the skull and pelvis. Vertebral bodies increase in size from cranial to caudal to resist increasing compressive forces placed upon them. At the craniocervical junction a large proportion of the weight of the skull passes through the vertebrae leading to less developed postvertebral muscles with a smaller area of attachment. Whereas, the increased weight transferring to the pelvis leads to a large fused sacrum and more efficient transfer of weight to the lower limbs.

The vertebral column is comprised of 24 mobile vertebrae (7 cervical, 12 thoracic, 5 lumbar), 4–5 fused sacral vertebrae, and 4 fused coccygeal vertebrae. Between the mobile presacral vertebrae motion is limited by the intervertebral discs, paired posterior synovial facet joints, intervertebral ligaments, and the paraspinal muscles. The interaction of these various elements is essential for normal spinal biomechanics and function. In adults the length of the column is 72–75 cm with one-quarter of this length being due to the intervertebral discs. Approximately 40% of overall height is due to the vertebral column and differences in height reflect differing limb lengths rather than the variation in the length of the column. In addition, diurnal variations in height of around 2 cm have been reported and there is a clear loss of height with increasing age due to dehydration of the intervertebral discs.

The primary roles of the vertebral column are to protect the spinal cord, provide both stability and mobility, and to control the transmittance of movement to the upper and lower extremities. The column is adapted to perform these functions with complex articulations that allow movement and provide stability at each level and globally over the whole spine. In the sagittal plane there is an anterior convexity in the lumbar and cervical regions (lordosis) and a posterior convexity in the thoracic and sacral regions (kyphosis). This pattern develops during the early years of growth as an individual begins to ambulate. The curve seen in the sacrum is permanent as these segments are fused, but the rest of the spine is mobile and the magnitude of these curves can vary to maintain posture. In the upright position the anterior column (consisting of the vertebral bodies and intervening intervertebral discs) is responsible for the majority of load transfer in the spine. The posterior elements protect the spinal canal and include the facet joints, which both permit and limit rotation, flexion, extension, lateral bending, and translation. A typical articulation between two adjacent presacral vertebrae (excluding between the first two cervical vertebrae) consists of two posterior intervertebral facet joints, between the inferior and superior articulating facets, and the intervertebral disc. This creates three points of articulation between each vertebra.

Vertebral anatomy and regional variation

Although there is regional variation in bony anatomy of the vertebrae there is a general trend for the width, depth, and height of the vertebral bodies to increase from cranial to caudal levels. This correlates with the increased compressive strength of the vertebra in response to the greater axial loads experienced in more caudal segments. The vertebral body consists of cancellous bone with an outer shell of cortical bone. The microarchitecture of the cancellous bone is adapted so that the trabeculae are orientated along the lines of application of load. This arrangement provides resistance to dynamic loading.

The C1 (atlas) vertebra (**Fig. 57.1A**) is atypical, as it has no vertebral body. There is an anterior arch, with the odontoid peg directly behind it, and a flattened posterior arch with a small midline posterior tubercle. The articular processes are medially orientated to permit both flexion/extension and rotational movements. C2 (axis) (**Fig. 57.1A**) is a more typical cervical vertebra and includes the odontoid peg, a superior bony extension of the vertebral body that lies behind the arch of C1. The largest spinous process in the spine is located at C2. There is a uniform morphology of cervical vertebrae from C3 to C7 (**Fig. 57.1B**), often called the subaxial spine. In this region the uncinate processes on the superior anterolateral aspects of the vertebral bodies articulate with a corresponding articulation of the vertebral body above. This articulation (the uncovertebral joint) aids rotation in the cervical spine. Thoracic spine vertebrae also exhibit a uniform morphology (**Figs. 57.1C** and **57.1D**) with long, inferiorly angulated spinous processes and facet joints that are vertically orientated. There are costovertebral joints from T1 to

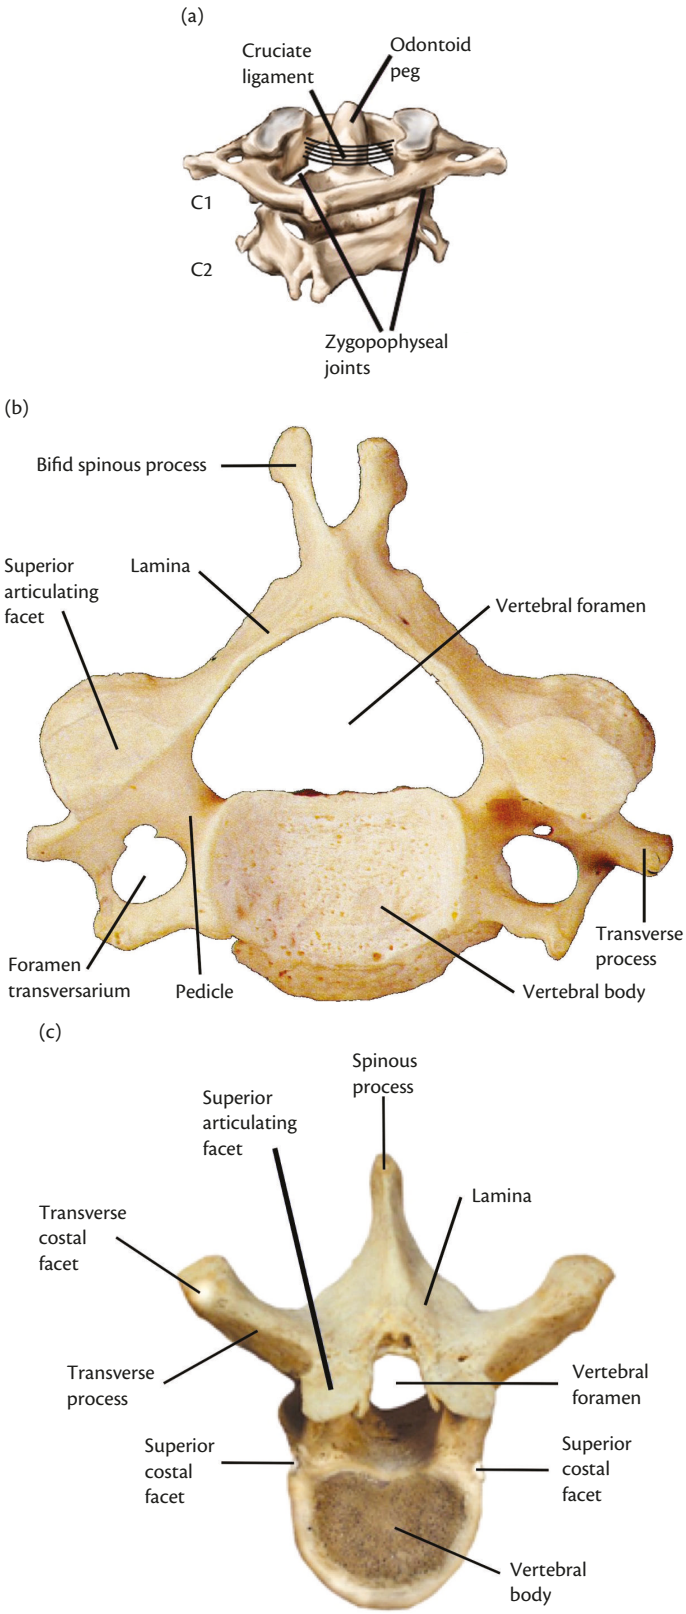

Fig. 57.1 Vertebral anatomy of (A) C1/C2 articulation; (B) axial view of a typical cervical vertebra; (C) axial view of a typical thoracic vertebra; (D) lateral view of a typical thoracic vertebra; (E) axial view of a typical lumbar vertebra; and (F) lateral view of a typical lumbar vertebra.

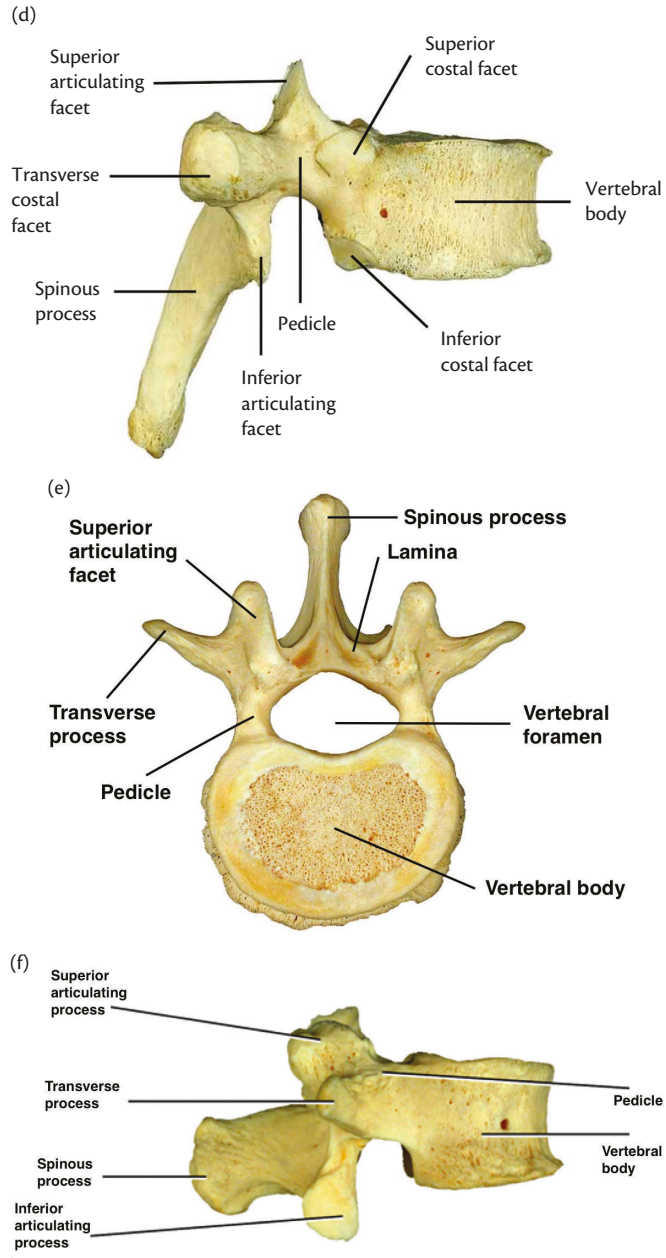

Fig. 57.1 Continued

T12 that provide an articulation between the vertebral body and the corresponding rib. There are also rib articulations on the transverse processes from T1 to T10. In this region the ribs, sternum, and intercostal structures provide extra stability. Lumbar vertebrae (Figs. 57.1E and 57.1F) have a stout, kidney-shaped body, straight spinous processes, and facet joints that are orientated in the sagittal plane.

Intervertebral disc

The intervertebral disc lies between the inferior end plate of the vertebra above and the superior endplate of the vertebra below. It is a composite structure with a central nucleus pulposus surrounded by a multiple layered annulus fibrosus (Fig. 57.2). It acts to transmit load,

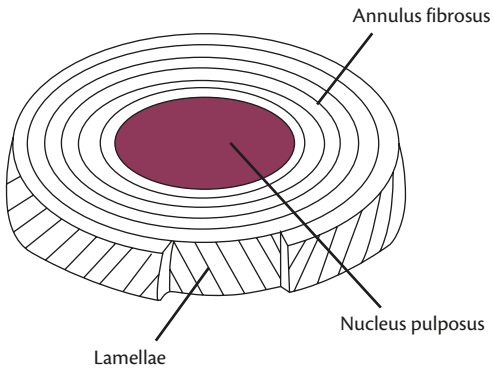

Fig. 57.2 Structure of the intervertebral disc.

allow movement, and provide stability. Axial load is transmitted effectively due to the structure of the disc. The nucleus is comprised mostly of water (80–90%), type 2 collagen, and multiple hydrophilic proteoglycans. The interaction between the annulus fibrosus and these proteoglycans leads to a unique hydrostatic structure. When the nucleus is loaded in compression water seeps out and the height of the disc is reduced, but the turgidity of the nucleus allows transmission of the force to the obliquely orientated fibres in the multiple layers (lamellae) of the annulus. The collagen fibres (type 1 collagen) are orientated at 60–70° to the vertical and this orientation alternates between each concentric layer. Fibres are connected to the cartilaginous vertebral endplates and to the cortical bone of the vertebral body walls (Sharpey's fibres). As the complex is loaded the fibres are placed under tension and this arrangement allows a multidirectional distribution of the tensile force and prevents formation of a cleavage plane through which the nucleus could herniate. The disc is poorly innervated and supplied by only sensory (mainly nociceptive) and postganglionic sympathetic (vasomotor efferent) nerve fibres.

The ability of the disc to resist axial compression decreases with age. The proteoglycan content of the nucleus changes and there is a decrease in the volume of water retained. Loss of disc height is observed alongside changes in the chemical composition of the nucleus due to sclerotic endplates impeding nutrient transfer. The orientation of the annular fibres resists tensile forces and is also effective at resisting rotation. However, they do not resist direct compression and as a result disc bulging is often seen on the concave side of a physiological or pathological curve of the spine. Asymmetric loading of the disc in a curved spine also leads to migration of the nucleus pulposus towards the convex side. Within a normal lumbar lordosis flexion therefore causes anterior compression of the annulus and a posterior migration of the nucleus pulposus. Disc bulges occur due to annulus compression and are often seen on magnetic resonance images of the spine. They should not be confused with a disc herniation where the nucleus pulposus is displaced from its normal anatomical location through a tear in the annulus to lie within the canal.

Posterior elements

The posterior elements include the laminae, spinous process, and bilateral facet joints. The posterior bony arch is formed by the laminae and provides protection for the neural elements within the canal. In the midline, the spinous processes provide a large surface area for ligamentous and tendinous attachments. The muscles and ligaments that attach onto the posterior elements act to move the spine and to provide global stability for the vertebral column. The spinous processes generally have a caudal orientation and this angulation increases in the cervical and upper thoracic spine. Less caudal angulation is seen in the thoracolumbar and lumbar regions. The spinous processes of C3-C6 are typically bifid.

The facet joints (apophyseal or zygapophyseal joints) are synovial plane joints between superior and inferior articulating processes on two adjacent vertebrae. The orientation of the joints varies in different regions of the spine and has a significant impact on the regional biomechanics. In the cervical spine the facet joints are orientated in the coronal plane. This produces the increased range of flexion-extension, lateral bending, and rotation observed in the cervical spine. In the lumbar region the orientation is in the sagittal plane and as such there is significant resistance to rotation but flexion-extension and lateral translation movements are still possible. There is an intermediate orientation in the thoracic spine providing multidirectional resistance to movement in this region. At the lumbosacral joint (L5/S1) the facet joints have a more coronal orientation and this is a factor in the lower incidence of anterior subluxation at this level. In the presence of intact facet joints, despite the vertical orientation of the disc space at L5/S1 a degenerative spondylolisthesis is more common at L4/5. During extension movements of the spine there is greater transfer of compressive load across the facet joints.

The size of the spinal canal varies throughout the column. It is most narrow in the thoracic spine with the T7 level showing the smallest cross-sectional area in most anatomical studies. The lumbar and cervical levels are more capacious. There can be a reduction in the canal diameter as a result of either pathological processes or normal ageing, processes that are more common in the cervical and lumbar spine due to the greater range of movement observed in these areas. Bulging of the annulus due to dehydration, overgrowth of facet joints due to osteoarthritis and folding in of the ligamentum flavum due to loss of disc height can narrow the canal in the lumbar spine. This can lead to the characteristic 'trefoil' appearance of the canal associated with lumbar spinal stenosis.

Anterior and posterior bony elements are connected by the pedicles. Variation in pedicle size and orientation is seen throughout the column and knowledge of this variation is critical in understanding the process of transpedicular instrumentation. Pedicle size is smallest at T4. On the lateral aspect of the column the transverse processes arise at the junction of the pedicle and the lamina. They provide points of attachment for the paraspinal muscles and therefore contribute to the control of movement and stability. Variation is seen in their angle of projection from the spine although this is largely in line with the orientation of the facet joints. The foramen transversarium lies in the transverse processes of the cervical vertebrae, and in C1 to C6 transmit the vertebral artery and vein. The foramina are present at C7 but the vertebral arteries lie outside of the foramen at this level.

Spinal ligaments and musculature

There are a large number of ligaments that provide stability to the spine including the interspinous ligaments, anterior and posterior longitudinal ligaments, ligamentum flavum, intertransverse ligaments, and capsular ligaments. The interspinous ligaments pass between the spinous processes at each level and provide significant

resistance to flexion due to their distance from the axis of rotation. The anterior longitudinal ligament (ALL) is a large ligament that runs from the skull base to the sacrum on the anterior aspect of the vertebral bodies. It has a strong attachment to the vertebral bodies but a weak attachment to the intervertebral discs. It is anterior to the axis of rotation and therefore resists extension. The posterior longitudinal ligament (PLL) is much smaller and passes from the clivus to the coccyx. It is significantly weaker than the ALL and provides limited resistance to flexion. It is considered to include two distinct layers (superficial and deep) and, in contrast to the ALL, it has a strong widened attachment at the level of the intervertebral disc and a loose attachment to the vertebral body. The tectorial membrane is a cranial extension of this ligament. The PLL acts as a constraint to herniation of the nucleus pulposus.

The ligamentum flavum extends from C2 to S1. It lies close to the axis of rotation and although it is has significant tensile strength, it offers relatively weak resistance to flexion of the spine. It is named after its yellow colour that occurs as a result of the high concentration of elastin. This prevents the ligament becoming lax in extension and buckling to narrow the canal diameter. It is deficient in the midline with a cleavage plane that allows safer access to the canal during midline decompression. The capsular ligaments also play a significant role in the maintenance of spinal stability, particularly in the cervical spine. The dura is anchored to surrounding structures throughout the spine by several epidural ligaments that appear to provide stability for the neural structures within the canal (Hoffman's ligaments) (Wadhwani et al., 2004).

The axial bones and the skull base are reinforced by several ligaments in addition to the ALL and PLL. The cruciate ligament consists of a small vertical portion running from C2 to the skull base and a more significant transverse portion that runs between the inside faces of the C1 lateral masses. This passes behind the odontoid peg and is essential for preventing C1/2 subluxation. The apical ligament is a weak ligament that runs from the tip of the odontoid peg to the skull base. It is thought to be of little functional significance but may contain notochord remnants. The alar ligaments run from the side of the odontoid peg to the skull base. These resist side movements of the head and limit rotation. Posteriorly the atlanto-occipital membrane runs from C1 to the skull base and the atlantoaxial membrane runs from C1 to C2. These membranes take the place of the ligamentum flavum in the axial spine.

Congenital variation in spinal anatomy

Congenital spine anomalies can be as a result of failure of segmentation or a failure of formation (McMaster and Ohtsuka, 1982). These are often seen alongside genitourinary, cardiac, or dysraphic anomalies, and can lead to development of a spinal deformity as the vertebral column grows. The resulting deformity can be three-dimensional, leading to a lateral deviation and rotational deformity (scoliosis), or an abnormal profile in the sagittal plane, leading to a hyperkyphosis or hyperlordosis. During growth, deformity can occur without congenital abnormalities and often there is no clear cause (idiopathic spinal deformity). Spinal deformity is covered in more detail in later chapters.

In the cervical spine multiple fused segments can be seen as a result of Klippel-Feil syndrome. This occurs either due to failure of formation or a failure of segmentation of the cervical somites at 3–8 weeks of gestation. Patients may present with the classic clinical triad of a low posterior hairline, short 'webbed' neck, and limited cervical range of movement (Kim, 2013). There may also be associated renal disease, congenital cardiac disease, brainstem anomalies, congenital cervical stenosis, and cervical scoliosis. Sprengel's deformity (an undescended scapula often associated with scapula winging, hypoplasia and omovertebral connections) is seen in 30% of patients with Klippel-Feil syndrome. Conservative treatment of any neck discomfort is the mainstay of therapy and surgical treatment is reserved for cases of spinal instability or neurological deterioration. Those affected with Klippel-Feil need to avoid collision sports and frequently develop degenerative cervical conditions in adult life.

Spinal biomechanics

Spinal biomechanics is the study of the structure and function of the spine when subjected to forces and displacements (Benzel, 2001). The functions of the spine can be static (protection of the spinal cord) or dynamic (provision of stability and mobility, and to control transmittance of movement to the upper and lower extremities). This section considers the normal movements of the spine and how the anatomical structures are adapted to balance stability and mobility as the spine is loaded.

Normal spinal movements

Flexion and extension occur primarily in the subaxial cervical and lumbar spine. There is approximately 15° permitted at C0/C1, 10° at C1/2, 7° at each level of the upper cervical spine and 20° in the lower cervical spine. In the lumbar spine the range of movement increases moving caudally to around 20° at L5/S1. In the thoracic spine flexion/extension movements are limited due to the splinting effect of the ribs. This increased range of flexion/extension seen in the cervical and lumbar spine is responsible for the higher rates of degenerative disease observed in these regions. Rotation is primarily in the cervical spine with 45° observed at C1/2. Between 7° and 10° of rotation is seen at each level from C2/3 down to T8/9. There is no rotation at C0/1 and very little in the lower thoracic and lumbar regions. Lateral flexion is more evenly distributed in the spine with approximately 5° at each level. C1/2 is the exception as there is no lateral flexion at this level.

Intrinsic stability

The interplay of anatomical structures within the spine confers intrinsic stability so that, despite the multisegmental structure, the vertebral column is relatively stable and can be held erect with only a small amount of muscle activity. The intervertebral disc does not permit a large amount of movement between levels and this is the case whether loaded or not, as the hydrophilic nature of the nucleus provides a 'preloading' effect with continuous tension on the fibres of the annulus. The resulting increase in disc height also has the effect of putting the longitudinal ligaments under tension. The mobile nature of the nucleus pulposus makes this a dynamic system where asymmetric loading produces migration of the nucleus away from the side loaded towards the convexity of the disc. These forces are also balanced by the posterior elements, particularly in flexion and extension movements. Given this inherent stability the most basic mechanical model for a spinal articulation is as a first-class lever; balanced forces around a fulcrum without

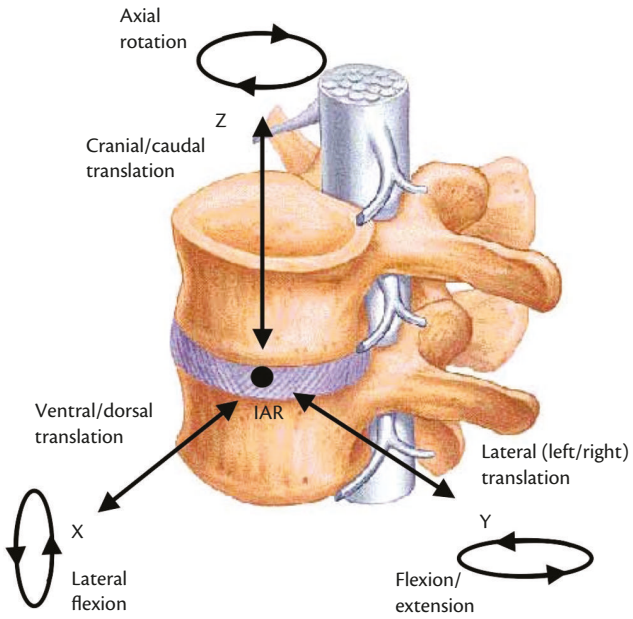

Fig. 57.3 Functional spinal unit showing the instantaneous axis of rotation and Cartesian coordinate system used to describe movement with six degrees of freedom.

gain in mechanical advantage. A lever may be considered as a simple rigid bar and the fulcrum is the point around which a lever rotates. In this model the fulcrum would be the apophyseal joints about which the elastic properties of the posterior ligaments and intervertebral discs are balanced.

Functional spinal unit

The functional spinal unit (FSU or motion segment) consists of two adjacent vertebrae with the intervening disc and associated ligaments (Fig. 57.3). It is the smallest anatomical spinal segment that can be considered to exhibit the biomechanical characteristics of the whole spine (White and Panjabi, 1990). Biomechanical testing of vertebrae has allowed us to understand the load and motion of individual FSUs and then whole spinal segments during normal activities and in pathological processes. Lumbar intervertebral discs are subject to 1–2.5 times body weight during normal walking (Huang et al., 2005). In the upright position approximately 80% of bodyweight is transferred through the anterior spine with the remainder being transferred through the posterior elements. Load transfer through the anterior spine is increased by flexion, while in extension load transfer increases in the posterior elements. During standing and loading of the column the anterior elements are compressed and the posterior elements provide anterior-posterior translational stability due to the vertical orientation of the facet joints in the lumbar spine. Spinal movements occur when an unbalanced force is applied to the FSU producing the basic movements of flexion, extension, lateral bending, and rotation.

Instantaneous axis of rotation

When forces act on an FSU a bending moment is produced and this causes a rotation or tendency to rotate about an axis. In the spine this is termed the instantaneous (helical) axis of rotation (IAR) and is defined as the point in space about which the vertebral body appears to rotate. The location of this is variable and depends on the vertebral level and motion of the spine. It generally lies posterior to the midline and inferior to the superior endplate. To describe movements around the IAR a standard Cartesian coordinate system is used with three axes—x, y, and z (Fig. 57.3). To consider this system in anatomical terms we identify these three axes as cranial/caudal, anterior/posterior (ventral/dorsal for neurological structures) and left/right. Both translation and rotation can occur about these axes and this produces 12 possible movements about the IAR, or six possible paired movements—'six degrees of freedom'. During spinal movements, the IAR of each spinal segment moves in a way analogous to movements of the nucleus pulposus—when an anterior bending moment is applied to an FSU the IAR moves in a posterior direction.

Load/deformation relationships

The mechanical models outlined earlier make the assumption that solid structures are rigid. In reality, no solid structure is truly rigid and this is certainly true for biological tissues. Hooke's law states that for small displacements the size of deformation is proportional to the force applied. This relationship occurs in the elastic phase of deformation for a material, where strain (change in length) totally recovers when the stress (force applied over an area) is removed. For larger displacements the elastic limit (yield point) of the material is reached and past this the linear relationship ceases to exist. This is termed the zone of plastic deformation and results in permanent change to the structure of the material so that strain would not fully recover when the stress is removed. This relationship is demonstrated in the stress-strain curve shown in Figure 57.4. Testing the structure to the point of failure will reveal the ultimate strength and the area under the curve is proportional to the energy absorbed before failure.

Bone, ligaments, and tendons all demonstrate a stress-strain relationship similar to that seen in Figure 57.4. However, they are also *viscolelastic* materials and so this relationship is both rate and time dependent. At lower loads application of a constant load results in viscous behaviour with progressive deformation over time, while at higher loads elastic behaviour is seen and progressive deformation does not occur. Viscoelasticity is apparent in the material properties of creep (progressive deformation over time when a constant load is applied) and stress-relaxation (progressive decrease in stress when a constant strain is applied). In addition, repeated loading can lead to different stress-strain curves with a net loss of energy (as heat), a property known as hysteresis.

Coupled movements

Movements in the spine are often coupled so that movement along one axis is linked to movement about another. This is mostly due to the orientation of the facet joints and is apparent in the cervical spine where lateral bending results in rotation of the spinal processes away from the concavity of the curve. The reverse is seen in the lumbar spine where lateral bending produces rotation of the spinous processes towards the concavity. This is an important concept to consider when understanding movements of the spine but is also key to the development of scoliotic deformities in the growing or degenerative spine. Here, lateral deviation leads to an obligatory rotation of the vertebral body creating the three-dimensional deformity which is seen clinically.

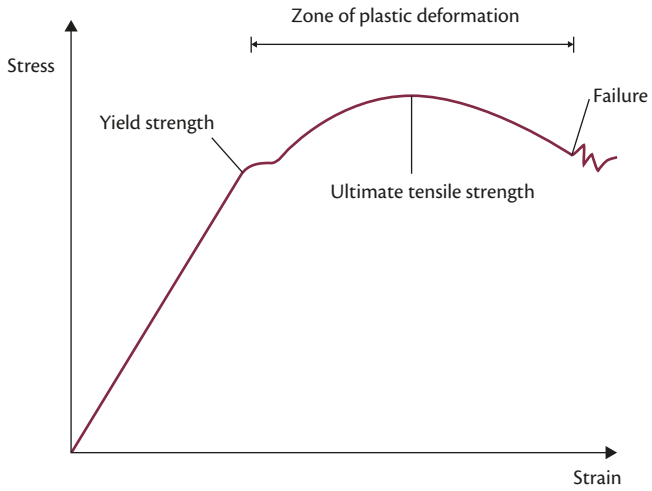

Fig. 57.4 Typical stress-strain curve for biological tissue.

Spinal stability

Clinical stability of the spine was described by White and Panjabi (1990) as 'the ability of the spine under physiological loads to limit patterns of displacement so as not to damage or irritate the spinal cord or nerve roots, and in addition to prevent incapacitating deformity or pain due to structural changes'. The application of this definition to clinical scenarios can lead to significant debate and this highlights the fact that varying degrees of stability can be seen depending on the mechanical or clinical situation. Panjabi (1992) also introduced the concept of the neutral zone for an individual FSU, the initial portion of the range of intervertebral motion during which there is minimal internal resistance. Within this range movement is not limited by the intrinsic stability at that vertebral level. When movement passes outside of this range the intrinsic stability leads to an increased stiffness and motion is limited. As clinicians, we are more often concerned with defining instability as this identifies situations where intervention might lead to improved outcomes.

Column theories

Identification of acute stability in a clinical setting has traditionally involved considering the spine as a series of columns. In 1963, Holdsworth described a two-column model to describe spinal fractures with an anterior column (vertebral bodies, intervertebral discs, ALL and PLL) that supported compressive loads and a posterior column (posterior elements) that resisted tension. In this series involvement of the posterior column suggested instability that might require stabilization. Prior to this, fractures had been described in terms of mechanism of injury. Denis developed the concept of a three-column theory in 1983, where the anterior column described by Holdsworth was divided into a middle column (posterior vertebral body, posterior annulus fibrosus and PLL) and an anterior column (anterior vertebral body, anterior annulus fibrosus, and ALL). He noted that consideration of the middle column was most useful in identifying the mechanism of injury and assessing stability (Holdsworth, 1963; Denis, 1983). More recent classification systems have further subdivided fractures according to the mechanism of injury and structures involved, and scoring systems have been developed to help identify where instability is present. These are discussed in detail in chapter 67.

Acute and chronic instability

An alternative method of categorizing instability is to consider the timescale over which instability occurs. There are no precise definitions for this but, as with most conditions, instability can be described as acute or chronic. Acute instability is most often seen following trauma but may also be seen where there is advanced degenerative disease, neoplasia, or infection. It can be further divided into overt, where there is a loss of integrity of all columns of the spine, and limited, where there is loss of integrity of the anterior or posterior columns in isolation. White and Panjabi (1990) developed a scoring system for acute clinical instability in the cervical, thoracic, and lumbar spine (Tables 57.1–57.3). Points are gained for both radiological loss of integrity and clinical evidence of pain or neurological compromise. A score of 5 or more indicates clinical instability. The system is comprehensive but complicated and is rarely used in clinical practice. In clinical practice we understand that there is a risk of delayed acute instability when muscle spasm occurs and the muscles act as an active stabilizer in the acute phase. When this spasm resolves at 10–14 days following an injury, instability may develop. This is apparent in the high risk of instability (10–45%) seen if patients receive long term follow up after cervical laminectomy. Almost all cervical injuries must be followed up with dynamic imaging for at least six weeks to ensure the spine remains stable.

Chronic instability is more difficult to define and usually involves a gradual progression of deformity that leads to physiological loading conditions causing undue pain or neurological irritation. This slow process can be described as 'glacial instability' with gradual progression of global deformity. Where there is excessive degeneration at a single level (due to degeneration, tumour, or infection) the affected level can be considered as a 'dysfunctional motion segment' and this contributes to chronic instability.

Table 57.1 Scoring system for acute instability in the cervical spine

Element	Point value
Anterior elements destroyed or unable to function	2
Posterior elements destroyed or unable to function	2
Positive stretch test	2
Radiographic criteria A. Flexion/extension X-rays 1. Sagittal plane translation >3.5 mm or 20% (2 points) 2. Sagittal plane rotation >20° (2 points) OR B. Resting X-rays 1. Sagittal plane displacement >3.5 mm or 20% (2 points) 2. Relative sagittal plane angulation >11° (2 points)	4
Abnormal disc narrowing	1
Developmentally narrow spinal canal 1. Sagittal diameter <13 mm OR 2. Pavlov's ratio <0.8[a]	1
Spinal cord damage	2
Nerve root damage	1
Dangerous loading anticipated	1

Global spinal alignment

The inherent stability of each motion segment confers a global stability on the vertebral column as a whole and allows the head to remain balanced above the pelvis with minimal muscle activity. Debousset (1994) described a 'conus of economy'—a narrow range in which the trunk remains balanced with minimal muscle action. Outside this range increased muscle activity is required to maintain an upright posture and this can lead to muscle fatigability and discomfort during standing and locomotion. In order to maintain a comfortable upright posture, the centre of gravity should fall between the feet while maintaining a horizontal gaze. This may not be the case where there is coronal or sagittal imbalance and over the last two decades interest in these concepts has increased dramatically.

The global sagittal alignment of the spine can be assessed using the sagittal vertical axis (SVA). This is the horizontal offset from a plumbline dropped from the C7 body to the postero-superior corner of the sacral dome (Jackson and McManus, 1994). SVA should be within 5 cm of this point. Imbalance is considered to be positive if the plumbline falls anterior to the sacral dome and negative if it falls posterior. The SVA provides a simple and quick measure of global sagittal balance but is highly sensitive to changes in posture and does not take into account the position of the pelvis. Assessment of coronal imbalance can be achieved in the same way by measuring the offset of the C7 plumbline to a line that bisects the sacrum in the coronal plane. Other measures of global sagittal balance have been described (spino-sacral angle, T1-pelvic angle, and the T1 and T9 spino-pelvic inclinations) and sagittal imbalance has been linked with poor clinical outcomes after spinal fusion surgery (Bess et al., 2016).

The relationship of the spine to the pelvis is more difficult to describe and there is considerable variation in pelvic morphology between individuals. Understanding this relationship is vital when attempting surgical correction of sagittal balance. The pelvic incidence defines the relative orientation of the sacrum with respect to the pelvis and is constant parameter during adult life (Duval-Beaupere et al., 1992). It is intimately related to the pelvic tilt and angle of slope of the sacrum (Fig. 57.5), following the formula:

$$\text{Pelvic Incidence (PI)} = \text{Pelvic Tilt (PT)} + \text{Sacral Slope (SS)}.$$

As PI is constant in adult life, changes in the SS due to global sagittal imbalance can be compensated by altering the PT but this affects the biomechanics of the lower limbs and can make standing uncomfortable. In asymptomatic adults the mean PI is 52 +/–10°, the mean PT is 13 +/–6°, and the mean SS is 41 +/–8° (Vialle et al., 2005). The pelvis should be considered to be a critical link between the spine and lower extremities and efforts to correct sagittal imbalance should include an assessment of these parameters and an attempt to restore the normal relationship of the spine and pelvis.

Table 57.3 Scoring system for acute instability in the lumbar spine

Element	Point value
Anterior elements destroyed or unable to function	2
Posterior elements destroyed or unable to function	2
Radiographic criteria A. Flexion/extension X-rays 1. Sagittal plane translation >4.5 mm or 15% (2 points) 2. Sagittal plane rotation >5° at L1–2, L2–3, and L3–4; >20° at L4–5; > 25° at L5-S1 (2 points each) OR B. Resting X-rays 1. Sagittal plane displacement >4.5 mm or 15% (2 points) 2. Relative sagittal plane angulation >22° (2 points)	4
Cauda equina damage	3
Dangerous loading anticipated	1

Bone diseases affecting spinal stability

Osteoporosis is a skeletal disease characterized by low bone mass per unit volume and deterioration of the microarchitecture of bone tissue, leading to enhanced bone fragility and a consequent increase in fracture risk (Consensus Development Conference, 1993). Diagnosis is made by estimating bone mineral density (BMD) using dual-energy X-ray absorptiometry (DEXA) scanning. Estimated density is compared to the mean for a healthy population and normal BMD is within 1 standard deviation of this mean. Osteopenia is considered 1–2.5 standard deviations below the mean, and osteoporosis is greater than 2.5 standard deviations below. Typically, two scores are given—a 'T score' where density is compared to a sex and race-matched healthy young adult population, and a 'Z score' where density is compared to an age, sex, and race-matched population.

Risk factors for developing osteoporosis include lifestyle factors (smoking, excess alcohol intake, low levels of physical activity, and

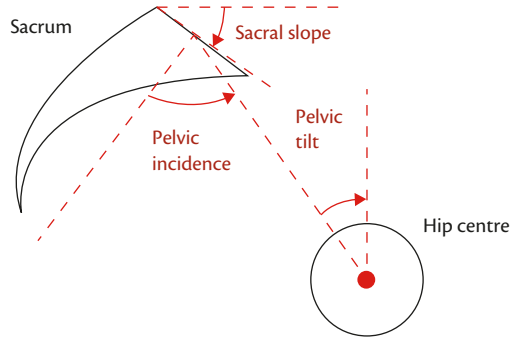

Fig. 57.5 Pelvic parameters affecting global spinal alignment.

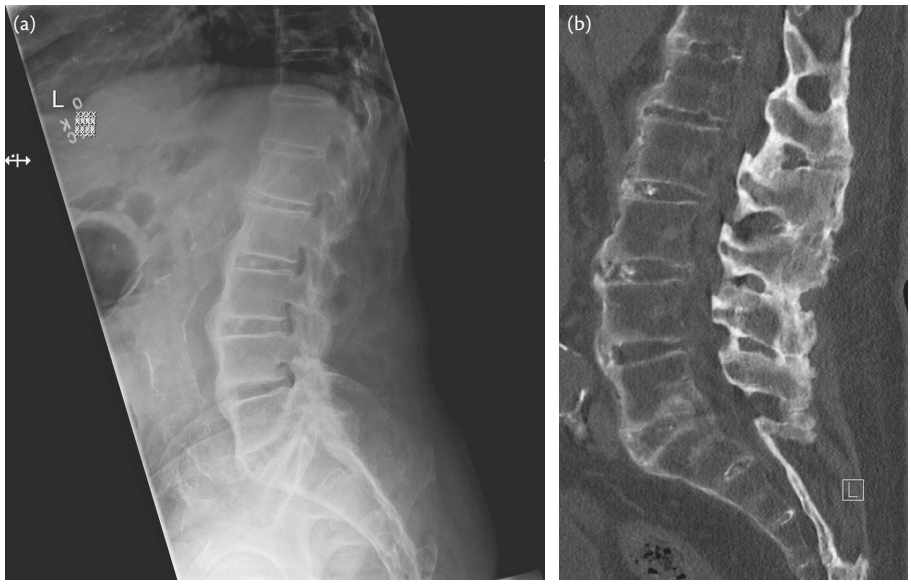

Fig. 57.6 (A) Lateral radiograph of the lumbar spine in a patient with ankylosing spondylitis showing the radiological features of vertebral squaring and vertical syndesmophytes and progressing to (B) midsagittal computed tomography (CT) scan in the same patient three years later showing almost complete ankylosis.

low body weight), family history, certain genetic polymorphisms, low calcium intake, low vitamin D levels, and medical history (corticosteroid use, thyroid conditions, malabsorption syndromes, chronic disease, e.g. rheumatoid arthritis, chronic liver and kidney disease, sarcoidosis, type 1 diabetes mellitus, and chronic obstructive pulmonary disease). Initial treatment should begin with lifestyle modification to reduce these risk factors and be focused on preventing fragility fractures, which can be associated with significant morbidity and mortality. Calcium and vitamin D levels should be checked and supplements taken if required. There are also several pharmacologic agents that have been shown to increase bone mineral density and reduce the risk of fragility fractures including bisphosphonates, conjugated oestrogen-progestin hormone replacement (HRT), oestrogen only replacement, and teriparatide.

In order to help guide which patients should be taking supplementation and pharmacologic agents the World Health Organization Collaborating Centre for Metabolic Diseases at Sheffield University developed the FRAX (Fracture Risk Assessment Tool) which includes the clinical risk factors and BMD at the femoral neck (Kanis et al., 2009). This score is available online and can be used to estimate the risk of a patient developing an insufficiency fracture. Medical treatment is recommended for postmenopausal women and men aged over 50 with:

- Hip or vertebral fractures
- T score between –1.0 and –2.5 PLUS
  - 10-year risk of hip fracture of 3% or more
  - 10-year risk of major osteoporosis fracture of 20% or more
- T score below –2.5

Ankylosing spondylitis

Ankylosing spondylitis is a spondyloarthropathy characterized by a positive HLA-B27 and a negative rheumatoid factor (RF) titre. Males are more commonly affected at a ratio of 4:1 and presentation is usually in the third decade of life. There is a genetic predisposition but the mode of inheritance is unclear. Back pain is a predominant feature from early in the disease and, as the clinical course progresses, spinal flexion deformity is seen with characteristic radiographic changes (squaring of the vertebrae, vertical syndesmophytes) (Fig. 57.6). An ascending ankylosis of the spine develops and the entire spine can become rigid. Advanced deformity in the cervical spine can lead to a 'chin-on-chest' appearance in this region and fractures are associated with a high rate of neurological injury and a high mortality rate.

Spinal tract anatomy

Overview

Extending from the foramen magnum as a continuation of the medulla oblongata to the superior lumbar region, the spinal cord is a broadly cylindrical highly organized collection of central nervous tissue and associated glial cells, enclosed by the protective vertebral canal. It is enlarged in the cervical and lumbar regions owing to the density of grey matter responsible for the motor function of the upper and lower limbs. The length of the cord is approximately 45 cm in males and 43 cm in females, and its terminal conus medullaris typically ends between the first and second lumbar vertebrae in adults, although this can vary (T12 to L3) (Saifuddin et al., 1998). During development, the spinal canal outgrows the spinal cord and hence the conus ascends from around L3–4 in newborns to the adult location by 10 years of age (Patten, 1996). From the apex of the conus medullaris extends a thinner fibrous band of modified pia mater, the filum terminale, which stabilizes the spinal cord via its coccygeal attachment. The spinal dura is a continuation of the meningeal layer of the cranial dura and this extends to cover the spinal cord and cauda equina. This whole structure is further stabilized at every vertebral level by dentate ligaments bilaterally. Functionally, the cord can be divided into 31 segments, each giving rise to bilaterally paired spinal nerves.

Blood supply to the spinal cord is via three arteries. The anterior spinal artery, arising from the two vertebral arteries, supplies the anterior cord, and receives input along its course from anterior segmental medullary arteries. Two posterior spinal arteries supply the posterior cord, typically arising from the vertebral arteries at the level of the medulla but occasionally arising from the posterior inferior cerebellar artery. They also receive supply from segmental medullary arteries. The artery of Adamkiewicz is the largest of the anterior segmental arteries to contribute to the anterior spinal artery, usually arising from the left side between the ninth to twelfth thoracic levels. Vascular spinal cord anatomy is covered in more detail in Chapter 64.

Cross-sectional architecture

In contrast to the organization of cranial nervous tissue, the grey matter of the spinal cord is centrally located, while white matter forms an external longitudinal layer (**Fig. 58.1**). When viewed in cross-section at any level, the grey matter resembles an H or butterfly-shaped region, bridged in the midline by the grey commissure with the central canal at its centre. This region can be divided into three 'grey columns': the anterior, posterior, and lateral columns. This grey matter has also been subdivided into a system of ten cytologically distinct layers known as Rexed laminae, progressing from lamina I to XII in a posterior to anterior direction. Rexed laminae X (the grey commissure and substantia gelatinosa centralis) corresponds to a pericentral canal of grey matter extending along the entire length of the spinal cord (Patestas and Gartner, 2016).

The anterior projection of grey matter is termed the ventral horn and conveys motor efferent information. It consists of large alpha motor neurons innervating extrafusal muscle fibres (namely Rexed lamina IX), smaller gamma neurons innervating intrafusal muscle fibres and a minority group of small interneurons (Rexed lamina VIII). Within Rexed lamina IX, motor neurons supplying extensor muscles are organized more anterior to those supplying flexor muscles.

The posterior projection (i.e. dorsal horn) receives sensory afferent information and is subdivided into several Rexed laminae (I to VI) specific to the nature of sensory information received. Most importantly, lamina II (substantia gelatinosa of Rolando) is the site of synapse between the first and second order neurones of the spinothalamic tract; lamina V deals with information from the cutaneous, muscle, joint, and visceral nociceptors, while lamina VI is involved in the simple spinal reflex of withdrawal from pain. Together, the neurons of these laminae (IV, V, and VI) constitute the spinothalamic tract.

The lateral column is a posterolateral projection of the anterior grey column present between the levels of T1 and L2 only and is concerned with preganglionic sympathetic autonomic activity. A less well-defined lateral column also reappears between the S2 and S4 segments, where it relays preganglionic parasympathetic autonomic activity.

Spinal cord tracts

These are the ascending and descending fibre tracts forming the white matter of the spinal cord. The major pathways are the sensory spinothalamic tract and dorsal (medial-lemniscal) columns and the motor corticospinal and extrapyramidal tracts.

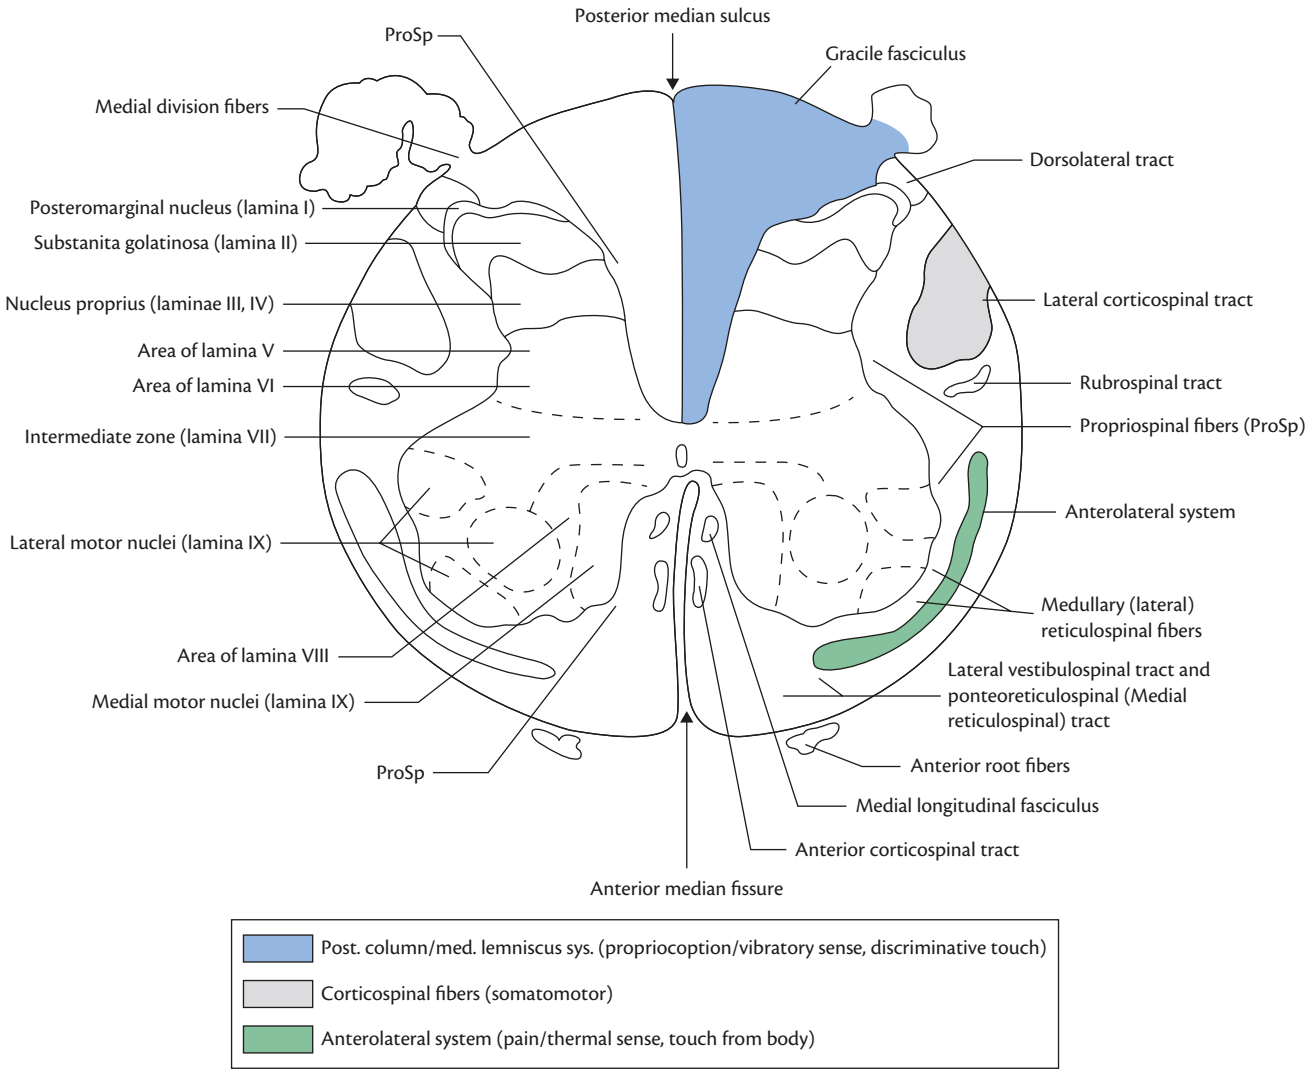

Fig. 58.1 Cross-sectional area of the thoracic spinal cord demonstrating the Rex lamina, ascending and descending tracts.
This image comes from: Figure 5.2, page 86, Haines DE, *Neuroanatomy: An Atlas of Structures, Sections and Systems*, 6th Edition, Lippincott Williams & Wilkins.

Spinothalamic tracts

Sensory information from the skin regarding pain and temperature is conveyed by the first order sensory axons of peripheral afferent neurones entering the cord within the dorsal roots. These axons enter the spinal cord via *Lissauer's tract* near the entry point of the posterior nerve roots where they ascend one to two segments to synapse with second order neurones in the substantia gelatinosa of Rolando (Rexed laminae II). These second order neurones decussate via the anterior commissure, within one or two spinal nerve segments above, to the anterolateral region of the contralateral spinal cord and ascend as the *lateral spinothalamic tract* via the rostral ventromedial medulla. They synapse in turn with axons of third order neurones in the ventral posterolateral nucleus (VPL) of the thalamus which relays information mostly to the sensory cortex in the postcentral gyrus.

An adjacent pathway, the *anterior spinothalamic tract*, conveys information regarding crude touch and pressure; the second order axons of this pathway also decussate through the anterior commissure to the anterior region of the contralateral spinal cord.

Pain and temperature sensation from the face is conveyed via the cranial nerves to the spinal trigeminal tract in the upper cervical spine, which is continuous with Lissauer's tract. The second order neurones involved decussate and ascend along with the lateral spinothalamic tract as the *trigeminothalamic (or quintothalamic) tract* to the ventral posteromedial (VPM) nucleus of the thalamus before synapsing with third order neurones that relay this information to the sensory cortex.

Within the substantia gelatinosa of the spinothalamic tract, which is continuous with the trigeminal nucleus, the sensation of pain is modulated further due to the many interactions that occur between second order afferent sensory neurones and other afferent neurones, interneurons, and descending neurones. Activation of thicker afferents conveying non-nociceptive sensation (light touch, vibration, and pressure) impedes transmission of painful stimuli via nociceptive afferents (A delta and smaller unmyelinated C fibres), through activation of inhibitory interneurons in the substantia gelatinosa (McCance and Huether, 2009). This interaction constitutes the basis of the gate theory of pain, which was proposed to explain why rubbing

a sore area can provide relief, and which is utilized by transcutaneous electrical nerve stimulation (TENS) devices. Spinothalamic tract fibres transmit information to the periaqueductal grey (PAG) in the midbrain via the *spinomesencephalic tract* which projects enkephalin-releasing neurones to the nucleus raphe magnus (NRM) in the midbrain. Serotonin neurotransmitter released from the NRM activates inhibitory interneurons within the substantia gelatinosa resulting in release of endogenous opioids (enkephalin or dynorphin); these bind to the mu-opioid receptors of nociceptive A delta and C afferent neurones. Occupation of mu-opioid receptors reduces release of substance P, and hence inhibits pain transmission (Patestas and Gartner, 2016).

Dorsal (medial-lemniscal) tract

The sensations of fine touch, vibration, and proprioception are conveyed from skin, muscles, and joints via first order axons of peripheral afferent neurones. The axons of these neurones ascend in the ipsilateral dorsal spinal cord uninterrupted as two tracts, the *fasciculus cuneatus* laterally (sensory information from the upper limbs) and the *fasciculus gracilis* medially (sensory information from trunk and lower limbs), to the lower medulla. There they synapse with axons of the second order sensory neurones of the nucleus cuneatus and nucleus gracilis, respectively. These axons decussate in the medulla as the *internal arcuate fibres* to form the *medial lemniscus*, which relays information to the VPL nucleus of the thalamus. There they synapse in turn with third order axons that project to the somatosensory cortex in the postcentral gyrus.

Corticospinal (pyramidal) tracts

Upper motor neurons (UMN) descend uninterrupted predominantly from the motor cortex (precentral gyrus) to the spinal cord. The majority (80–90%) of these decussate in the lower medulla at the level of the superior aspect of the C1 vertebral body before continuing on as the *lateral corticospinal tract.* The lateral corticospinal tract fibres primarily innervate the limb musculature.

Those fibres that do not decussate form the *anterior corticospinal tract* and cross through the anterior commissure at or a few levels above their functional level. This tract is present only in the upper cord, disappearing completely by the mid thoracic region. The anterior corticospinal tract carries fibres that innervate proximal and trunk muscles.

The fibres of both of these tracts innervate the lower motor neurons (LMN) of the contralateral ventral horn, usually known as the anterior horn cell, which gives rise to axons innervating the muscles of the trunk and upper and lower limbs.

Ascending *dorsal* and *ventral spinocerebellar tracts* fine-tune motor function further via proprioceptive sensory information from muscle spindles, Golgi tendon organs, and tactile and pressure receptors. These transmit information via primary afferent neurones terminating in the dorsal horn, which synapse with second order neurones conveying information directly to the cerebellum. The origin of the dorsal spinocerebellar tract primary neurones is known as Clarke's column (or nucleus dorsalis, Rexed lamina VII) at the T1 to L3–4 levels; from here, second order neurones ascend ipsilaterally to the cerebellum via the inferior cerebellar peduncle, whereas those of the ventral spinocerebellar tract decussate twice to reach the ipsilateral cerebellum via the superior cerebellar peduncle. The dorsal spinocerebellar tract processes information from the lower limbs. An analogous *cuneocerebellar tract,* consisting of axons rostral to Clark's column, which pass via the inferior cerebellar peduncle to the cuneate nucleus in the medulla, conveys information from the upper limbs (Latash, 2008).

Extrapyramidal tracts

The midbrain and brainstem give rise to other descending motor tracts which are modulated by the cerebral cortex, basal ganglia, and cerebellum.

Axons from the red nucleus in the rostral midbrain decussate immediately in the ventral tegmental decussation and descend as the *rubrospinal tract* in the lateral funiculus, ventrolateral to the lateral corticospinal tract, to terminate in the cervical spine. It receives afferents from both the cerebellum via the red nucleus and the cerebral motor cortex to modulate muscle movement and tone. Stimulation results in limb flexion and inhibition of limb extension (Snell, 2010).

The *medial* and *lateral reticulospinal tracts* arise in the reticular formation of the pons and medulla respectively and influence reflexes and motor function at all spinal levels. The reticular formation receives input from the red nucleus, vestibular nucleus, and basal nuclei, which are in turn influenced by the cerebellum. Axons of the former tract descend ipsilaterally to synapse upon alpha and gamma motor neurones, facilitating voluntary movement and increasing tone. Axons of the latter tract descend bilaterally to achieve the opposite, inhibiting movement and reducing tone.

The *medial vestibulospinal tract* receives input from the ipsilateral medial vestibular nucleus and descends as an extension of the medial longitudinal fasciculus to the cervical and upper thoracic cord only, influencing head movement and posture. It also stimulates lower motor neurones of the spinal accessory nerve. Ultimately it facilitates appropriate orientation in response to postural and balance changes. Largely under cerebellar control, the *lateral vestibulospinal tract* receives axons from the lateral vestibular (Deiter's) nucleus and descends ipsilaterally to terminate on alpha and gamma neurones at all spinal levels to modulate extensor motor function, in addition to contributing to the maintenance of posture through stimulation of lower limb extensors and inhibition of flexor muscles (Sengul and Watson, 2012).

The *tectospinal tract* is thought to influence posture in response to visual stimulation of the contralateral superior colliculus of the midbrain. Its axons project from the superior colliculus, decussate in the dorsal tegmental decussation, and descend to terminate in the cervical spinal cord (Rexed lamina VI, VII, and VIII).

Spinal autonomic function

Spinal autonomic function is divided into sympathetic outflow from T1–L3 and parasympathetic outflow from the S2–S4 segments (**Fig. 58.2**). Parasympathetic afferent and efferent pathways in the cranial nerves will not be covered in this section. Spinal autonomic outflow is essential in maintaining normal visceral function, including bowel, bladder, and sexual function, as well as homeostasis (**Figs. 58.3** and **58.4**).

Sympathetic nervous system

Sympathetic preganglionic axons exit the spinal cord from T1 to L3 to synapse in either the paravertebral ganglia at the same or adjacent

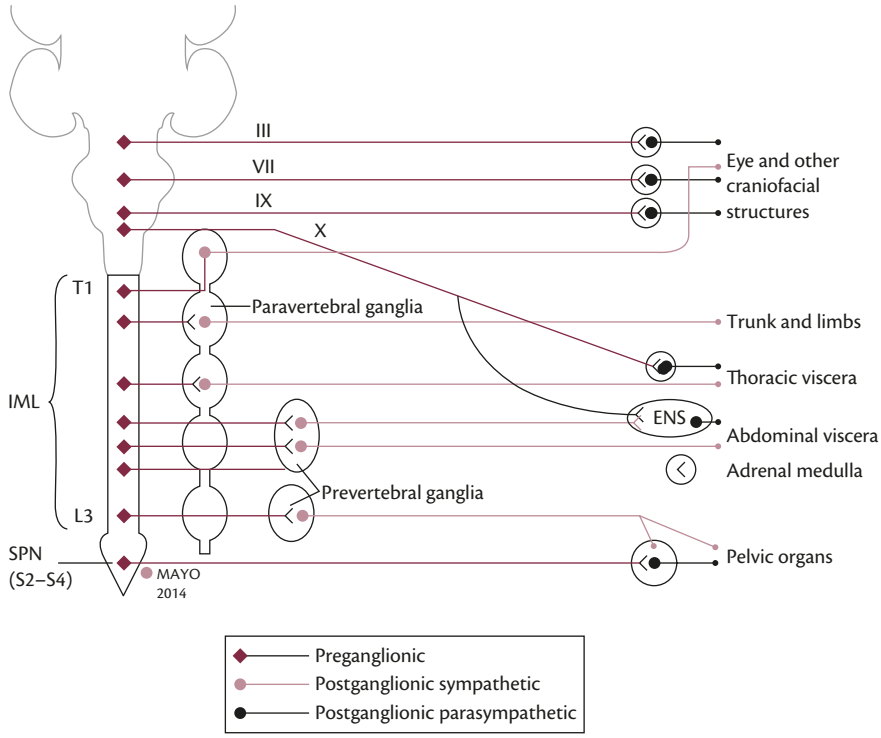

Fig. 58.2 The autonomic nervous system. IML, intermediolateral nucleus; SPN, sacral parasympathetic nucleus; ENS, enteric nervous system.

levels of the sympathetic chain or pass through the sympathetic chain to innervate the prevertebral ganglia and the adrenal medulla.

The paravertebral sympathetic postganglionic efferents innervate the face, trunk, limbs, and thoracic viscera. The prevertebral postganglionic sympathetic efferents innervate the abdominal and pelvic viscera. Preganglionic sympathetic neurons are cholinergic, postganglionic sympathetic neurons, except those innervating sweat glands are adrenergic.

Parasympathetic nervous system

The spinal parasympathetic outflow originates in the sacral parasympathetic nucleus (SPN), located between the levels of S2 to S4 and innervates the bladder, rectum, and sexual organs. Preganglionic and postganglionic parasympathetic neurons are cholinergic (Benarroch, 2006).

Spinal control of bladder function

The normal control of bladder function requires a contribution from the pontine micturition centre, which is in turn modulated by input from multiple supratentorial regions predominantly in the frontal lobes. This includes the anterior cingulate gyrus, preoptic hypothalamus, amygdala, bed nucleus, stria terminalis, and septal nuclei. The pontine micturition centre, via parasympathetic, sympathetic, and somatic afferent and efferent neurones coordinates the function of normal urinary storage, as well as micturition. Disruption in any of these pathways results in disturbed bladder function (Fig. 58.3).

Parasympathetic innervation of the bladder

Efferent preganglionic parasympathetic fibres originating from the S2–S4 roots synapse in the hypogastric plexus, where postganglionic fibres originate and go on to innervate the detrusor muscle and internal sphincter. The postganglionic parasympathetic innervation releases large amounts of acetylcholine at the onset of voiding that results in detrusor contraction and internal sphincter relaxation.

Afferent parasympathetic fibres, via the pudendal nerve convey distension of the bladder wall and internal sphincter. This is transmitted in myelinated Aδ-fibres which run in the intermediolateral column of the spinal cord.

Sympathetic innervation of the bladder

Efferent preganglionic innervation of the bladder originates from T9 to L2, via the pelvic nerves, hypogastric plexus, and hypogastric nerve to the inferior hypogastric ganglion. Postganglionic fibres innervate both the detrusor and internal sphincter, where noradrenaline release results in detrusor relaxation and internal sphincter contraction during the storage phase of micturition.

There is also a small contribution from sympathetic afferents running in the hypogastric nerves, which also convey the sensation of bladder distension.

Somatic innervation of the bladder

The external, or urethral sphincter is composed of striated muscle and therefore receives somatic efferents, originating in the S2–4 anterior horn cells, the motor neurones are in Onuf's nucleus (which also contains the parasympathetic nuclei) and are transmitted via the pudendal nerve.

Coordination of voluntary voiding

The storage phase of micturition requires relaxation of the detrusor muscle and contraction of the internal sphincter, via sympathetic

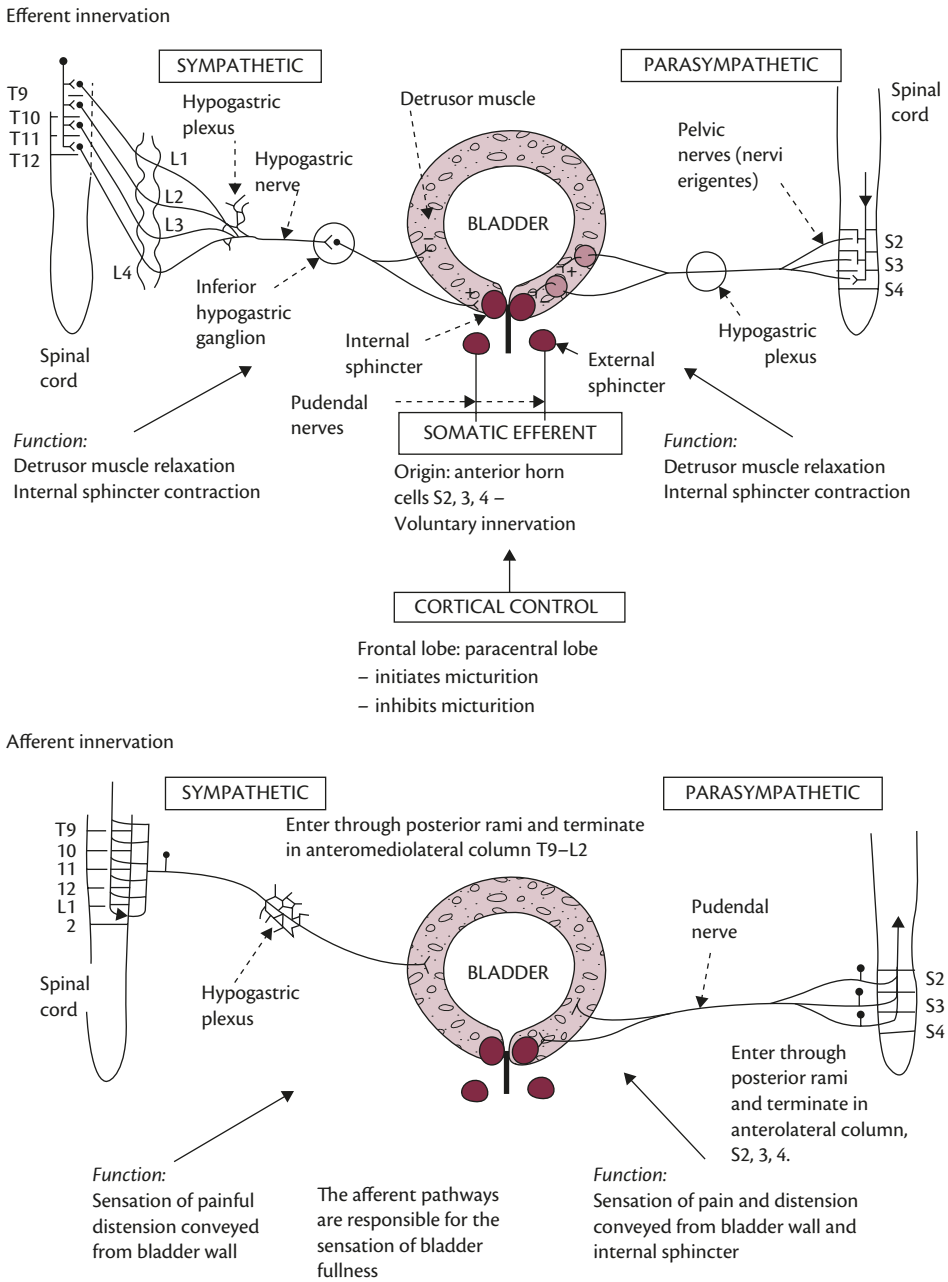

Fig. 58.3 Autonomic innervation of the bladder.

innervation as well as conscious inhibition of micturition and contraction of the external sphincter.

The initiation of voluntary micturition involves coordination of activity between the pontine micturition centre, sacral spinal cord, detrusor muscle, and both internal and external sphincters. Micturition is preceded by relaxation of the striated muscle of the external sphincter, mediated via the pudendal nerve and relaxation of the muscle of the internal sphincter, mediated via the parasympathetic outflow from the hypogastric plexus. The parasympathetic innervation from the hypogastric plexus also causes detrusor contraction and bladder emptying.

Voluntary inhibition and initiation of micturition is controlled from the paracentral lobule of the frontal lobe, and coordination of sphincter relaxation and detrusor contraction via the pontine micturition centre (Fowler et al., 2008)

Dysfunctional voiding

Patterns of dysfunctional voiding vary depending on the level of the lesion in the pathways controlling micturition.

Suprapontine lesions can result from focal frontal lobe pathology, or global neuronal degeneration in conditions such as Parkinson's disease. As a result, there is loss of the inhibition of the pontine micturition centre, which causes symptoms of urinary urgency, frequency, and nocturia.

Spinal cord injuries above the lumbosacral level show an early and late pattern of urinary dysfunction. In the early stages with the

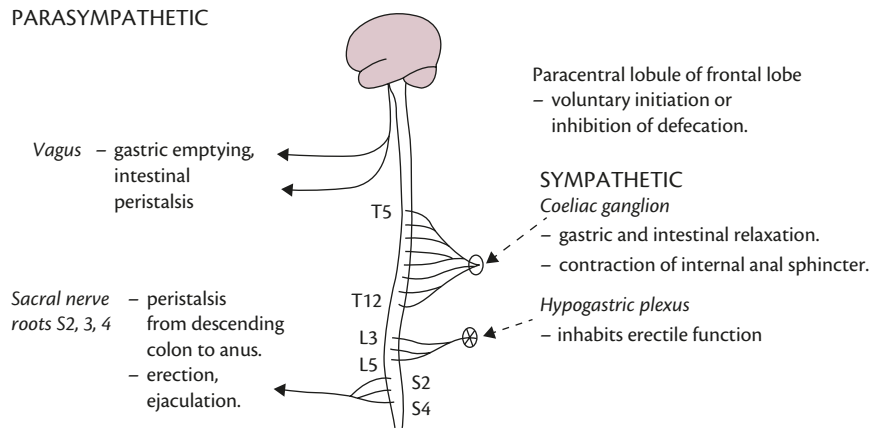

Fig. 58.4 Autonomic innervation of the bowel.

loss of supraspinal control of voiding patients develop an areflexic bladder and urinary retention. In later stages with a return of spinal reflexes there is automatic micturition; however, due to detrusor-sphincter dyssynergy, this is an inefficient process and patients are often required to intermittently self-catheterize.

Lumbar-sacral lesions affecting the cauda equina lead to a loss of bladder tone and painless bladder dilatation but due to the intact urinary sphincter sympathetic outflow there is urinary retention and dribbling overflow incontinence (Fowler et al., 2008; Lindsay et al., 2010).

Spinal control of bowel function

The parasympathetic innervation of the gastrointestinal tract up to and including the initial two-thirds of the transverse colon is via the vagus nerve. Parasympathetic innervations of the descending colon, rectum, anus, and internal anal sphincter originate from the anterior rami of S2–4 via the pelvic splanchnic nerves and subsequently inferior hypogastric plexus. Parasympathetic efferents cause contraction of the rectum, anal canal, and relaxation of the internal anal sphincter, assisting defecation (Fig. 58.4).

Sympathetic innervation of the lower gastrointestinal tract which is derived from T11–L2 results in rectal and anal canal relaxation and internal sphincter contraction, inhibiting defecation.

The external anal sphincter consists of striated muscle and is therefore under voluntary control. It is innervated via the pudendal nerve.

With rectal distension of faeces there is a cortical awareness of the need to defecate, causing a reduction in sympathetic tone, relaxation of the internal anal sphincter and pelvic floor. This is followed by the voluntary opening of the external sphincter and subsequent parasympathetic activity resulting in peristaltic contraction of the rectum and evacuation of faeces (Lindsay et al., 2010).

Spinal control of sexual function

The control of erection and ejaculation in males and the arousal response in females results from coordinated output from parasympathetic, sympathetic, and somatic innervations of the genitals.

Parasympathetic outflow originating from S2 to S4 pass via the pelvic plexus and form the cavernosal nerves. The cavernosal nerves innervate erectile tissue in the penis and clitoris.

Sympathetic genital innervation originating from L3 to L5 passes through the hypogastric plexus and passes via the hypogastric plexus to the paired hypogastric nerves.

Afferent genital innervation is via the pelvic and pudendal nerves in the sacral region and hypogastric nerves in the thoracolumbar region.

The process of penile or clitoral erection, vaginal lubrication, and ejaculation, with simultaneous inhibition of bowel and bladder function occurs from a coordinated increase in parasympathetic outflow and reduction in sympathetic inhibition.

Spinal control of blood pressure, glucose, and temperature

Thoracic sympathetic efferents, exiting via the T1–T12 roots are divided into three groups: thermosensitive, glucosensitive, and barosensitive. Hypothermia, hyperventilation, and emotional states result in predominantly cutaneous vasoconstriction via thermosensitive efferents. Glucosensitive efferents are activated in response to hypoglycaemia and exercise and result in the release of adrenaline from the adrenal medulla.

Activation of barosensitive efferents results in systemic constriction of resistant arterioles, other than those in the skin. Barosensitive efferents to the adrenals cause release of noradrenaline and renal efferents result in increased renin secretion, increased renal sodium absorption and blood flow (Guyenet, 2006).

Patterns of spinal cord injury

Spinal cord injury (SCI) is associated with almost half of all spinal trauma and may be classified as complete or incomplete (Teufack et al., 2012). Incomplete injuries are further subdivided according to the pattern of spinal cord involvement. It is therefore important for the clinician to understand the anatomy and physiology of the spinal cord for accurate diagnosis and correct decision-making (Wheeler

Table 58.1 Patterns of spinal cord injury

Injury type	Tracts affected	Clinical presentation
Complete	All	Complete loss of motor and sensory function, including sphincter function, below the level of injury
Anterior	Corticospinal tracts Spinothalamic tracts	Paralysis with loss of pain and temperature sensation below the level of injury
Central	Corticospinal tracts	Limb weakness with arms more affected than legs
Posterior	Dorsal columns	Loss of light touch, vibration, and joint position senses
Brown-Séquard	Corticospinal tract Spinothalamic tract Dorsal column	Ipsilateral loss of motor function and light touch, vibration, and joint position senses Contralateral loss of pain and temperature

and Fok, 2003; Krishna et al., 2014). Table 58.1 outlines the classical features of each.

Complete cord injury

This implies complete loss of spinal cord function below the level of the injury (i.e. ASIA A) due to complete cord transection, severe contusion, or haemorrhage to the cord (Wheeler and Fok, 2003). The loss of sensory and motor function following such an injury may not always directly correspond to the level of spinal trauma.

There is complete motor and sensory loss starting at the level of the injury due to loss of function to all the ascending and descending tracts. The autonomic nervous system may also be affected, as described next. However, due to ascending oedema as part of the pathophysiology of the injury, the patient may also exhibit reduced function for two to three levels above the actual injury level (e.g. patients with C6/7 dislocation may have complete loss of function below C6 with weakness of the shoulders and altered sensation in the upper arms). The deficits seen above the level of injury often improve with time, unlike the complete loss of function below. There is complete loss of perineal and perianal sensation and loss of anal tone due to loss of sacral efferents. The patient, if male, may also present with priapism on admission. This is a sign of autonomic dysfunction (loss of S2–4 parasympathetic outflow to the cavernous nerves) and is a predictor for extremely poor prognosis.

Autonomic dysfunction may also present as neurogenic shock or autonomic dysreflexia. The former manifests as bradycardia and hypotension due to loss of vasomotor tone. This is related to loss of thoracic sympathetic (barosensitive) outflow. As a result, it is seen in injuries above the level of T1 (although T6 is the major efferent and therefore disruption between T1 and T6 may also result in neurogenic shock). Autonomic dysreflexia occurs most commonly when the patient urinates or defaecates, resulting in uncontrolled hypertension. The management and significance of this will be described in the following chapters.

Incomplete cord injury

This implies that some function is maintained below the level of the injury (i.e. ASIA B to D) (Krishna et al., 2014). There may be no specific pattern to this diminished function, but a few conditions have been described for specific functional losses.

Anterior cord syndrome

This is most likely due to anterior spinal artery compromise with resulting cord ischaemia and infarction. The anterior spinal artery is a single vessel, originating from both vertebral arteries, which descend on the ventral part of the spinal cord to the level of the filum terminale and supplies both the anterior and lateral corticospinal tracts and the anterior and lateral spinothalamic tracts. It is augmented by multiple radicular arteries arising from the aorta, most notably the artery of Adamkiewicz which tends to enter from the left side between T9 and T12. Disruption of the artery or the contributory vessels will lead to ischaemia and infarction of the ventral spinal cord.

The corticospinal tracts and motor nuclei in laminae X are affected most and patients present with a dense paraplegia. The spinothalamic tracts are also involved although the dorsal columns are spared and this may lead to dissociated sensory loss (i.e. loss of pain and temperature but retained light touch, vibration sense, and proprioception). Prognosis is poor with only 10–20% of patients recovering function.

Central cord syndrome

This tends to occur in elderly patients with pre-existing cervical spinal canal stenosis suffering a hyperextension injury. It is postulated that this may be due to either contusion to the spinal cord or actual haemorrhage. Either way, there is disruption to the central area of the spinal cord, affecting mainly the corticospinal tracts but also the spinothalamic tracts and dorsal columns, depending on the extent of the injury.

The corticospinal tract is arranged topographically, with the proximal fibres (upper limbs) more medially and distal fibres (lower limbs) laterally. This results in a typical loss of motor function worse in the arms than the legs. The dorsal columns, however, are arranged with the lower limb fibres medially (tractus gracilis) and the upper limb fibres laterally (tractus cuneatus) and therefore sensory loss may not follow the same pattern as the motor dysfunction.

Posterior cord syndrome

This is very rare with only case studies in the literature and is included for completeness. There are two posterior spinal arteries, arising from their respective vertebral arteries (occasionally from the posterior inferior cerebellar arteries), with good collateral from segmental arteries, hence it is uncommon to see pure posterior cord injuries and infarction. The dorsal columns (both tractus gracilis and tractus cuneatus) alone are affected and patients present with loss of light touch, vibration sense, and proprioception but retained pain and temperature sensation.

Brown-Séquard syndrome

Hemisection of the spinal cord, most likely a result of penetrating spine injury, results in this syndrome. The three main tracts affected are the corticospinal tract, spinothalamic tract, and the dorsal columns.

The corticospinal tract and dorsal columns both decussate in the medulla before descending, hence the patient would get an ipsilateral loss of motor power and light touch, vibration sense, and proprioception. The spinothalamic tract, on the other hand, decussates in the spinal cord and the patient would therefore have a contralateral loss of pain and temperature. However, the spinothalamic tract does not decussate horizontal, but rather over several levels. This means an injury at a particular level would affect the decussated fibres from two to three levels caudal, but also the non-decussated fibres at the level of injury.

Medical pathologies of the spinal cord

Chris McGuigan, Karen O'Connell, Eavan McGovern, and Iain McGurgan

Introduction

Medical pathologies of the spinal cord can present in an acute, subacute, or chronic manner, often mimicking neurosurgical presentations. A neurosurgical opinion may be sought prior to the involvement of a physician or neurologist and therefore it is important that neurosurgeons have knowledge of common medical conditions that can affect the spinal cord and recognize some examination findings that may assist in the diagnosis, thereby avoiding unnecessary investigations or interventions.

This chapter will discuss common symptom presentations that mimic surgical spinal pathologies including acute spastic paraparesis and acute flaccid paralysis. The chapter also covers medical disorders of anterior horn cells, nerve roots, peripheral nerves, the neuromuscular junction, or muscles which can be confused with neurosurgical disorders with focal presentations.

Section 1: Acute spastic paraparesis/tetraparesis

Acute spastic tetra/paraparesis with a medical aetiology is most commonly caused by inflammation of the spinal cord, usually referred to as transverse myelitis (TM), a term first used by Suchett-Kaye in 1948 (Suchett-Kaye, 1948) to describe a case of postinfectious myelitis. It is clinically characterized by acute or subacute motor, sensory, or autonomic spinal cord dysfunction. Transverse myelitis is often secondary to other primary neurological or systemic conditions including multiple sclerosis or neurosarcoidosis. In children, the most common cause is a postinfectious or postvaccination autoimmune phenomenon. Transverse myelitis may be idiopathic in 15–30% of cases.

The estimated incidence ranges from 1.3 to 8 cases per million (Bhat et al., 2010) with higher rates when demyelinating disorders such as multiple sclerosis are included. Prognosis is highly variable and usually dependent on the underlying cause with most of the recovery seen in the first three months, but symptoms may continue to improve for up to a year after the initial presentation. Signs of spinal shock (severe weakness, hypotonia, and areflexia) may be present at onset rather than the usual upper motor neurone signs and are associated with a poorer outcome.

Clinical findings

Transverse myelitis is an all-encompassing term and thus clinical symptoms and severity can vary, depending on the size and location of the lesion. Typical symptoms include any, or a combination of, weakness, numbness or altered sensation, pain, ataxia, and bladder or bowel dysfunction. Careful history taking often reveals that symptoms typically evolve over hours to days rather than having maximal severity at onset. In the acute phase it is often clinically indistinguishable from other causes of acute myelopathy including compressive lesions and warrants prompt urgent imaging and assessment.

Symptoms are usually bilateral but not always symmetrical; for instance in the classic Brown-Séquard syndrome with a hemi cord lesion the patient has ipsilateral motor weakness and contralateral sensory disturbance. The weakness is commonly associated with hyperreflexia and extensor plantars pointing towards a central cause. Clinicians should be mindful, however, that in the early phase of the disease there may be a flaccid paralysis and diminished deep tendon reflexes mimicking peripheral nervous system disorders such as Guillain–Barré syndrome. A well-defined sensory level is common, and can help distinguish between spinal or cerebral lesions. Often the sensory level is clinically many segments below the actual spinal lesion and this needs to be considered when ordering subsequent imaging studies, for instance, a sensory lesion at T5 may be the result of a cervical myelitis and therefore imaging of the whole cord above the sensory level should be considered. This is particularly relevant for the neurosurgeon seeking to exclude cauda equina syndrome in the patient with bladder disturbance. Neuropathic pain can present as a 'band-like' or tight sensation around the chest or abdomen offering further clues that the cause is spinal in origin.

Diagnosis and investigations

The diagnosis should be suspected when there is a clinical history of an acute or subacute onset of spinal sensorimotor or autonomic dysfunction where a compressive lesion has been ruled out. There needs to be evidence of underlying inflammation either on magnetic resonance imaging (MRI) (Fig. 59.1) or lumbar puncture (always performed after imaging) making MRI and lumbar puncture essential to establishing the diagnosis. Diagnostic criteria for idiopathic acute transverse myelitis have been proposed and are outlined in Table 59.1. Other tests are directed towards identifying the underlying cause.

Fig. 59.1 Sagittal T2 MRI of cervical spine showing short segment lesions consistent with demyelination.

Causes of transverse myelitis

Transverse myelitis can be associated with autoimmune, infectious, paraneoplastic, systemic inflammatory or multifocal neurological conditions. The paragraphs that follow outline some of the key features of the more commonly associated conditions.

Table 59.1 Criteria for idiopathic acute transverse myelitis

Inclusion criteria	Exclusion criteria
Development of sensory, motor, or autonomic dysfunction attributable to the spinal cord	History of previous radiation to the spine within 10 y
Bilateral signs and/or symptoms (though not necessarily symmetric)	Clear arterial distribution, clinical deficit consistent with thrombosis of the anterior spinal artery
Clearly defined sensory level	Abnormal flow voids on the surface of the spine c/w AVM
Exclusion of extra-axial compressive aetiology by neuroimaging (MRI or myelography, CT of spine not adequate)	Serologic or clinical evidence of connective tissue disease (sarcoidosis, Behçet's disease, Sjögren's syndrome, SLE, mixed connective tissue disorder, etc.)[a]
Inflammation within the spinal cord demonstrated by CSF pleocytosis or elevated IgG index or gadolinium enhancement. If none of the inflammatory criteria is met at symptom onset, repeat MRI and lumbar puncture evaluation between 2 and 7 days following symptom onset meet criteria	CNS manifestations of syphilis, Lyme disease, HIV, HTLV-1, Mycoplasma, other viral infection (e.g. HSV-1, HSV-2, VZV, EBV, CMV, HHV-6, enteroviruses)[a]
Progression to nadir between 4 h and 21 d following the onset of symptoms (if patient awakens with symptoms, symptoms must become more pronounced from point of awakening)	Brain MRI abnormalities suggestive of MS[a]
	History of clinically apparent optic neuritis[a]

[a] Do not exclude disease-associated acute transverse myelitis.

Reproduced with permission from Transverse Myelitis Consortium Working Group, Proposed diagnostic criteria and nosology of acute transverse myelitis, *Neurology*, Volume 59, Issue 4, pp. 499–505, Copyright © 2002 Wolters Kluwer Health, Inc.

Multiple sclerosis

Transverse myelitis may occur at any time in those with a diagnosis of multiple sclerosis (MS) or as the first ever neurological event (clinically isolated syndrome) as outlined in **Box 59.1**. The L'hermitte sign, characterized by an electric shock sensation radiating down the spine or limbs and usually brought on by neck flexion (extension of a dorsal column lesion), is considered one of the clinical hallmarks of demyelinating disease and should raise suspicion for MS or neuromyelitis optica spectrum disorder (see next). In MS, spinal lesions seen on MRI are usually short, typically spanning one vertebral segment or less (**Fig. 59.1**). They tend to be located in an eccentric, dorsal, or lateral position, and usually involve less than half the cord. The diagnosis may be also be supported by evidence of cerebral demyelination on MRI brain (**Fig. 59.2**) and positive oligoclonal bands on cerebrospinal fluid analysis.

Neuromyelitis optica spectrum disorders

Neuromyelitis optica (NMO) is an inflammatory condition affecting the central nervous system distinct from MS. It classically involves the optic nerves and spinal cord manifesting as recurrent episodes of optic neuritis and myelitis. It is associated with serum aquaporin-4 immunoglobulin antibodies. In contrast to MS, lesions are usually longitudinally extensive spanning more than three segments and are centrally located within the cord. In the acute phase there may also be evidence of cord oedema. The prognosis is usually not as good as for multiple sclerosis as individual attacks are more likely to result in permanent disability with 50% of patients requiring assistance with walking and blind in at least one eye five years from diagnosis (Wingerchuk and Weinshenker, 2003).

A proportion of patients presenting with recurrent episodes of optic nerve or spinal inflammation have a clinical phenotype consistent with neuromyelitis but is negative for aquaporin-4 IgG. The term neuromyelitis spectrum disorders (NMOSD) has been developed to encompass those with and without aquaporin-4 IgG antibodies but with a consistent clinical phenotype (Wingerchuk et al., 2015). Detection of myelin oligodendrocyte glycoprotein (MOG) antibodies accounts for approximately 20% of NMO aquaporin-4 antibody negative cases of NMOSD and tends to have a more favourable clinical course with preponderance of short segment lower spinal cord lesions on spinal MRI (Sato et al., 2014).

Box 59.1 Case 1

A 23-year-old girl with no past medical history, presented to the emergency department complaining of progressive weakness of both her legs and a numb sensation extending up her legs to her chest over the last four days. She also noticed she had difficulty passing urine. On exam she had reduced power (grade 4/5) in both her legs more marked on her right than her left, with brisk deep tendon reflexes and extensor plantar responses bilaterally. She also had reduced pinprick sensation to T6. On flexion of her neck she described an 'electric shock' sensation radiating down both arms and her back. Spinal MRI demonstrated an enhancing lesion at C6. Subsequent MRI brain showed a number of non-enhancing lesions in a typical distribution for demyelination. Lumbar puncture revealed positive unmatched oligoclonal bands. These findings supported the diagnosis of clinically isolated syndrome likely as a first presenting event of multiple sclerosis.

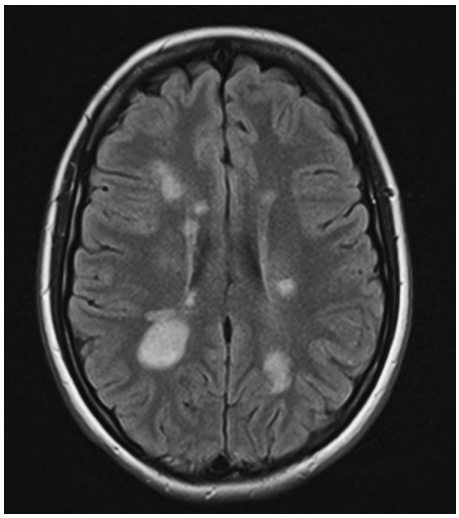

Fig. 59.2 Axial T2 FLAIR of brain showing multiple periventricular lesions consistent with demyelination, typical of multiple sclerosis.

Neurosarcoidosis

Sarcoidosis is an immune-mediated multisystem disease characterized by the presence of non-caseating granulomas. It can affect the nervous system in approximately 10% of cases. Patients usually have a prior history of systemic sarcoidosis or evidence of systemic involvement is found on subsequent investigations. Isolated neurosarcoidosis is rare. The most common manifestation is cranial neuropathies but spinal cord involvement is not uncommon and is usually associated with a worse outcome as a result of spinal cord atrophy and residual disability (Sohn et al., 2014). The most common site is the cervicothoracic spine, with most intramedullary lesions extending over three segments. In 50%, leptomeningeal enhancement is also seen (Fig. 59.3). Box 59.2 outlines a less common presentation with involvement of the cauda equina and conus medullaris. When compared to NMO onset, neurosarcoidosis is usually more gradual and patients may have coexistent radiculopathy or cranial neuropathy suggesting more diffuse central nervous system (CNS) involvement. Definitive diagnosis relies on a biopsy of CNS tissue but given associated morbidity, most patients are diagnosed with probable disease if there is pathological evidence of extraneural involvement, in combination with a compatible neurological syndrome.

Fig. 59.3 Post IV gadolinium sagittal lumbar spine MRI T1 demonstrates diffuse, nodular, leptomeningeal enhancement of the conus medullaris and cauda equina due to sarcoidosis.

Box 59.2 Case 2

A 39-year-old lady presented to the neurology service with a 6-month history of progressive walking difficulty requiring a crutch to mobilize and, recurrent urinary tract infections and constipation. She had been diagnosed with pulmonary sarcoidosis 5 years previously for which she did not require any treatment. On examination she had evidence of bilateral lower limb weakness more marked proximally (grade 4/5) and reduced pinprick sensation extending to L2 level bilaterally. Reflexes were reduced and plantar responses were flexor. She had an urgent MRI spine (Fig. 59.3), which revealed extensive leptomeningeal enhancement of the cauda equina and conus medullaris in keeping with neurosarcoidosis. She was given a diagnosis of probable neurosarcoidosis based on previous pathological evidence of pulmonary sarcoidosis in combination with her clinical and radiological findings.

Connective tissue disorders

Systemic lupus erythematous (SLE) and Sjögren syndrome may also present with transverse myelitis and should be included in the differential diagnosis. Lesions usually extend over multiple segments similar to NMO. Screening for autoantibodies including ANA, anti-Ro, and anti-La may aid diagnosis.

Paraneoplastic disorders

These are extremely rare causes of inflammatory myelitis. There will usually be diffuse CNS involvement with evidence of encephalitis, movement disorders, or seizures. Myelitis in isolation is rare and typically has a much more insidious course compared to other causes of transverse myelitis. There are a number of onconeuronal antibodies, which can be screened for, and their neurological presentation usually precedes the diagnosis of the underlying tumour.

Treatment

Patients can be treated empirically with high dose corticosteroids if they are felt to have inflammatory myelopathy. Further treatment is tailored towards the underlying cause.

Section 2: Acute flaccid paralysis

Medical conditions causing acute flaccid paralysis may be confused with cauda equina syndrome and causes of spinal shock. When assessing a patient with acute onset of limb weakness a careful history and examination can help distinguish medical and surgical causes and often an anatomical approach to localizing the level of the pathology can establish the likely cause.

Differential diagnosis based on anatomical location

Box 59.3 describes a woman presenting with acute flaccid paralysis, areflexia, and an antecedent history of a diarrhoeal illness. The most common medical cause of this presentation is Guillain–Barré syndrome (GBS) (Marx et al., 2000). The differential diagnosis for medical causes of flaccid paralysis is broad and may be considered by anatomical location (Table 59.2).

Box 59.3 Case 3

A forty-two-year-old woman was admitted to hospital with symmetrical bilateral limb weakness, ten days following consumption of undercooked chicken and a brief diarrhoeal illness. Examination revealed a sinus tachycardia (110 bpm), flaccid weakness, and areflexia of the lower limbs. There was evidence of bilateral facial weakness on assessment of the cranial nerves. Of note, there was no sensory level present on examination of pin prick sensation. Initial blood investigations were normal. MRI of the brain and spine was normal. Lumbar puncture was performed and cerebrospinal fluid (CSF) analysis demonstrated a normal cell count and glucose level, with an elevated protein concentration.

Complete or anterior spinal cord

Acute complete transverse myelitis may initially present as 'spinal shock', as discussed earlier. During this period, paradoxical motor signs present with flaccid paralysis and absent deep tendon reflexes.

It is important to consider an anterior spinal cord infarction if the flaccid paralysis is abrupt in onset and painful. Causes of this presentation include atherosclerosis of feeder vessels (artery of Adamkiewicz), aortic dissection, and aortic surgery. Rarer possibilities are thrombosis of the anterior spinal artery, vasculitis, and infective endocarditis.

Anterior horn cell

Certain viruses have a predilection for the anterior horn cell of the spinal cord and may result in a flaccid paralysis. They include enteroviruses (polio virus, enterovirus 71, group B coxsackie virus), flavivirus (West Nile virus, Japanese encephalitis), and rhabdovirus (Rabies virus) (Berger, 2012). Enteroviruses are easily spread and transmitted via respiratory and gastrointestinal secretions. West Nile virus is the most likely flavivirus to cause flaccid paralysis. It is transmitted via mosquito bite and is highly prevalent in the United States (Davis et al., 2006). Rabies virus is transmitted via bats, small animals, and dogs. One-third of infected patients present with 'paralytic rabies' and a clinical presentation of acute flaccid paralysis (Yousaf et al., 2012).

Motor neurone disease (MND) is clinically heterogeneous and is characterized by progressive degeneration of motor neurons. The typical clinical presentation is that of a progressive motor syndrome with clinical evidence of upper and lower motor neuron signs (Turner and Talbot, 2013). It can, however, present as a lower motor neuron-predominant picture. Subtypes of MND with a predilection for the anterior horn cell include progressive muscular atrophy and flail leg syndrome (Ludolph et al., 2015). Clinically, motor neurone disease can present with a foot drop or seemingly focal weakness so a thorough clinical examination looking for mixed upper and lower motor neurone signs and evidence of bulbar dysfunction should be completed. A compressive cervical myelopathy with an incidental peripheral neuropathy in the same patient may mimic mixed upper and lower motor neurone signs hence cervical spine imaging is typically performed in the diagnostic work up for MND.

Peripheral nerve

Guillain–Barré syndrome, as described in the aforementioned case, is the most common medical presentation of flaccid paralysis. If the clinical symptoms continue to deteriorate after eight weeks, one should consider chronic inflammatory demyelinating polyneuropathy. Lyme disease is transmitted by the ixodes tick and is endemic to North America, Europe, and Asia (Solomon and Shapiro, 2014) Clinically, it can cause a polyradiculopathy and may also involve the lower motor division of the facial nerve.

Certain viruses directly invade the spinal nerve roots and peripheral nerves (HIV, CMV, VZV, EBV). Porphyria, although rare, may present as a flaccid paralysis, but tends to be asymmetrical. This condition is typically preceded by abdominal and psychiatric symptoms.

Neuromuscular junction

Neuromuscular conditions such as myasthenia gravis and botulism can present with flaccid weakness. However, associated features such as fatigable weakness, cranial nerve involvement, and pupillary involvement assist in excluding neuromuscular conditions as a potential diagnosis.

Muscle

Acute myositis may present following a recent viral illness. Clinically, the weakness is associated with pain in the involved muscles and there may be an associated fever. Acute hypokalaemic periodic paralysis presents with weakness following exertion and a carbohydrate-rich meal. Frequently there is a positive family history; two-thirds of cases are autosomal dominant (Maurya et al., 2010).

Differential diagnosis based on history

An important initial step in evaluating this clinical scenario is a detailed clinical history. Questions to consider when taking the history include; recent travel history (polio-endemic areas, travel to the United States), antecedent infection (upper respiratory or gastrointestinal infective symptoms), insect or animal bites (tick or dog-bite), recent vaccination (H1N1 influenza vaccination), vascular risk

Table 59.2 Differential diagnosis of acute flaccid paralysis

Complete/Anterior spinal cord	Anterior horn cell	Peripheral nerve	Neuromuscular junction	Muscle
Transverse myelitis *(HSV, EBV, VZV, M. pneumonia)*	Enterovirus *(Polio virus, Enterovirus-71)*	Lyme disease, Tick paralysis	Botulism	Acute myositis
Vascular *(Anterior spinal artery syndrome)*	Rhabdovirus *(Rabies virus)*	Viruses *(HIV, CMV, EBV, HSV)*	Myasthenia gravis	Periodic paralysis *(Acute hypokalaemic periodic paralysis)*
	Herpes virus *(HSV2)*	Porphyria	Critical care	

factors (previous stroke/TIA) and family history (familial hypokalaemic periodic paralysis). In this case, the patient had a prodromal diarrhoeal illness and subsequently tested positive for campylobacter jejuni infection. Campylobacter jejuni is the most commonly associated infection with GBS and is observed in 30% of cases, often with onset of neurological symptoms after 10 days (Poropatich et al., 2010).

It is also important to consider symptom evolution when considering the differential diagnosis. Weakness, that is maximal at onset, without further evolution, is likely to be vascular (anterior spinal artery occlusion). Whereas, weakness that evolves gradually, over days to weeks, is more likely due to an inflammatory, immune-mediated, or an infectious process. A more slowly progressive course, evolving over months, should prompt consideration of a neurodegenerative condition, such as MND.

Differential diagnosis based on examination findings

Examination findings can provide useful clues to help to narrow the differential diagnosis further. Abnormal vital signs (increased temperature, hypotension) can assist in identifying a potential infectious cause of flaccid paralysis.

Autonomic instability, as noted in the aforementioned case, frequently presents in GBS. Patients presenting with complete transverse myelitis will have autonomic dysfunction below the level of the lesion, as described earlier. The absence of a sensory level on examination in the earlier case was useful. If present, one might consider transverse myelitis. Bladder involvement may also be observed in the latter. It is important to inspect for a rash on examination and to enquire about evidence of a preceding rash from the clinical history. Erythema migrans is the most common clinical manifestation of Lyme disease (Solomon and Shapiro, 2014). It typically appears at the site of the original tick bite, one to two weeks later. It may resemble a bull's eye with a central area of erythema, surrounded by a halo. A vesicular rash in the buccal mucosa and on the hands and feet suggests enterovirus-71, whereas, rash in a dermatomal distribution is suggestive of herpes zoster.

An additional useful finding in this case was bilateral facial weakness. The presence of bilateral facial weakness and symmetric flaccid paralysis makes a diagnosis of GBS highly likely. Involvement of the facial nerve may be also seen in Lyme disease. It is worth noting that despite flaccid paralysis being included in the diagnostic criteria of GBS, 10% of patients present with preserved or increased reflexes (Fokke et al., 2014).

Differential diagnosis based on investigatory workup

An important initial investigation is MRI of the spine to rule out an inflammatory, ischaemic, or structural cause to account for the clinical presentation. GBS may present with enhancement of the proximal nerve roots on MRI with gadolinium. A lumbar puncture can assist in narrowing the differential further. One would anticipate an albuminocytologic dissociation (high protein, normal white cell count) in GBS, as seen in this case. Meanwhile, viral aetiologies present with a lymphocytosis, high protein concentration, and a normal glucose level.

In suspected infectious cases, the diagnosis is typically confirmed by pathogen-specific serology or antigens in the cerebrospinal fluid (CSF) or serum (HSV2, VZV, Enterovirus, Borrelia Burgdoferi). When considering MND, the diagnosis is clinical, but neurophysiological tests can provide support for the presence of denervation.

Section 3: Focal presentations of medical disorders mimicking surgical pathology

Regional pain

Pain is a common early feature in several neurosurgical presentations including cord compression, where it often proceeds neurological disturbance and radiculopathies. Acute or chronic neurogenic pain is also a feature of numerous medical disorders and could be confused with surgical presentations. Central poststroke pain is a frequently encountered central neuropathic pain syndrome that may produce chronic hemi-body pain, particularly in the context of thalamic and lateral medullary infarcts, so previous history of stroke should be considered for diffuse pain syndromes.

Pain with sensory disturbance and/or weakness confined to a single limb points to a disorder of the peripheral nervous system and is often investigated initially for nerve root compression.

Complex regional pain syndrome (CRPS, formerly known as reflex sympathetic dystrophy, causalgia, or Sudeck's atrophy) produces a burning or throbbing pain in a body region (typically a limb) in its early stage. It has a strong female predominance and an inciting event such as trauma, surgery, myocardial ischaemia, cerebrovascular events, or emotional disturbance may precede episodes (Veldman et al., 1993). Signs in later stages of the condition such as soft tissue oedema, muscular atrophy, skin thickening, contracture development, and bony demineralization are useful for differentiating CRPS from differential diagnoses including radiculopathy and peripheral neuropathy, although this distinction can be more challenging at symptom onset. Examination findings at initial presentation that can help diagnose CRPS include a distribution of pain or sensory disturbance that is not in keeping with that of a nerve root, peripheral nerve, or plexus trunk. In addition, temperature or skin tone discrepancy between the affected area and the contralateral side is a useful sign. The diagnosis is made clinically; however, investigations including autonomic testing and bone scintigraphy are occasionally employed.

Herpes zoster (also known as shingles) results from the reactivation of latent varicella-zoster virus infection in the dorsal root ganglia. Burning or stabbing pain in the effected dermatome, usually thoracic and lumbar, is the most common clinical feature and occurs as a prodromal symptom prior to the development of the classical vesicular rash. In some cases, an associated myelopathy can also occur (Frohman and Wingerchuk, 2010). Diagnostic laboratory tests where the cause is uncertain include viral culture or polymerase chain reaction (PCR). The persistence of pain for more than one month after resolution of the rash is defined as postherpetic neuralgia and is thought to represent viral damage-induced hypersensitivity of the dorsal horn neurons. Unilateral neuropathic pain in the affected dermatome associated with allodynia and anaesthesia could be misinterpreted as radiculopathy and thus underlies the importance of eliciting a preceding history of skin rashes in all cases of regional pain.

Medical conditions affecting peripheral nerve plexuses can also mimic some spinal cord lesions. One of the more common

non-traumatic brachial plexopathies is brachial neuritis, also known as neuralgic amyotrophy or Parsonage-Turner syndrome. This idiopathic male-predominant condition typically presents with acute onset severe unilateral shoulder pain. Bilateral pain may occur in up to one-third of cases, but this is asymmetrical when present (van Alfen and van Engelen, 2006). This is followed usually within a few weeks of onset by the development of weakness typically in muscles innervated by the upper trunk (e.g. serratus anterior, deltoid, supraspinatus, infraspinatus). Sensory symptoms also occur in the majority of cases, with numbness or hypaesthesia found in the distribution corresponding to that of the nerves supplying the weakest muscles, and reflexes may be reduced or absent. Around half of patients report an antecedent illness or event such as viral or bacterial infection, trauma, surgery, connective tissue disorders, vaccination, or pregnancy. A hereditary (autosomal dominant) form also exists, characterized by recurrent episodes of pain with additive weakness beginning in childhood or early adulthood. The diagnosis is primarily made clinically but magnetic resonance (MR) imaging is useful to rule out compression or infiltration of the brachial plexus, and nerve conduction and electromyographic (EMG) studies can be used to rule out mononeuropathies/radiculopathies and confirm denervation, respectively. Management is largely conservative.

Sensory disturbance

Unlike the widespread causes of sensory disturbance discussed earlier, sensory loss restricted to part of a limb strongly suggests a peripheral process, as does involvement of all sensory modalities (touch, temperature, pain, vibration, and proprioception).

Symmetrical sensory loss

The differentiation of central (i.e. myelopathy) and peripheral (i.e. polyneuropathy) causes of symmetrical sensory loss can occasionally be challenging. Thorough neurological examination should aid this distinction, with increased tone, an upper motor neuron pattern of weakness (weaker upper limb extensors and lower limb flexors), hyperreflexia, and a lack of both fasciculations and severe atrophy suggesting a central cause. Disproportionate loss of proprioception and vibration sense in patients with bilateral sensory disturbance is suggestive of disorders affecting the posterior columns of the spinal cord, such as vitamin B_{12} deficiency (subacute combined degeneration of the cord), tertiary neurosyphilis (tabes dorsalis), and more rarely acquired copper deficiency, but is also a feature of demyelinating polyneuropathies (as outlined next).

The term polyneuropathy refers to a disorder of multiple peripheral nerves that is typically symmetrical and affects distal nerves most prominently. Patients usually present with symmetrical distal sensory (burning pain or numbness) or motor (weakness) symptoms. Depending on the cause, the presentation may be gradual in onset and follow a chronic clinical course, or symptoms may develop acutely and be self-limiting. Polyneuropathies are typically classified as either axonal or demyelinating and this represents a useful differentiator in terms of underlying medical pathologies, although there is considerable overlap.

Axonopathies typically involve the lower extremities first (i.e. they are length-dependent), with gradual development of sensory loss and dysaesthsias, most notably a burning pain sensation in the feet, with later involvement of the upper limbs (the so-called glove-and-stocking distribution) and motor symptoms. Examination findings include distal loss of sensation and reflexes. These most often result from metabolic and toxic disorders; however, infectious or vascular disorders can cause asymmetrical axonal polyneuropathy.

Demyelinating polyneuropathies tend to preferentially affect motor fibres, with weakness representing an early clinical presentation and later development of dysaesthesias and reduced proprioception. Generalized weakness may be elicited on examination, more noticeable in distal muscles, in association with diffuse hypo/areflexia and predominantly large-fibre (heavily myelinated) sensory disturbances (impaired proprioception and vibration sense).

Several hereditary peripheral neuropathies exist, the pathology of which can either be axonal or demyelinating. Although a wide range have been described, including many that occur as part of more widespread systemic disorders, hereditary motor and sensory neuropathy (HMSN, also known as Charcot-Marie-Tooth disease) is the most commonly occurring family of such hereditary neuropathies. Seven categories of HMSN have been described with over 30 constituent disorders recognized to date, and causative mutations in myelin genes are continually being identified (Klein et al., 2013). HMSN type 1 and 2, both usually dominantly inherited, together account for the majority of cases. HMSN 1 is a demyelinating form characterized by gross nerve hypertrophy and slow nerve conduction velocities. HMSN 2 in predominantly axonal and is associated with borderline slow/normal nerve conduction velocities. If a clear family history is not available or not present (e.g. late presentation or mild disease that has not been diagnosed in relatives), certain features of the history and examination point towards a diagnosis of an inherited peripheral neuropathy. These include a history of recurrent childhood falls, ankle sprains or fractures, a prolonged slowly progressing history, deformities such as pes cavus or an inverted champagne bottle appearance of the legs (due to leg muscle atrophy), and the presence of sensory loss without definite sensory symptoms. Diagnosis is based on clinical suspicion, electrophysiological studies, and genetic testing that can avoid the need for invasive investigation with nerve biopsy. No specific treatments for HSMN have been developed, and management is largely supportive with a large emphasis on physiotherapy.

Asymmetrical sensory loss

Sensory loss limited to part of an extremity suggests a disorder of the peripheral nerve or nerve root. Mononeuropathies and radiculopathies result from disorders of individual peripheral nerves or nerve roots, respectively. The distinction of clinical signs corresponding to either the distribution of a single nerve or to that of a nerve root (i.e. dermatome/myotome) can be difficult in some cases and nerve conduction studies and EMG may be required. Non-compressive causes of mononeuropathies and radiculopathies include infection (in particular herpes zoster and Lyme disease), diabetes, vasculitis with nerve/nerve root ischaemia, infiltration by neoplasms, granulomatous disease or amyloidosis, and demyelination.

Mononeuritis multiplex is characterized by isolated damage to at least two separate nerves causing an asymmetrical sensory and motor peripheral neuropathy. Common associated conditions include diabetes mellitus, vasculitis, connective tissue disorders, and amyloidosis, wherein inflammation-induced occlusion of the vasa nervorum

results in peripheral nerve ischaemia. Pain is typically present at onset and a foot drop is a frequent manifestation. In addition to blood tests to assess for associated conditions and nerve conduction studies/EMG, peripheral nerve biopsy (in particular of the easily accessible and frequently involved sural nerve) is useful in establishing the diagnosis prior to commencing treatment (Bennett et al., 2008).

Pathology at the level of the dorsal root ganglion can also result in asymmetrical sensory loss. Sensory neuronopathies are relatively rare disorders characterized by a degeneration of sensory neurons in dorsal root ganglia that result in a non-length-dependent distribution of almost pure sensory loss (Camdessanché et al., 2009). They may be paraneoplastic, or may be associated with Sjögren's syndrome, HIV infection, and cisplatin toxicity. The diagnosis is based on electrophysiological studies in addition to testing for the aforementioned associated disorders, and recently skin biopsy has been used to confirm non-length-dependence of small fibre degeneration.

Weakness

Localized muscle weakness is a common finding in compressive myelopathy; however, a range of medical disorders must be considered in the differential diagnosis.

As described earlier, distal symmetrical weakness, manifesting as a bilateral foot drop or decreased grip strength, for example, is commonly associated with polyneuropathy. Proximal symmetrical muscle weakness, presenting with difficulties ascending stairs, rising from a seated position, or combing one's hair, for example, is typically an indication of a myopathic rather than a neuropathic disorder, such as polymyositis, dermatomyositis, or inclusion body myositis. Metabolic disorders such as hypothyroidism, hypoparathyroidism, and drug-induced myositis (e.g. with statin treatment for lowering cholesterol) should all be considered. Other features suggestive of a myopathic process include isolated muscle weakness (absence of sensory symptoms and preserved reflexes) and delayed muscle atrophy, which in general occurs earlier with neuropathy. EMG helps to exclude primarily neurogenic processes and is a useful diagnostic adjunct, while muscle biopsy and MR scanning are often employed.

Pathology of degenerative cervical spinal disease

Degenerative cervical spinal disease is a broad term encompassing a number of pathologies resulting in structural changes in the joints (i.e. the intervertebral disc, facet joints and the uncovertebral joints), which potentially lead to compression of neural structures, deformity, pain, and disability. An understanding of spinal biomechanics and the pathological processes involved will aid in the treatment and management of symptomatic patients.

Degeneration of musculoskeletal tissues is a biological inevitability, but the rate of degeneration is related to loading and intensity of use over time. Additional risk factors include smoking, genetic predisposition, localized trauma, and infection, which can accelerate degenerative changes.

In the cervical spine, the intervertebral discs bear the load of the head and neck. Axial loading through the nucleus pulposus of the disc is converted to hoop stresses acting on the annulus fibrosus and vertebral endplates. This continuous mechanical loading alters the cellular composition of the nucleus pulposus with reduction in hydrophilic proteoglycans and increase in collagen (type II, III, VI, and IX) (Urban et al., 2000). Subsequently the mechanical properties of the discs change, the intervertebral height is reduced and eventually cracks and fissures appear in the annulus and vertebral end plates predisposing to nucleus pulposus herniation. Altered stresses are transferred to facet joints leading to segmental hypermobility with osteophytic spurs deposited in an adaptive remodelling process meant to confer increased stability (Galbusera et al., 2014). Histological changes observed in ligamentous hypertrophy include hyperplasia of non-fibrous cartilage, metaplasia, and capillary hyperplasia (Inamasu et al., 2006).

The commonest levels affected are C6/7 and C5/6. Below the age of 55 years, a soft disc prolapse consisting of herniated nucleus pulposus encroaches into the spinal canal or neural exit foramina causing compression of the spinal cord and/or exiting nerve roots resulting in the clinical syndromes of myelopathy and/or radiculopathy, respectively. In older patients, neural compression is more commonly caused by osteophytes and a thickened annulus (hard disc). Multilevel degenerative changes may alter normal cervical lordosis, leading to straightening or the adoption of kyphotic, hyperlordotic, or scoliotic curvatures.

Degenerative changes in the cervical spine can lead to stenosis of the spinal canal and myelopathy results if the reduction in the cross-sectional area is greater than 30% (Yu et al., 1986). A normal cervical spinal canal measures approximately 18 mm in the anteroposterior plane and the normal cervical spinal cord measures 10 mm in diameter.

There are various pathophysiological mechanisms that contribute to cord injury in degenerative cervical myelopathy. Static compression in canal stenosis results in direct trauma and chronic cord ischaemia with dynamic compression resulting from excessive translational movements (>3.5 mm). A neuroinflammatory response triggers a cascade of cellular events causing demyelination of the corticospinal tracts, central grey matter degeneration with loss of interneurons, anterior horn cell atrophy and gliosis (Kalsi-Ryan et al., 2013).

Clinical presentation and investigation

There is heterogeneity in clinical presentation with variable severity and speed of progression. Patients with myelopathy tend to have symmetrical involvement of motor and sensory tracts within the spinal cord. Bilateral weakness below the affected level (paraparesis or quadriparesis), paraesthesia, numbness, tingling, and sensory loss with a discrete sensory level can be seen. Clinical examination reveals signs including increased tone, brisk and pathological reflexes (Hoffman's and Babinski sign). There may be symptoms of difficulty with sphincter control. The onset of symptoms can be insidious and a steady deterioration in hand control especially with fine tasks may be noted progressing to increased clumsiness, unsteadiness of gait, and recurrent falls.

It is more common for degenerative cervical spinal disease to present clinically with features of radiculopathy. Radiculopathy from compression of a nerve root can lead to motor and sensory deficits with reduced deep tendon reflexes in the distribution of the involved nerve root. Pain, with associated reduced movements in the cervical spine, is the predominant symptom radiating from the neck into the arm as brachialgia. Sensory symptoms especially pins and needles are found in the distribution of the nerve. Positive root compression tests can reproduce pain.

MRI imaging of the cervical spine is used to confirm the diagnosis. Further dynamic cervical spine radiographs may assist in

identifying instability which can affect surgical planning. In a few cases a computed tomography (CT) scan of the cervical spine may be useful for assessing the degree of osteophytosis and the extent of foraminal stenosis. Oblique cervical spine films can occasionally demonstrate foraminal narrowing. Myelography has excellent sensitivity for detecting spinal cord compression but may miss very lateral nerve root foramen stenosis.

Treatment

An individualized treatment approach should be adopted, accounting for ventral versus dorsal compression, sagittal alignment, focal versus diffuse disease, presence or absence of radiculopathy, significant axial cervical pain, age, comorbidities, and surgical familiarity with an approach.

Surgical decompression is advocated in most patients with cervical myelopathy because the majority (80%) deteriorate over time with spontaneous regression being uncommon. The timing of surgery is more controversial in patients with mild features of myelopathy or asymptomatic cord compression. Patients should be counselled with regard to the risk of cord injury secondary to degenerative disc disease in the context of trauma.

Earlier intervention in symptomatic cervical myelopathy is associated with improved outcomes. Chronic neurological deficit is unlikely to improve. The risks of surgical intervention versus the benefits of surgery need to be discussed with the patient.

For cervical radiculopathy, randomized studies have shown that surgery results in rapid improvement of symptoms compared to non-operative measures like physiotherapy, but in the long term both methods are equally effective (Engquist et al., 2013). Conservative management is therefore recommended as a first line of treatment. If symptoms are persistent and debilitating, then surgery can be offered.

Degenerative cervical myelopathy patients are consented with the primary aim of surgical decompression being to halt disease progression. Following surgery, 60–70% of myelopathic patients improve with another 30% having stable disease and 10% continue to progress. For patients with radiculopathy, up to 90% have improvement in their arm symptoms.

Ossification of posterior longitudinal ligament (OPLL) and ossification of ligamentum flavum (OLF)

OPLL is more prevalent in Japan (2–4%) compared to Western countries (0.1–1.7%). The genetic basis of this geographical variation remains undetermined. Non-insulin dependent diabetes mellitus, impaired glucose tolerance, excessive weight gain, hypoparathyroidism, and hypophosphataemic rickets have all been implicated. Ectopic bone forms within the ligaments, the histological characteristics of OPLL and OLF include ossification, ligamentous hyperplasia, cell proliferation, and vascular ingrowth.

OPLL has been classified into four types as follows: (a) continuous type with ossification spreading over a number of vertebral levels; (b) segmental type with ossification localized posterior to the vertebral bodies; (c) mixed type (combination of continuous and segmental features) and (d) localized/circumferential type (ossification is confined to the disc space).

OPLL impacts on the choice of operative approach owing to different segmental kinematics and the loss of tissue planes. This complicates anterior surgical decompression and dramatically increases the risk of intraoperative durotomy. When ossification bridges the disc spaces, segmental mobility is reduced, and the posterior longitudinal ligament fuses with the thecal sac. A posterior approach is usually indicated but if adopting an anterior approach more extensive vertebrectomy decompressions are frequently required.

OLF also has a higher prevalence in Japan, affecting women more than men and typically becomes symptomatic over the age of 50 years. Ossification is within the layers of the ligamentum flavum and noted to originate from the lamina in a contiguous manner.

Rheumatoid arthritis (RA)

Rheumatoid arthritis is a systemic autoimmune disease (1% of adults in Europe and the United States) that can affect the cervical spine. Advances in disease modifying antirheumatic drugs and biological agents have reduced the number of patients presenting with RA-related cervical spinal disease (Kaito et al., 2013). The use of modern therapeutic agents when started early can prevent the destructive joint pathology from occurring but are unable to prevent progression of cervical spine lesions if already present.

The pathobiology of RA involves novel antigenic expression by synovial cells leading to persistent cellular activation and immune complex production (rheumatoid factor-IgM). Cytokine-mediated (IL-1, IL-6, TNF-α) chronic inflammation is initiated. This results in granulation tissue deposition within the synovium (rheumatoid pannus), which in itself produces proteolytic enzymes capable of destroying adjacent cartilage, ligaments, tendons, and bone (Reiter and Boden, 1998).

Within the cervical spine, destructive synovitis leads to ligamentous laxity and bony erosions with subsequent instability and subluxation of the vertebrae. Compression of neural structures can result from instability or direct compression from pannus formation. The upper cervical articulations at occiput/C1 and C1/C2 are primarily affected because the normal ligamentous structures surrounding the occipito-atlantoaxial region that confer a significant proportion of strength and stability are degraded as part of the disease process. The most common cervical spine pathologies in RA are C1/2 instability (65%), basilar invagination (20%), and subaxial subluxation (15%) (Kim et al., 2015).

Subaxial subluxation results from facet and uncovertebral joint instability. Translational movement of the vertebrae in the sagittal and coronal planes with or without rotation can occur. Abnormal alignment may include spondylolisthesis, kyphosis, scoliosis, or a 'staircase' deformity. Surgical decompression and arthrodesis may be necessary in cases of instability and canal compromise with cord compression and neurological dysfunction.

Craniocervical pathologies

Atlantoaxial subluxation

C1-C2 instability (atlantoaxial subluxation) results from destruction of the transverse, apical, and alar ligaments, for example, from rheumatoid pannus. It also occurs in ankylosing spondylitis, achondroplasia, Down's syndrome, Morquio's syndrome, and secondary

to trauma. It is becoming less common as steroid sparing drugs have allowed patients with rheumatoid arthritis to be managed with much lower doses of steroids.

The subluxation can be seen on dynamic cervical spine radiographs or kinematic MRI as excessive translational movements of C1 on C2. The normal anterior atlanto-dental interval is less than 3 mm (<5 mm in a child), as measured from the posterior aspect of the anterior arch of C1 to the anterior aspect of the dens. Surgical stabilization has been advocated in asymptomatic patients when this interval is more than 8 mm and in all patients with myelopathy. Neck pain is a feature of cervical instability in these patients. Surgical outcomes are good in the absence of preoperative myelopathy so early C1/2 fusion surgery is usually advocated. However, it is not uncommon to see RA patients who are neurologically intact with significant C1/2 subluxation and use of the anterior atlanto-dental interval has been shown to correlate poorly with neurological outcomes. The posterior atlanto-dental interval is measured from the posterior aspect of the dens to the anterior aspect of the C1 lamina and should be more than 14 mm and it correlates better with neurological outcome.

Rotatory atlantoaxial subluxation

Atlantoaxial rotatory subluxation is most common in children and is covered in Chapter 85.

Basilar invagination

Basilar invagination occurs from erosion of occiput/C1 and C1/2 joints such that the dens, migrates into the foramen magnum. It may present with hydrocephalus, syringomyelia, or progressive myelopathy. A number of radiographic measurements have been described for identifying basilar invagination (Fig. 60.1). Chamberlain's line extends from the hard palate to the opisthion (back of the foramen magnum) and the tip of the dens should be =<3 mm above this line. McGregor has modified this for when the opisthion cannot be identified. McGregor's line extends from the hard palate to the most caudal point of the occipital curve and the dental tip should by less than 4.5 mm above this line. The simplest line, however, is McRae's line drawn from the basion (front of the foramen magnum) to the opisthion. The superior tip of the dens is normally 5 mm below but should not be cephalad of this line. McRae's line is also used to diagnose Chiari 1 malformations where the cerebellar tonsils, which should normally be above this line, are seen to descend more than 3mm in children and 5 mm in adults. It may be difficult to identify the dens due to erosion and pannus. In this situation, it is possible to use the position of the anterior C1 arch in relation to the C2 body. A severe abnormality is identified when the anterior arch of C1 is adjacent to the lower third of the C2 body.

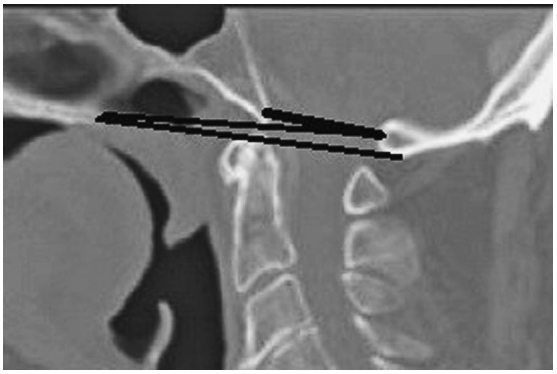

Fig. 60.1 McRae's line runs across the foramen magnum from the basion to the opisthion, Chamberlain's line runs from the back of the hard palate to the posterior margin of the foramen magnum (opisthion). McGregor's line is similar running from the palate to the lowest visible part of the occiput. The tip of the dens should be =<3 mm above Chamberlain's line, less than 4.5 mm above McGregor's line and usually 5 mm below but not above McRae's line.

Some authors differentiate this radiological appearance when it is caused by softening of the bones at the skull base and term it 'basilar impression'. In this case, there is dislocation superiorly of the upper spine onto the foramen magnum with brainstem compression as a result of skeletal anomalies of the basi-occiput and condylar segment of the occipital bone leading to infolding of the foramen magnum vs. 'basilar invagination' which involves upward migration of the dens into the foramen magnum from pathological ligamentous disruption.

The most common cause of basilar invagination is rheumatoid arthritis, but other causes include Klippel-Feil, osteogenesis imperfecta, achondroplasia, Chiari malformations, cleidocranial dysostosis, Schwartz-Jampel syndrome 2, Morquio's syndrome, hyperparathyroidism, osteomalacia, rickets, and Paget's disease.

Different procedures have been used to treat basilar invagination either on their own or in combination including traction, anterior decompression, and craniocervical fusion with or without foramen magnum decompression. There is little consensus on the best way to treat these patients. The location of the vertebral arteries must be considered. The presence of ventral tissue contraction may make an anterior approach essential. When there are no cranial nerve palsies a posterior fusion is usually adequate, preoperative traction may help to predict whether adequate reduction can be achieved intraoperatively. Where cranial nerve palsies exist or where traction is considered unsafe then an anterior transnasal or transoral resection of the odontoid peg should be considered. In some cases C1 and C2 will already have fused but in others surgical C1/2 fusion will be required either anteriorly or with a combined posterior approach. Most authors recommend performing the anterior decompression first followed by the posterior fusion, but a few authors do recommend the reciprocal.

Platybasia

Platybasia is described as flattening of the skull base and is usually asymptomatic unless associated with other anomalies. The skull base angle is formed by a line joining the nasion with the centre of the pituitary fossa and a line joining the anterior border of the foramen magnum with the centre of the pituitary fossa. Platybasia is present if this angle is more than 143°, basilar kyphosis is present if it is less than 125°. Platybasia is associated with basilar invagination and achondroplasia, Down's syndrome, Chiari malformations, craniocleidodysostosis, craniofacial anomalies, osteogenesis imperfecta, Paget's disease, osteomalacia, rickets, fibrous dysplasia, and hypoparathyroidism.

Seronegative spondyloarthropathies

These include a number of inter-related chronic inflammatory conditions of unknown aetiology; ankylosing spondylitis, Reiter's

syndrome, psoriatic arthritis, arthritis of inflammatory bowel disease and undifferentiated spondyloarthropathies.

Ankylosing spondylitis is the commonest and is associated with the HLA-B27 genotype seen in 80–98% of affected patients. Systemic inflammatory processes lead to an enthesopathy (inflammation at the insertion of tendons and ligaments into the bone) with subsequent bridging syndesmophyte (bone spur) formation. The cervical spine manifestations are typically stiffness from joint and ligament ossification, and kyphosis which when severe, manifests as a 'chin-on-chest' deformity. The chin-brow vertical angle is measured using standing whole spine radiographs and/or clinical photographs to assess overall spinal deformity and balance. Correction of cervical deformity should only be entertained if concomitant abnormalities of the thoracolumbar spine and hip/knee joints have been excluded. Osteopaenia occurs as part of the disease process and affects surgical planning involving instrumentation.

Diffuse idiopathic skeletal hyperostosis (DISH)

Also known as Forestier disease, DISH has an overall incidence of 6–12% and is more common in patients over the age of 50 years. It is characterized by the presence of non-marginal syndesmophytes at three successive levels (involving four contiguous vertebrae) and appears radiologically as flowing anterior ossification of the anterior longitudinal ligament with disc space preservation. The disease process differs from ankylosing spondylitis in that there is an absence of facet joint ankylosis, sacroiliac joint erosion, sclerosis, or intra-articular osseous fusion, and there is usually no osteopaenia.

Symptoms include stiffness and pain. Associated degenerative changes in the disc with osteophytes can lead to myeloradiculopathy. The stiff cervical spines seen in ankylosing spondylitis and DISH are more prone to fracture in minor to moderate trauma. Most cases are treated if canal stenosis results in symptomatic myeloradiculopathy. With large anterior syndesmophytes, dysphagia, stridor, and hoarseness of voice may also, rarely, be surgical indications.

Anterior cervical approaches

Anterior cervical spine approaches have been used since the 1950s (Cloward, 1958) to decompress the spinal cord and nerve roots.

Anterior techniques for decompression include discectomy and corpectomy. Following decompression, a decision is made either to fuse the joint (arthrodesis) or to preserve motion (arthroplasty). In fusion, autograft (e.g. iliac crest, fibula strut), allograft or synthetic graft may be used. This may be supplemented with anterior cervical plating.

Indications for an anterior approach

Anterior compression of neural elements should be treated with an anterior approach. Correction of cervical kyphosis is also possible with this approach. Contraindications to an anterior approach include posterior compression and OPLL. Previous anterior cervical surgery and/or neck radiotherapy with or without vocal cord dysfunction should also be considered a relative contraindication. Asymptomatic recurrent laryngeal nerve palsy is common after anterior cervical spine surgery so redo surgery should be on the same side as the first operation unless laryngoscopy has been performed to prove that both vocal cords are working. Patients reliant on their voice (e.g. opera singers) should be counselled with regard to the risk of vocal cord injury.

Technical considerations

Extensive dorsal osteophytes extending beyond the disc space, especially if associated with OPLL may require a corpectomy for more complete decompression.

Fusion rates for a single level discectomy approach 100%, but decrease with multilevel discectomies. If multilevel discectomy is indicated, supplemental anterior plating may confer a biomechanical advantage with increased stability while fusion occurs. Smoking and non-steroidal anti-inflammatory drugs can impair fusion.

More than one-level corpectomy is associated with a higher rate of implant dislodgment and failure. Therefore, many surgeons favour multilevel discectomies or augment the anterior construct with posterior instrumented fusion, which improves biomechanical stability and fusion.

Evidence suggests that for a single level discectomy, there is no difference in outcome between decompression alone, compared to decompression with the addition of a graft. Not using a graft reduces the cost and operative time as well as avoids graft related complications such as harvest site pain. Autograft has classically been the gold standard with which other techniques are compared. However, with modern synthetic cages made of carbon fibre, titanium, polyether-ether-ketone (PEEK), the morbidity of donor site including pain, wound infection, haematoma, and peripheral nerve injury or irritation is avoided.

Supplemental anterior plating adds stability and strength in extension. It provides the strongest possible anterior surgical construct and is useful in correcting kyphosis but there is evidence that plates can increase the incidence of dysphagia.

Different plate/screw combinations are available with the major determinant being dynamic versus constrained or semi-constrained plates. Dynamic or even semi-constrained systems allow for natural settling of the vertebral body on the implant increasing load sharing between the plate and the graft which may translate to improved fusion rates.

Conclusion

In terms of long-term outcome, there appears to be no superiority of anterior cervical discectomy alone with or without a cage, over anterior cervical discectomy and fusion with instrumentation, or corpectomy and fusion with instrumentation. Each technique has its advantages and disadvantages. The optimal approach to achieve the best outcome for the patient should be based on pathological factors and the surgeon's experience. See **Box 60.1** and **Fig. 60.2**.

Anterior cervical discectomy

The patient is positioned supine on a head ring with a jellyroll or rolled towel in the midline under the shoulders. A chinstrap can also improve access. A small degree of head up tilt can help reduce venous pressure but will also angle the disc space.

Box 60.1 Case 1—multilevel anterior cervical fusion with instrumentation

This 54-year-old gentleman presented with neck pain, increasing urinary urgency, balance, and mobility problems consistent with myelopathy. An MRI demonstrated multilevel cervical spondylitic changes with a broad-based disc and osteophyte bars at C4/5, C5/6 and most marked at C6/7 with increased cervical cord signal changes. He had a three-level anterior cervical discectomy and fusion with plating (**Figs. 60.2A–C**).

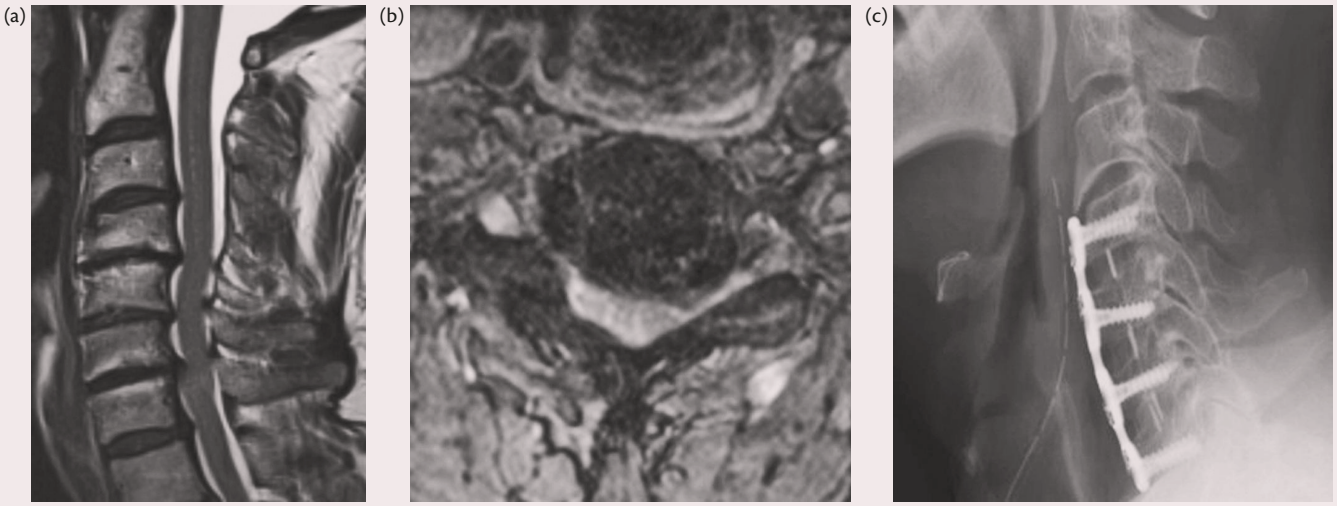

Fig. 60.2 (A) Preoperative sagittal T2W MRI. Compression from anterior primarily with C6–7 the worst affected level with subtle myelopathic signal change seen in the spinal cord. (B) Preoperative axial T2W MRI. Confirms narrow cervical canal with broad-based disc and osteophytic disc bar compressing the cord at C6–7. (C) Postoperative day 1 following surgery. Satisfactory position of screws and interbody fusion cages.

The skin incision is placed at the pathological level using surface anatomical landmarks and radiographic confirmation; C3/4 is just caudal to the hyoid bone, C4/5 is at the level of the thyroid cartilage, C5/6 is at the cricothyroid membrane and C6/7 at the level of the cricoid cartilage.

The incision is normally transverse in line with natural skin creases as this heals with less scarring or occasionally longitudinal along the anterior border of sternocleidomastoid. The approach may be from the left or right. The recurrent laryngeal nerve takes a less predictable course on the right and is more vulnerable to damage on this side while the thoracic duct on the left is at risk especially with low approaches nearer the cervicothoracic junction. Most right-handed surgeons prefer to approach from the right and vice versa.

The platysma is divided horizontally or split longitudinally and undermined superiorly and inferiorly. The superficial cervical fascia is opened and the bloodless avascular plane between the sternocleidomastoid muscle and carotid sheath laterally and the trachea and oesophagus medially are used to access the prevertebral fascia. Blunt dissection will normally achieve adequate exposure. It is important to palpate, identify, and protect the carotid sheath.

The prevertebral fascia is incised exposing vertebral bodies, discs, and the longus colli muscles. The medial border of longus colli is undermined bilaterally and elevated with diathermy. Retractors are sited underneath the muscle avoiding damage to the sympathetic chain which runs superficially along the muscle ~1 cm lateral to the medial border. A contoured spinal needle is placed into the disc space and the correct cervical level confirmed radiologically.

The disc space is incised with exposure of the uncovertebral joint, the uncinate processes defines the lateral margin of the exposure (Fig. 60.3). Disc space distraction can be achieved with caspar pins or skull traction. Anterior osteophytes are removed. The discectomy is completed with a combination of curettes, rongeurs, and a drill. Care must be taken to prevent excessive endplate removal as this predisposes to graft settling and subsidence.

The cranio-caudal orientation of fibres helps identify the posterior longitudinal ligament and it is removed exposing the thecal sac. For myelopathic patients, adequate central decompression must be achieved with undercutting of dorsal osteophytes. For radiculopathy decompression of neural exit foramina is required.

Following discectomy, a graft can be inserted. If using an anterior plate, care must be taken to avoid impingement on adjacent levels. Closure is with dissolvable sutures and most surgeons will use a drain.

Anterior cervical corpectomy

For single level corpectomy, exposure is the same as for discectomy. Discectomies are performed at the rostral and caudal levels with a central channel of bone removed from the intervening vertebra. In most patients a width 15–18 mm is sufficient for decompression.

A rigid or an expandable cage filled with bone graft can be used to reconstruct and restore alignment. A plate is used. Table 60.1 shows the complications that may occur with anterior approaches to the cervical spine.

Cervical arthroplasty

Cervical arthroplasty is a recognized alternative to anterior cervical discectomy and fusion. The principle is to preserve segmental kinematics. Controversy exists regarding the implants long-term survivability and its impact on adjacent segment disease (see controversies section).

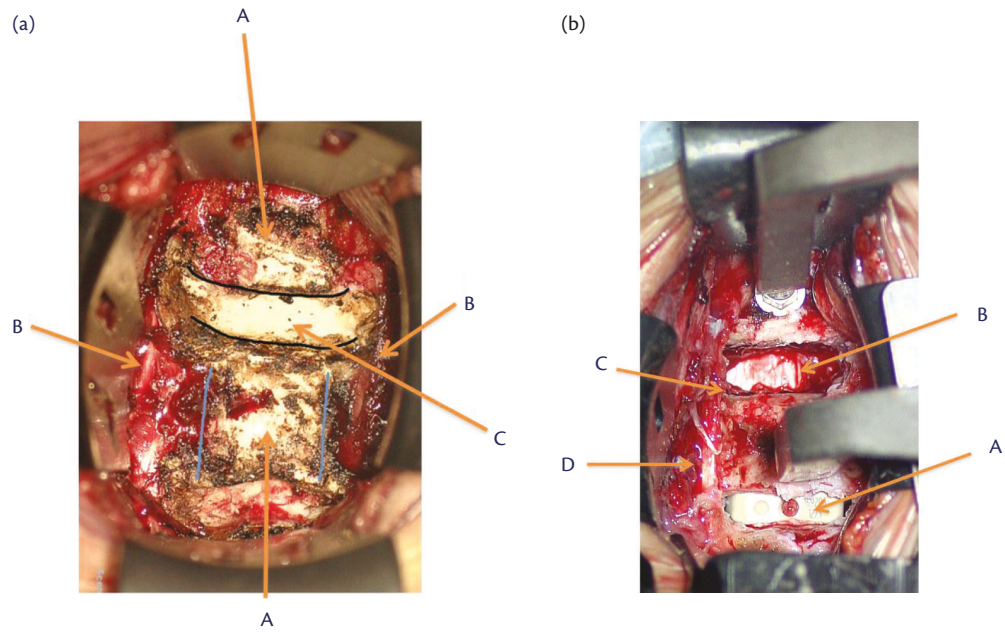

Fig. 60.3 (A) Exposure in preparation for C5/6 anterior cervical decompression. **A**—C5 (superior) and C6 (inferior) vertebral bodies visible. **B**—The right and left longus colli muscles are visualized. **C**—The C5/6 disc is visualized. The black lines demonstrate the superior and inferior endplates of the C6 and C5 vertebra respectively with the upslope of the respective uncovertebral joints which delineate the lateral margin for excision limits ('smiley face'). The blue lines demonstrate the lateral margins along the C6 vertebral body along which trenches should be drilled for vertebral corpectomy procedure.
(B) C5/6 and C6/7 Anterior cervical discectomies performed. **A**—C6/7 decompression complete with insertion of cage with bone graft within. **B**—C5/6 decompression complete with visualization of the spinal cord in the depth. **C**—the upslope demonstrating the start of the uncovertebral joint is just visible on the superior endplate of the C6 vertebral body. **D**—the right longus colli muscle is visible. Pins have been inserted into the C5 and C6 vertebra for the purposes of distraction

Table 60.1 Complications associated with anterior cervical spine approaches

Complication	Incidence	Comments
Hoarseness of voice	4%	Usually secondary to a recurrent laryngeal nerve palsy, bilateral palsies may present with complete airway obstruction. Compression is thought to occur between retractors and the cuff of the endotracheal tube (ETT) as the nerve runs in the tracheo-oesophageal groove underneath the inferior constrictor muscle. Deflating and reinflating the cuff of the ETT after positioning of the retractors might reduce the incidence of this complication
Dysphagia	10%	Risk factors include multilevel surgery, older age, high profile plates, and surgery at lower levels. Exclude implant migration
Haemorrhage	2–3%	Risk factors include absence of a postoperative drain and inadequate haemostasis (especially during exposure). Haemorrhage can precipitate airway obstruction and postoperative swelling
Dural tear	0.5%	More common in patients with OPLL (up to 25%) Perform intraoperative repair (stitches, clips, fibrin sealant)
Oesophageal injury	<1%	Risk factors include scarring from previous surgery Can be life-threatening, involve ear, nose, and throat (ENT), or upper gastrointestinal (GI) surgeons
Paralysis Worsening myelopathy	0.5% Up to 5%	Careful positioning and avoid over extension of the neck Avoid overdistraction of the disc space or excessive thecal manipulation Do a postoperative MRI early to exclude a haematoma
Horner's syndrome	<1%	Caused by excessive dissection of longus colli too laterally Usually resolves in most cases
Infection	1%	Risk factors include systemic immune suppression (e.g. diabetes), and oesophageal perforation Treat with antibiotics, implants may not require removal
Adjacent segment disease	2.9% per annum	Symptomatic disease requiring treatment is about 2.9% per annum following fusion (~25% of patients in 10 years)
Other rare complications		Extrusion of graft Vascular injury (vertebral artery, carotid artery, jugular vein) Thoracic duct injury Death (0.1%)

Arthroplasty should be considered in younger patients with predominantly soft disc herniations. Contraindications include inflammatory arthropathies (ankylosing spondylitis, rheumatoid arthritis), infectious arthropathy, OPLL, DISH, significant osteophytosis and cervical instability (translation ≥ 3.5 mm or angulation ≥ 11 degrees).

A preoperative CT and dynamic x-rays should be performed in all patients considered for arthroplasty.

The surgical technique for arthroplasty is identical to exposure and decompression for anterior cervical discectomy but care should be taken to avoid excessive decompression of the uncovertebral joints. In certain prostheses, destabilization of the uncovertebral joint may cause hypermobility of the treated segment and potential instability and implant failure. Care must be taken to minimize the amount of bone dust created during the arthroplasty procedure with the aim being to reduce the risk of postoperative osteophyte formation or heterotopic calcification. In this regard, a prosthesis that avoids drilling into the bone may be preferential. The use of non-steroidal anti-inflammatories has been documented to reduce the risk of early fusion. See **Box 60.2**.

Posterior cervical approaches

Posterior cervical decompression procedures include laminectomy or laminoplasty for myelopathy and foraminotomy or posterior cervical discectomy for radiculopathy. The indications for choosing a posterior approach include, hypertrophic ligamentum flavum and facets, multilevel disc disease, OPLL, congenital multilevel canal stenosis, and foraminal compression.

Posterior decompression may be preferable in older people where multilevel disease is more common and postoperative cervical instability is of less concern than in younger patients. Posterior approaches avoid the risks of hoarse voice, dysphagia, and adjacent segment disease. If there is evidence of instability or kyphosis, then supplemental fusion should be considered.

The surgical goal is to achieve adequate decompression of neural elements. Review studies have shown outcomes from posterior decompression comparable to anterior cervical decompression (Luo et al., 2015).

Cervical laminectomy

Cervical laminectomy is performed with the patient positioned prone with the head slightly flexed and fixed in a skull clamp. A midline exposure through the nuchal ligament minimizes blood loss. Subperiosteal muscle elevation is preferable to minimize muscle trauma. The level is confirmed with X-ray. Excessive muscle stripping and exposure of adjacent facets should be avoided to prevent instability and progressive deformity (postlaminectomy kyphosis and 'swan-neck' deformity). The incidence of instability following laminectomy is reported as being anywhere from 6% to 46% (McAllister et al., 2012).

Laminectomy can be performed *en bloc* by drilling troughs bilaterally at the lamina-lateral mass junctions. The ligamentum flavum can then be dissected away from the theca to achieve decompression. Alternative methods include use of bone nibblers and kerrison rongeurs for piecemeal removal. The medial border of the lateral masses should be the extent of the decompression. Haemorrhage from epidural venous plexuses can be troublesome and haemostasis should be meticulous. See **Box 60.3**.

Modified posterior approaches

Alternative procedures to cervical laminectomy have been developed that reduce muscle dissection and preserve the posterior cervical tension band with the aim of reducing the risk of postoperative cervical instability (**Table 60.2**).

Posterior cervical foraminotomy

Facet joint spondylosis, uncovertebral osteophytes, and foraminal disc herniation can cause nerve root compression and radiculopathy without myelopathy. Foraminotomy is used to decompress the nerve root without exposing the midline structures.

Box 60.2 Case 2—two-level cervical arthroplasty

This 41-year-old lady presented with neck stiffness and brachialgia with radicular pain affecting the C5 and C6 nerve roots. She had subtle weakness (4/5) and positive Lhermitte's sign on the left. Imaging confirmed two-level degenerative disc disease at C4/5 and C5/6. Two-level decompression with cervical arthroplasties was performed (**Figs. 60.4A–C**).

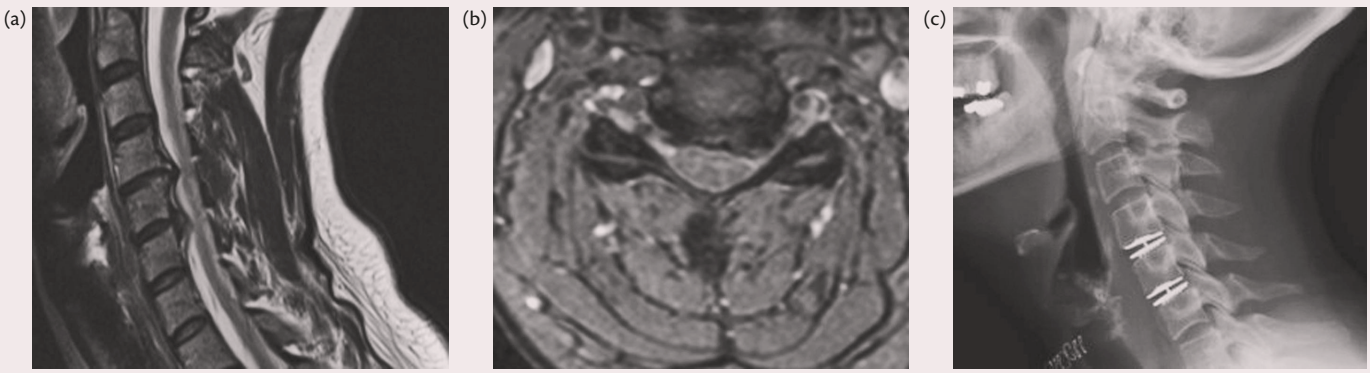

Fig. 60.4 (A) Preoperative sagittal T2W MRI. Compression from anterior at C4–5 and C5–6 with left paracentral disc prolapses. (B) Preoperative axial T2W MRI. Left paracentral disc prolapse at C4–5 with narrowing of central canal and foraminal stenosis and left C5 nerve root impingement. (C) Postoperative day 1 following surgery. Satisfactory position of disc replacements.

Box 60.3 Case 3—cervical laminectomy and lateral mass screw fixation

This 74-year-old presented with features of cervical myelopathy. Imaging confirmed severe canal stenosis and cord compression with intramedullary signal change at C3–4. A posterior approach with instrumented fusion was chosen because of atherosclerotic carotid disease and loss of cervical lordosis (Figs. 60.5A–C).

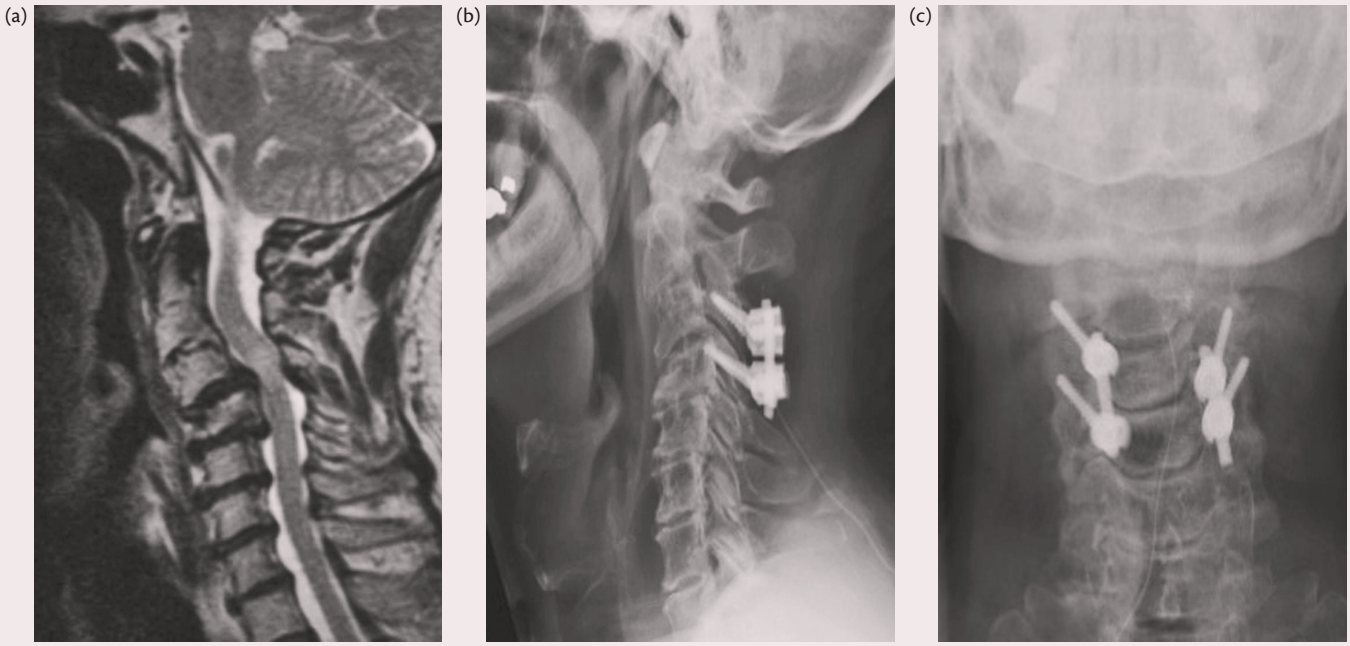

Fig. 60.5 (A) Preoperative sagittal T2W MRI. C3–4 cord compression with cord signal change secondary to spondylosis with loss of cervical lordosis and kyphosis. (B) Lateral X-rays confirming C3 and C4 lateral mass screw fixation following C3–4 laminectomy decompression. (C) Coronal x-rays demonstrating lateral mass screw fixation trajectory.

The patient positioning is as for cervical laminectomy. Exposure can involve either ipsilateral muscle stripping (open procedure) or muscle splitting (minimally invasive with tubular retractors or an endoscope). The cranial and caudal laminae and the facet overlying the exiting nerve root are exposed. The level is confirmed with intraoperative fluoroscopy. Fenestration is achieved by removing bone from the cranial and caudal lamina and undercutting of the medial facet to decompress the exiting nerve root. This can be achieved with a high-speed drill, small kerrison rongeurs or ultrasonic aspiration (Fig. 60.6D). Removal of more than half of the facet compromises shear strength of the spine and should be avoided (Raynor et al., 1985).

Table 60.2 Modified posterior cervical exposures

	Comments
Skip laminectomy	Described by Shiraishi et al. (2002), alternate standard laminectomies at selected levels allow partial preservation of midline structures. See Fig. 60.6A
Cervical laminoplasty	The spinal canal diameter is augmented by re-positioning the laminae and removing the ligamentum flavum. The two common variants are *Trap Door* (Fig. 60.6B; Hirabayashi et al., 1983) *and Double Door* (Fig. 60.6C; Kurokawa et al., 1982)

Rarely a herniated foraminal soft disc can be removed by increasing the margins of the foraminotomy inferiorly and partially removing part of the inferior pedicle. A blunt hook is passed underneath the nerve root and loose disc fragments removed. See Box 60.4.

Complications of the posterior approaches include persistent neck pain and kyphotic deformity. Careful patient selection will minimize complications. Instrumented fusion can be considered if there is concern about instability. Postoperative neurological deficit has been documented especially C5 nerve root palsy. Care must be taken during patient positioning to avoid hyperflexion and traction in myelopathic patients (Nassr et al., 2012). Overall, posterior cervical decompressions are well-tolerated, safe, and effective procedures.

Surgery for atlantoaxial subluxation

Surgical stabilization of an unstable atlantoaxial C1/2 complex (Fig. 60.8) has been performed with posterior approaches using sublaminar wiring (Gallie, Brooks-Jenkins, Dickman-Sonntag) and interlaminar clamps but these techniques are rarely used now except as an adjunct (Table 60.3). Magerl's C1/2 transarticular screw fixation or the Harms–Goel technique of posterior C1 lateral mass screws with C2 pars/pedicle screws are the two most commonly performed procedures and are described here later. Internal screw fixation is biomechanically superior to wire/clamp techniques as it directly inhibits motion at the C1/2 articular surfaces. Anterior

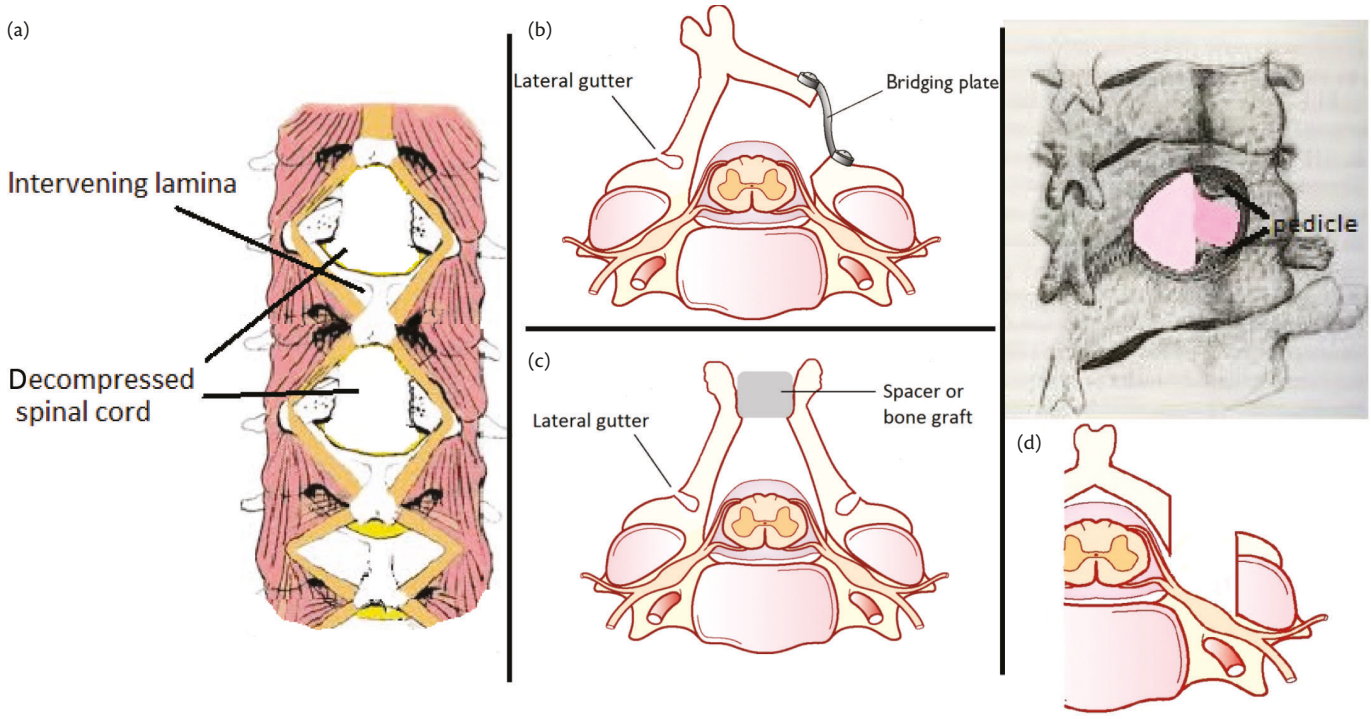

Fig. 60.6 Minimally invasive exposures for posterior cervical decompression. (A) Skip laminectomy. Removal of alternate laminae and ligamentum flavum with preservation of intervening laminae and structures. Muscles are not detached from adjacent spinous processes. (B) Trap door laminoplasty. The laminae are disconnected on one side and thinned on the other allowing for bone to be hinged outwards and held open with implants. (C) Double door laminoplasty. The spinous processes are split in the midline and the laminae are thinned bilaterally to allow for spinal canal expansion and allow undercutting of ligamentum flavum. Interposition of bone graft or spacers maintains increased canal cross-sectional area. (D) Foraminotomy. Decompression of the exiting nerve root between the adjacent pedicles by removal of overlying bone and ligaments. Adequacy is confirmed with passage of a probe.

Box 60.4 Case 4—minimally invasive cervical foraminotomy

This 41-year-old who had a previous C5/6 anterior cervical discectomy presented with right upper limb brachialgia. He had features of right C7 radiculopathy. MRI confirmed a right posterolateral C6/7 disc prolapse with impingement of the exiting right C7 nerve root. A posterior right C6/7 foraminotomy was performed with a minimally invasive technique (**Figs. 60.7A–C**).

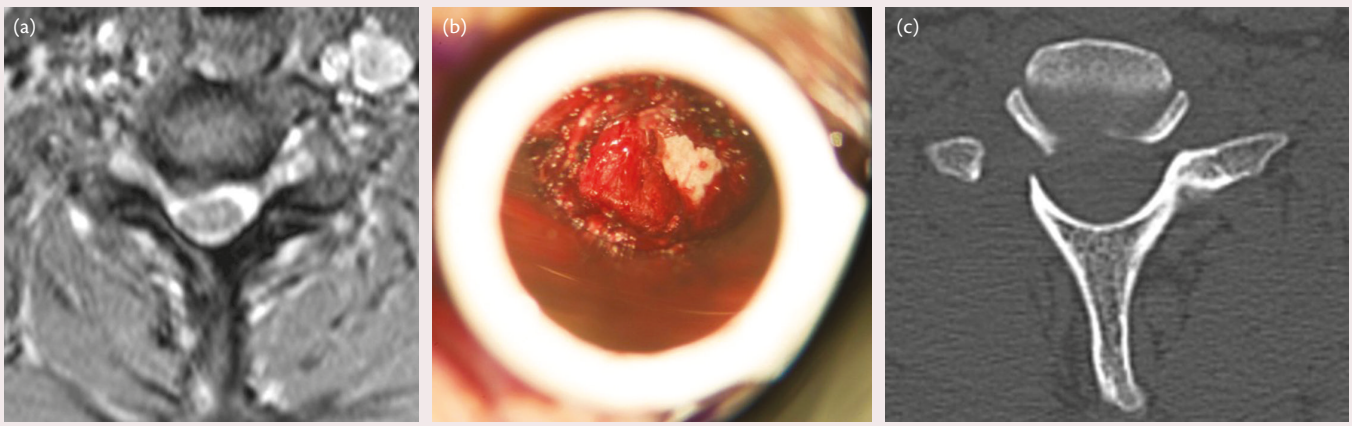

Fig. 60.7 (A) Preoperative axial T2W MRI. Right C6–7 disc prolapse with impingement of exiting right C7 nerve root with radiculopathy. (B) Intraoperative microscopic picture of right C6–7 minimally invasive foraminotomy demonstrating C7 nerve root and decompression. (C) Postoperative axial CT scan demonstrating right C6–7 foraminotomy and decompression of nerve root.

Fig. 60.8 Surgical techniques for atlantoaxial stabilization. (A) Posterior view of the anatomy of the normal C1/C2 (atlantoaxial) joint including position of the vertebral artery. Posterior techniques demonstrated on the left (B to D) and anterior techniques on the right (E to F); the vertebral artery position is visualized in each image. (B) Posterior wire fixation technique with sublaminar wiring and bone graft in between C1 and C2. (C) Magerl's transarticular posterior screw fixation with entry point marked and the trajectories in two planes (sagittal—inferior to superior; axial—lateral to medial). (D) Harms–Goel interarticular fixation with C1 lateral mass screw and either C2 Pars or C2 pedicle screw fixation. Note the entry point varies depending on whether it is a C2 pars or C2 pedicle screw. (E) C1–C2 anterior transarticular fixation with the entry point (just beneath superior articular process of C2, 5 mm lateral from the midline at the base of the odontoid (PEG) and trajectory demonstrated. (F) C1–C2 anterior plate fixation with entry points into C1 and C2 demonstrated. Anterior fixation is much rarer compared to posterior fixation.

transoral approaches including transarticular C1/2 screws and C1 lateral mass to C2 vertebral body plate and screw fixation has also been described.

Magerl's C1/2 transarticular screws

A single screw on each side is placed through the pars interarticularis of C2 passing through the C1/2 joint directed at the lateral mass of C1 (Magerl and Seeman, 1986; Fig. 60.8). It provides the most stable and rigid fixation biomechanically of the C1/2 joint with almost complete obliteration of rotation. A major contraindication would be an anomalous high-riding vertebral artery. It is technically demanding with increased risk of vascular injury and care must be taken to avoid anterior perforation of the C1 lateral mass, which could result in injury to the pharynx, internal carotid artery, and/or lower cranial nerves.

A preoperative CT Angiogram helps define the course of the vertebral artery. Intraoperative fluoroscopy guides the screw trajectory. The patient is positioned prone in a skull clamp with neck flexion. The C1 posterior arch and lateral masses, C2 laminae, C2 pars and the C2/3 facet joints are exposed. Separate stab incisions caudally may be required to achieve the trajectory for the transarticular screw (usually 1–2 cm lateral to C7/T1 spinous process). The C1/2 joint capsule can be opened to denude the articular surface. Figure 60.8 demonstrates the entry point and trajectory. Drilling for screw placement is guided with fluoroscopy or alternatively intraoperative navigation can be used. The C1/2 transarticular screw is placed after tapping the hole. Bone graft can be sited on exposed bone surfaces to supplement the fusion. The fixation is often augmented by a Dickmann–Sonntag posterior sublaminar wire.

Harms–Goel C1 lateral mass and C2 pars/pedicle screws

Harms and Melcher (2001) and Goel et al. (2002) employed an interarticular fixation with C1 lateral mass and C2 pars/pedicle screws (Fig. 60.8) as an alternative to C1/2 transarticular fixation.

Specific advantages include that anatomic reduction of C1/2 is not essential and it can be used with a high-riding vertebral artery.

The positioning and exposure are as for the transarticular screw technique. Preservation of the C2 nerve root is optional. The entry point and trajectories are highlighted in Figure 60.8. The C1 lateral mass screw is partially threaded to reduce irritation of the C2 nerve root and subsequent neuropathic pain. Fusion rates are high.

Complications

The major complication of both procedures is vertebral artery injury (<5%), which can occur during exposure or screw placement. If arterial perforation occurs during screw preparation, the screw should be implanted for tamponade. The contralateral side is left uninstrumented and the patient should have an angiogram to assess the posterior cerebral circulation.

If C1/2 screw fixation is not possible, alternative strategies could include occipito-cervical fixation or external orthotic stabilization with a HALO. Patients should be consented for these alternatives prior to surgery.

Anterior surgical approaches to the craniocervical junction

Surgical anatomy and biomechanics

The atlanto-occipital articulation between the occipital condyle and the C1 superior facets allows about 15° of flexion and extension while the C1/C2 articulation contributes to 45° of rotation which is about 50% of the rotation occurring by the cervical spine. The stabilizing ligaments are the transverse ligament attached to a tubercle on the medial aspect of one C1 lateral mass to the other and located posterior to the dens and the alar ligaments attached from dorsolateral dens passing rostro-lateral to the medial tubercle of the occipital condyle at the anterior lip of foramen magnum. Supplementary ligaments include the apical ligament, anterior atlanto-occipital and tectorial membranes in continuity with the ALL and posterior longitudinal ligament (PLL) and also the posterior atlanto-occipital membrane and ligamentum flavum. The longitudinal fibres dorsal to the transverse ligament complete the formation of the cruciate ligament (see Chapter 57, Fig. 57.1). The transverse ligament limits flexion and anteroposterior (AP) translation of the atlantoaxial articulation. The alar ligaments limit atlanto-occipital rotation.

Open anterior approaches

Anterior transoral and transnasal approaches for C1/2 fixation are utilized when there is a need for anterior decompression and resection of the dens. These procedures may be performed open or using an endoscope. They are now rarely indicated for rheumatoid disease as rheumatoid pannus normally resolves following posterior fusion alone. Oropharyngeal infection is a contraindication.

Patients are positioned supine with biplanar intraoperative fluoroscopy available. Neuro-navigation can also be used. A decision regarding open surgery versus endoscopic surgery is made based on surgical familiarity. Two fixation techniques are available: C1-C2 transarticular screws or T-plate fixation with C1 lateral mass and C2 vertebral body screws (Fig. 60.8).

The pharyngeal mucosal incision for C1/2 transarticular screws is usually linear whereas for a T-plate a U-shaped flap is preferred. Vertebral artery injury is avoided by keeping the lateral dissection within 12 mm of the midline at the C2 vertebral body. If extended exposure is required, a transoral mandibular splitting approach is used.

The use of anterior techniques is largely confined to specialist centres. Complications include injury to viscera including the oesophagus, trachea, pharynx, tongue, internal carotid artery, internal jugular vein, and cranial nerves IX–XII.

Specifically, the potential technical complications are related to the healing of the pharyngeal mucosal flap, velopharyngeal incompetence with regurgitation and speech dysfunction from soft palate incision if needed and teeth malocclusion due to the osteotomies for transmaxillary or transmandibular approaches.

Endonasal Endoscopic Extended surgical approaches

Endoscopic odontoidectomy is considered in cases of basilar invagination. The nasopalatine line (as described by Kassam—which is a line on the midline sagittal images from the inferior tip of the nasal bone to the posterior aspect of the hard palate extended to the anterior spine) is used to indicate the lower limit of this approach. The high-riding dens found in cases of basilar invagination, allows endoscopic drilling at the base of the odontoid. Further inferior extension, if required, can be performed with a transoral endoscopic-assisted approach.

A direct incision in the nasopharyngeal wall in the midline or a flap is used to expose the lower clivus, anterior lower lip of the foramen magnum and anterior arch of the atlas. This approach avoids the need for a palatal incision. The anterior arch of the atlas is resected

Table 60.3 The evolution of surgical principles underlying sublaminar wiring and interlaminar clamping techniques

Technique	Principle	Bone graft	Advantage	Disadvantage
Gallie (1939)	Midline Sublaminar wire beneath C1 arch wrapping around C2 spinous process	Single bone graft strut abutting C1 arch and overlying C2 spinous process	Avoids sublaminar wire passage beneath C2	Non-fusion rates as high as 25% Poor rotational stability
Brooks & Jenkins (1978)	Paramedian 2 Sublaminar wires beneath C1 and C2 arches	Two bone grafts between C1 and C2 laminae	Fusion rates up to 93% Better rotational stability than Gallie	Additional risk due to sublaminar wire passage beneath C2
Dickman et al. (1991) (Fig. 60.8)	Midline Sublaminar wire beneath C1 arch and looped caudally around C2 spinous process	Single bone graft between C1 and C2 laminae	Fusion rates (with HALO) up to 97% Improved rotational stability Avoids sublaminar wire beneath C2	
Interlaminar clamps	Hooks over superior surface of C1 arch and inferior surface of C2 arch held in compression	Single bone graft between C1 and C2 laminae	Avoids sublaminar wire passage	Translation/migration of bone graft

using a high-speed drill and the base of the odontoid is drilled and 'egg-shelled' until the underlying transverse ligament and dura are reached and disconnected from the C2 body. The bone is then carefully pulled down from the foramen magnum and may require additional removal of the anterior lip of this foramen to allow sharp division of the apical and alar ligaments. The totally free odontoid bone is removed and the theca is decompressed (Fig. 60.9). The edges of the incision are approximated and do not necessarily require suturing, unless there is cerebrospinal fluid (CSF) leak. Subsequently fixation is required as this procedure makes C1/2 unstable.

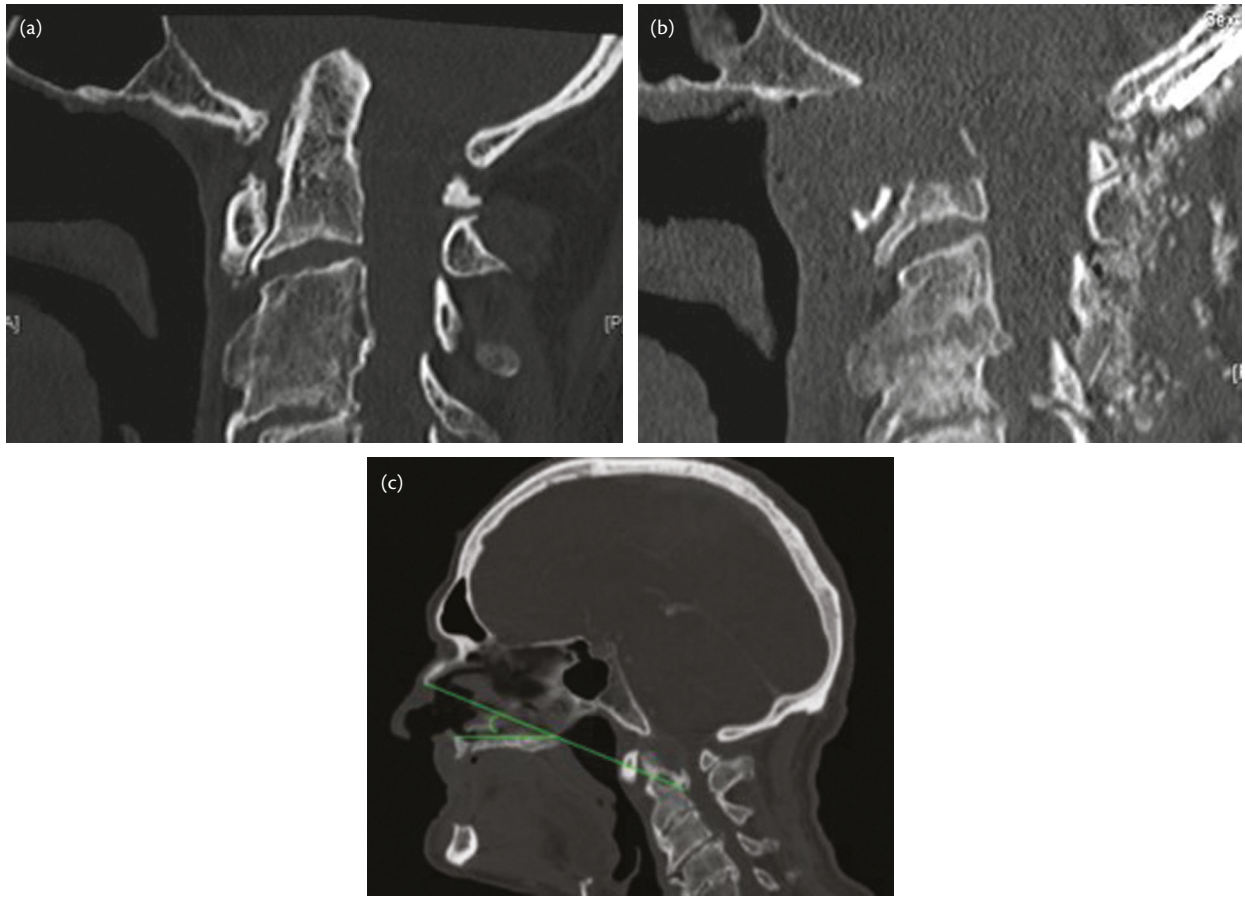

Fig. 60.9 Endonasal endoscopic odontoidectomy and craniocervical junction decompression.
(A) Preoperative midsagittal CT reconstruction demonstrating basilar invagination. (B) Postoperative midsagittal CT reconstruction following endoscopic removal of odontoid PEG. (C) Kassam's nasopalatine line demonstrated in a further patient. This demarcates the most inferior limit of the endonasal endoscopic approach.

Controversies in degenerative cervical spinal disease management

Few clinical studies provide high-class evidence to guide decision making in degenerative cervical spinal disease. Commonly debated issues include indications and timing of surgery, minimally invasive versus open techniques and anterior versus posterior approaches. There is no level I or II evidence comparing anterior versus posterior approaches and studies have shown equivalent efficacy (Fehlings et al., 2013; Lawrence et al., 2013).

Adjacent segment disease is a recognized problem in patients who have had an anterior cervical discectomy. Hilibrand et al. (1999) noted symptomatic disease requiring treatment in 2.9% per annum. Debate is ongoing about whether this is due to the arthrodesis or the natural history of the disease. Studies have demonstrated increased biomechanical strain (intradiscal pressure) and increased motion at adjacent levels following arthrodesis.

Prospective trials have examined the kinematic effect of cervical disc replacements on the spine and have compared the outcomes between arthroplasty and arthrodesis. Cervical arthroplasty has shown equivalent results compared to arthrodesis for single level discectomy (Buchowski et al., 2009) but for multilevel degenerative disc disease, there is a suggestion of reduced re-operation rates in patients with arthroplasty. Arthroplasty is more expensive. Clinical results do tend to favour arthroplasty (Ren et al., 2014). Although arthroplasty is a valid option to offer to patients being considered for anterior cervical discectomy more robust long-term outcome data are awaited.

Thoracic spinal disease

Kieron Sweeney, Catherine Moran, and Ciaran Bolger

Introduction

The thoracic spine occupies a unique position with respect to anatomical, biomechanical, pathological, and surgical considerations. The kyphosis of the thoracic spine is offset by the lordosis in the mobile cervical spine and the principal load bearing lumbar spine maintaining a sagittal balanced posture. The thoracic spine and its articulation with the rib cage maximizes the stability of the thoracic spine while minimizing its mobility leading to the low incidence of thoracic disc prolapse.

Incidence

The incidence is reported as 1 per 1 000 000 patient years (McInerney and Ball, 2000). Thoracic disc herniations identified incidentally on work up for other spinal pathologies are reported as frequently as 11% (Awwad et al., 1991). Between 0.2% and 4% of all symptomatic protrusions of an intervertebral disc are in the thoracic spine and thoracic disc extrusion accounts for 0.2% to 1.8% of all operations performed on symptomatic herniated discs. There is an approximate 1:1 male to female ratio and it more frequently occurs in the third to sixth decades which mimics cervical and lumbar disc herniations (McInerney and Ball, 2000). Due to the structural stability provided by the upper thoracic cage the majority of thoracic disc herniations occur below the level of T7 with the most common level being T11/T12. The majority of disc protrusions are central or centrolateral. Degeneration is the leading cause of thoracic disc herniation with only 25% due to trauma. Traumatic disc herniations usually occur in the younger age group. Some 30–70% of discs are reported to be calcified with a high incidence of calcified discs being intradural (Fig. 61.1).

Presentation

Myelopathy consisting of spastic paraparesis, sensory disturbance, bladder or bowel dysfunction and pain, and both axial back pain and radicular pain radiating around the anterior chest wall, are the most common clinical features and presenting complaints (Stillerman et al., 1998). However, there is significant variation in the presenting symptoms and signs of thoracic disc herniation from case to case. This is dependent on the spinal level, position, and size of the herniated disc and bony canal, duration of compression, and degree of neurovascular compromise and aetiology. The majority of the literature demonstrates that pain is the predominate symptom at presentation. Pain can be unilateral or bilateral and the region it radiates to depends on the level. T1/T2 discs can present with upper limb radiculopathy with pain radiating down the upper limb and weakness of the intrinsic muscles of the hand. Pain due to mid-thoracic discs can radiate across the chest wall whereas lower thoracic discs can present as abdominal or lumbar pain. There appears to be a chronological and progressive sequence of symptoms. In disc herniations due to degeneration the sequence is firstly, pain (thoracolumbar or radicular pain) followed by sensory disturbance, then motor dysfunction and bladder and bowel dysfunction (Arce and Dohrmann, 1985). In traumatic disc protrusions, pain is quickly followed by myelopathy (Arseni and Nash, 1960). However up to 25% of patients present without pain, complaining of a subtle neurological deficit or gait disturbance which can contribute to a delayed diagnosis.

Pathogenesis

Neurological signs and symptoms are due to direct neural compression and vascular insufficiency. Compression at the levels T4-T9 can have a significant impact of the spinal cord due to the vulnerable blood supply at this level.

Management

Conservative

There is little published information regarding the natural history of asymptomatic thoracic disc protrusion. The reported incidence of asymptomatic thoracic disc protrusion ranges from 15% (S&S) to as high as 37% (Wood et al., 1995). The authors reviewed the thoracic MRI from 90 asymptomatic individuals assessing for anatomical abnormalities. They then followed these individuals for a mean of 26 months with MRIs and concluded that over the follow-up period, the herniated discs remained asymptomatic but small discs tended to remain unchanged or increase in size, whereas large discs tended to decrease in size (Wood et al., 1997).

Surgical

Indications for surgery include pain refractory to medical management, evidence of myelopathy, bladder or bowel disturbance, or any long-tract signs. The main indication for surgery is neurological dysfunction in the form of myelopathy, progressive or otherwise. It

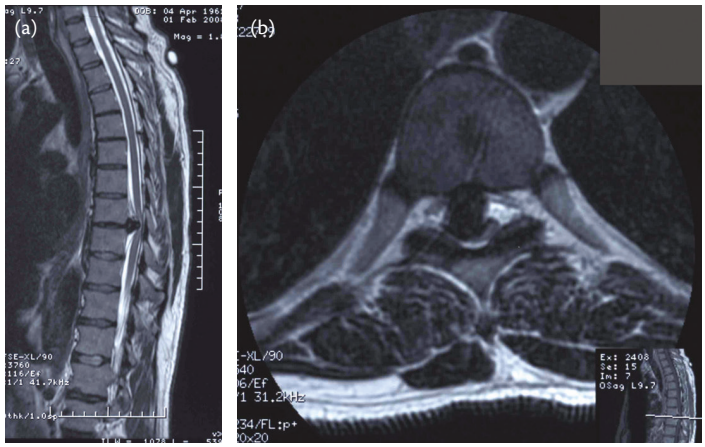

Fig. 61.1 Giant thoracic disc. Note marked cord compression on T2 images.

is the authors' experience that although patients may present with a long history of fixed neurological deficit due to delayed diagnosis, surgical decompression can still result in significant functional recovery. Cases presenting with radicular pain only, once the level is confirmed using a nerve root block, can be treated via a less extensive surgery for exiting nerve root decompression. In most cases, however, the intervention needs to be more extensive. In these cases the surgical strategy depends on the level of the disc prolapse, the position of the disc in relation to the neural structures, the consistency of the disc (soft vs. calcified) and whether or not the disc is intradural (Arts and Bartels, 2014). Of these variables, it is the level of the disc herniation and its position relative to the neural structures that dictates the optimum approach Table 61.1.

Prior to operative intervention, all cases should have a whole spine MRI, to confirm level, and a computed tomography (CT) scan of the affected area, to determine if calcification is present in the prolapsed disc.

Approaches to a thoracic disc prolapse

When considering the most appropriate surgical approach to remove a prolapsed thoracic disc the most important elements to consider prior to surgery are the location of the prolapse, central, centrolateral, or lateral, the size of the prolapse, any associated or expected deformity which may require fixation, any evidence of calcification of the prolapse which may also point to an intradural component, the size of the prolapse and the thoracic level. The historical laminectomy used for treatment of thoracic discs was associated with a morbidity of up to 60% (Fessler and Sturgill, 1998) and has no role to play in the safe management of these cases today.

Preoperative marking is recommended, marking the head of the articulating rib with dye before the surgery. Intraoperative verification with the use of C-arm or intraoperative CT scanning is essential. The use of intraoperative monitoring is optional but in the authors experience, a suitable approach which allows visualization of the prolapsed disc fragment without any manipulation of the already compromised cord is more important.

Localization of the correct level is a major consideration. The level should be localized using both anteroposterior (AP) and lateral radiographs, counting up from the sacrum and down from C2 if possible. It is essential to have a whole spine MRI on which the actual level of the prolapsed disc can be confirmed with reference to C2 and the Sacrum.

Table 61.1 Central disc herniation

Level	Approach
T1–T4	Trans-sternal
T2–T6	Right transthoracic
T6–T12	Left (or right) transthoracic

Anterior approaches: Trans-sternal

The indications for using this approach are T1-T4, central, calcified, intradural disc prolapses.

The technique is as follows. The patient is positioned supine with a shoulder bag between the scapulae to allow for slight neck and shoulder extension. An orogastric tube is placed to allow for easy identification by palpation of the oesophagus.

The incision is along the ventral border of the sternocleidomastoid muscle (SCM) to the angle of Lewis. Some authors recommend the left SCM incision as the left recurrent laryngeal nerve is more easily identifiable in the trachea-oesophageal groove. The platysma is divided along its fibres. Subperiosteal dissection of the sternal and clavicular insertion of the strap muscles, SCM, and sternohyoid, follows allowing these to be retracted. A plane is then developed by finger dissection underneath the sternum and into the upper mediastinum. The thymus may be swept laterally. The sternum can then be split with an oscillating saw and a sternal retractor is placed. The pleural is dissected and retracted laterally.

Similar to the anterior cervical approach, an avascular plane is developed by blunt dissection between the trachea and oesophagus medially and the carotid laterally. The left brachiocephalic vein and artery may be retracted inferolaterally. The plane of dissection is continued between the oesophagus and prevertebral fascia allowing identification of both longus coli muscles. At which point retractors are placed (Zengming et al., 2010). Closure is in a stepwise fashion with a chest drain and postoperative chest X-ray.

The important complications are vascular injuries, thoracic lymphatic duct injury, tracheal injury, oesophageal injury, and pleural injury/pneumothorax.

Anterior approaches: Transthoracic

The transthoracic approach gives the most anterior view of the spinal cord and disc prolapse, it is especially useful in central disc prolapses and is essential in the skill set of any surgeon treating this condition. It is the approach the author would recommend in all calcified and newly termed 'giant' disc herniations. These are defined as occupying greater than 40% of the canal on preoperative imaging (Hott et al., 2005)

The indications for this approach are T2–T12, central, calcified, intradural disc prolapses.

The technique is as follows (Figs. 61.2–61.6): The patient is positioned in a lateral decubitus position with an axillary roll. The legs are flexed with a pillow between the knees. For higher disc spaces (T2–T6) skin preparation should include the scapula and shoulder as to allow for mobilization of the scapula. A right sided approach for higher lesions allows for better visualization of the spinal surface

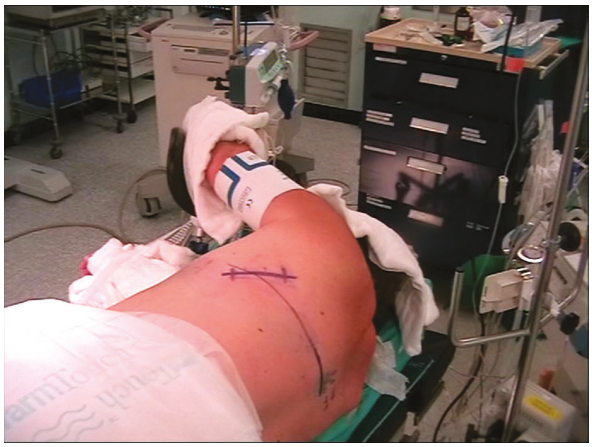

Fig. 61.2 Patient positioning and incision marked in mid-axillary line, centred over relevant disc space which was marked with AP and lateral X-ray.

as the arch and descending aorta are closely related to the left side of the vertebral bodies. A left sided approach allows for easier exposure of T8 and below as the liver and diaphragm can obscure an approach from the right. A left sided approach also minimizes the risk to the thoracic duct. A double lumen endotracheal tube is used.

An incision is made after intraoperative localization of the desired spinal and intercostal level. For a full open approach to the upper levels the incision is from the spinous process of T1 and carried medially parallel to the medial border of the scapula to the inferior angle of the scapula and continued laterally to the costal margin of the seventh rib. For lower levels, the skin incision is placed on the line of the rib to be resected. Whether a full or mini-open procedure is to be utilized, the incision should be planned so that its midpoint overlies the appropriate disc space at the level of the mid-axillary line.

The approach for higher levels includes identification and division of the dorsal shoulder girdle muscles including trapezius, latissimus dorsi, rhomboids, and serratus muscles which allow for retraction of the scapula to expose the chest wall. For lower approaches latissimus dorsi and serratus anterior are identified and divided exposing the rib. The intercostal muscles of the rib are stripped and the undersurface of the rib cleared with a periosteal elevator. The muscle

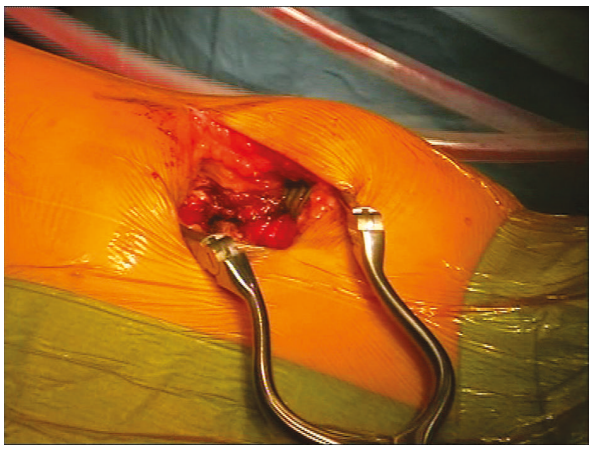

Fig. 61.3 Incision over appropriate rib.

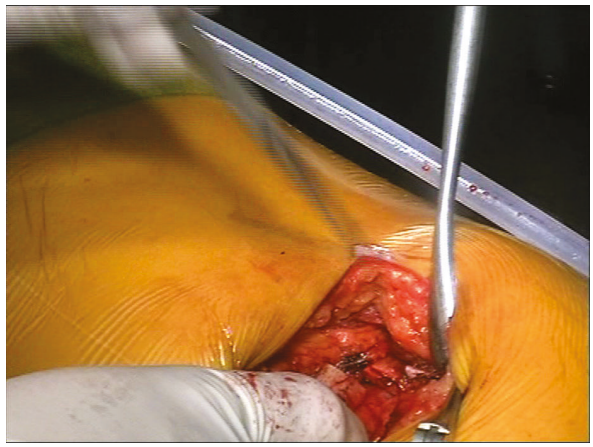

Fig. 61.4 Rib is fractured and displaced inferiorly to expose the pleura.

dissection is continued along the rib as far anteriorly and posteriorly along the rib as possible.

The rib is then cut as close to the rib head/costotransverse junction and as far anteriorly to the costal junction as possible. With mini-open approaches, the rib is not cut anteriorly, but a chest spreader is placed, and at this point the surgeon can go transpleural or retropleural. If done retropleurally, the lung should be left inflated to allow for easier dissection of the pleura and minimize pleural tears. If transpleural, the lung is deflated and the parietal pleura is incised over the desired disc space, with the flap based medially.

Careful identification of the azygous vein, aorta on the left, sympathetic plexus, intercostal bundle, and rib head is required. The intercostal artery and vein are ligated and divided close to their origin to minimize the risk of vascular compromise, at least 1 cm from the intervertebral foremen. The rib head is then removed to expose the disc space. The disc space is cleared together with a portion of the vertebral body above and below. The extent of the bony removal is dependent on the superior/inferior extent of the disc prolapse. To fully expose the prolapsed disc along its length, for very large discs, it may be necessary to partially remove the superior or inferior pedicles. The purpose is to create a cavity, anterior to the cord, into which the prolapsed disc can be delivered. The prolapsed portion of the disc is then delivered anteriorly, away from the cord.

Closure is in a stepwise fashion with repair of any dural defect, and a chest drain if a transpleural approach was used. If there is a dural defect a lumbar drain should be placed.

Complications include vascular injuries, thoracic lymphatic duct injury (right), oesophageal injury, pleural/pneumothorax injury, and sympathetic plexus injury.

Posterior-lateral approaches: Costotransversectomy

The indication for this approach is a lateral, soft disc protrusion.

The technique is as follows: The patient is positioned prone on chest rolls. A midline incision with a 'T' or paramedian straight or curvilinear incision is made, centred on the desired level.

The trapezius or latissimus dorsi is identified and divided close to the transverse process. The superficial surface of the rib is cleared from remaining muscle attachments and the undersurface of the rib cleared with a Doyan periosteal elevator. The transverse process and lamina are cleared of any remaining muscle fibres. The rib head is

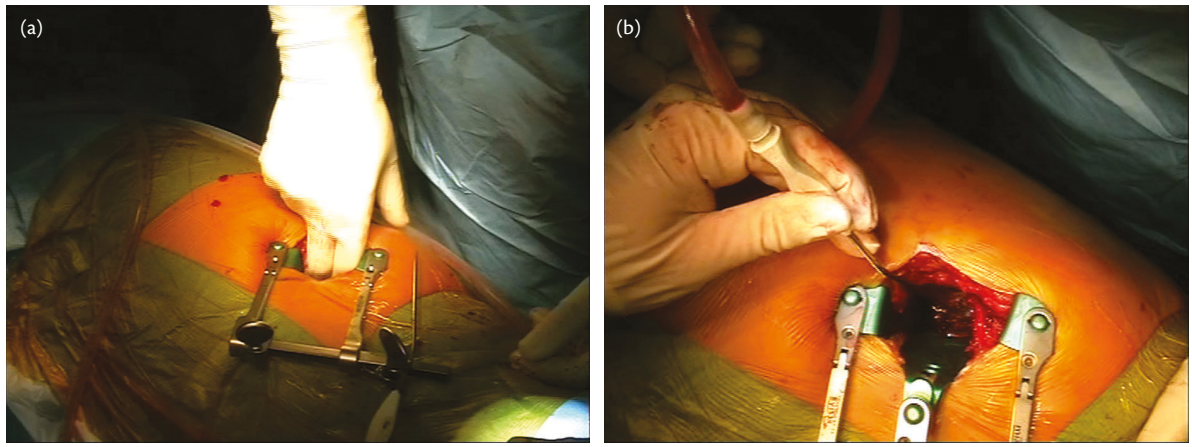

Fig. 61.5 Pleura is stripped from chest wall by blunt dissection. And deep retractor inserted on the vertebral surface.

disarticulated and the rib is cut anteriorly. This allows the rib to be disarticulated with the costotransverse process and removed completely after identification of the neurovascular bundle. The transverse process is resected exposing the pedicle. The parietal pleura is then retracted to allow resection of the pedicle. The rib removal performed in the standard procedure can be too limiting to allow for pleural retraction, and the ventral and even, lateral exposure can still be too limited. Bilateral costotranversectomies can be performed to allow for a pan-ventral exposure.

The main complications are vascular injuries, thoracic lymphatic duct injury (right), oesophageal injury, pleural/pneumothorax injury, and sympathetic plexus injury.

Posterior-lateral approaches: Lateral extra cavity

The indication for this approach is a lateral, soft disc protrusion.

The technique is as follows: The patient is positioned prone on chest rolls. The incision depends on the level either a midline incision over the spinous processes or curvilinear incision with the straight segment over the spinous process skirting along the inferior angle of scapula is used. The trapezius or latissimus dorsi is identified and divided close to the transverse process. The lateral border of the erector spinae muscles are identified and reflected medially. The superficial surface of the rib is cleared from remaining muscle attachments and the undersurface of the rib cleared with a Doyan periosteal elevator. The transverse process and lamina are cleared of any remaining muscle fibres.

The rib head is disarticulated and the rib cut greater than 12 cm laterally. The rib can then be disarticulated from the costotransverse process and removed completely after identification of the neurovascular bundle. The transverse process is resected exposing the pedicle. The parietal pleura is then retracted to allow resection of the pedicle. The level in the thoracic spine must be considered and above T4 is difficult due to the presence of the scapula. Dissection through the rhomboids and trapezius is required and carries high morbidity.

Complications include vascular injuries, thoracic lymphatic duct injury (right), oesophageal injury, pleural injury/pneumothorax, sympathetic plexus injury, dural tear, CSF leak, the need for thoracostomy, nerve root injury, and infection. The rate is quoted as

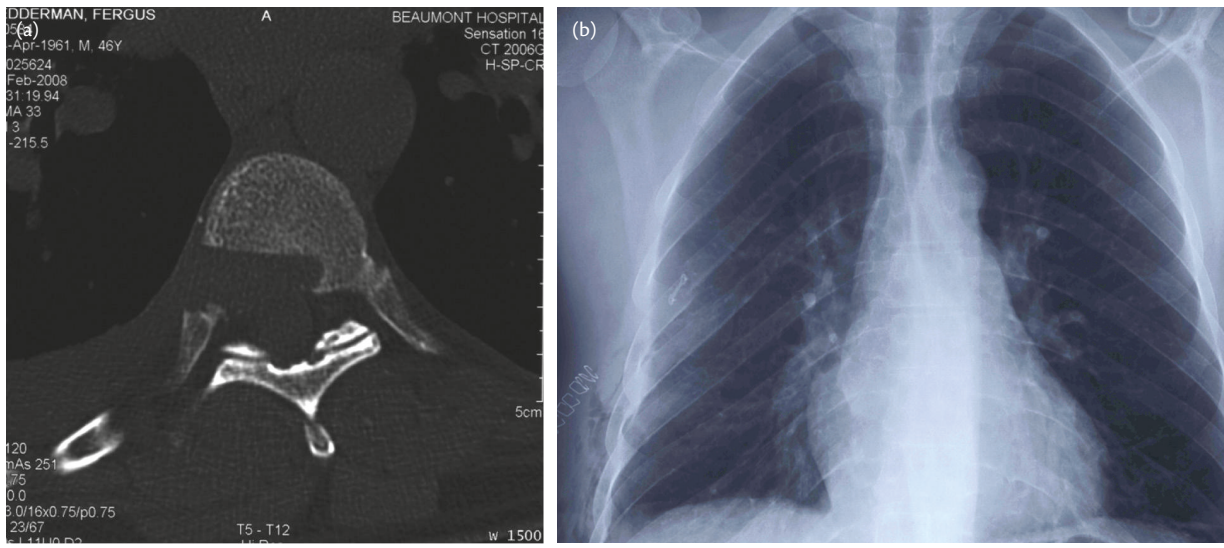

Fig. 61.6 (A) Postoperative CT shows extent of bony resection and complete removal of prolapsed disc. (B) Postoperative chest X-ray with mini plate approximating rib.

high as 53% in some series (Lubelski et al., 2012). The muscle dissection required for this exposure can result in increased blood loss, postoperative pain, and an increased hospital stay.

Posterior-lateral approaches: Transpedicular (unilateral or bilateral)

The indication for this approach is a lateral, soft disc protrusion. Bilateral approaches may achieve central disc decompression but are more destabilizing.

The technique is as follows: the patient is positioned prone on chest rolls. A midline incision is made over the spinous processes. The approach is subperiosteal dissection down along the spinous processes and lamina laterally to the facet joint. Using Kerrison's rongeurs with a small footplate a lateral laminotomy is performed to identify the nerve root and thecal sac. The inferior facet of the superior vertebra and the superior facet of the inferior vertebra along with the superior margin of the transverse process is resected exposing the caudal pedicle. The cancellous bone of the pedicle is drilled staying within the cortical bone. The superior and inferior cortical shell remaining is then resected. Cortical bone adjacent to the spinal canal is removed laterally and a partial laminectomy is then performed. A portion of the superior and inferior facets are also drilled down. The lateral disc space is incised and 'emptied' using curettes and rongeurs, gently making room medially to deliver the disc fragment in the space created.

Post-op instability is rare, thus fixation is not necessary. Complications include nerve root and spinal cord injury

Posterior-lateral approaches: Transfacet pedicle sparing

The indication for this approach is a lateral, soft disc protrusion.

The technique is as follows: The patient is positioned prone on chest rolls. A midline incision over the spinous processes is made. The approach is subperiosteal dissection down along the spinous processes and lamina laterally to the facet joint. Using Kerrison's rongeurs with a small footplate a lateral laminotomy is performed. The medial aspect of the inferior facet of the superior vertebra is resected exposing the nerve root and thecal sac. Closure is in a stepwise fashion. Complications include nerve root and spinal cord injury

Minimally invasive procedures

Minimally invasive techniques (MIT) have become increasingly popular in Neurosurgery. These techniques have been reported to reduce morbidity by reducing approach related tissue trauma, however paradoxically, have a steep learning curve which can lead to significant complications (Elhadi et al., 2015). MITs range from mini-open approaches to video-assisted thoracoscopic and endoscopic techniques. Eihadi et al. performed a systematic review comparing outcomes of MIT to conventional open approaches and concluded that soft disc herniations confined to a single level, are suitable for a minimally invasive approach but patients with calcified discs adherent to the dura would benefit from an open approach. However, their review did not include min-open approaches.

Thoracoscopic discectomy

The patient is positioned in a lateral position and is intubated using a double lumen endotracheal tube, after incisions are made for ports the ipsilateral lung is deflated. Thoracoscopic portals, 15 mm in diameter and flexible, are inserted in three different port openings for the working instruments, as well as a 1 cm port for the endoscope. The pleura is dissected from the vertebral column. The morbidity of severe postoperative neuralgia caused by muscle dissection and rib retraction, part of a large thoracotomy, is avoided. Like an open thoracotomy the head of rib and pedicle are first drilled and the spinal cord is identified clearly, a trough in the vertebral body adjacent to the prolapsed disc is drilled and the disc fragment is then slowly 'worked' into this space.

Mini-open technique

The author has previously published the mini-open retro-pleural approach. In this procedure a 4 cm incision in the mid-axillary line is performed, followed by a single rib cut, the pleura is then carefully dissected off the inside of the thoracic cavity using blunt, peanut dissectors, insertion of a long retractor may allow for the ipsilateral lung to remain inflated and negates the need for a post-op chest drain. The disc prolapse is resected as just described and the rib is reattached using a universal quick flap. For large central disc prolapses the author approaches from the left side as the more robust aorta is easier to manipulate. Various authors have reported success utilizing a mini-open approach (Moran et al., 2012; Snyder et al., 2014). Other factors to consider include surgeon experience in the various techniques (Falavigna and Piccoli Conzatti, 2013).

Prognosis

In cases where surgical intervention is indicated recovery of neurological function and pain control is seen in the majority of patients, even those with 'giant' discs (Moran et al., 2012). Historically the surgical morbidity, including postoperative neurological worsening and paralysis, was high—complications from laminectomy have been quoted as anywhere between 18 and 75% (Arseni and Nash, 1960; Fessler and Sturgill, 1998).

Clinical outcome following surgical intervention has improved dramatically since abandoning this approach and using, instead, more ventral approaches, either transthoracic or dorsolateral. However, post-thoracotomy pain syndrome has been reported in up to 50% of patients postprocedure, continuing long term in up to 30% (Karmakar and Ho, 2004).

Osteoporosis and vertebral compression fractures

Osteoporosis is a skeletal disorder resulting in an increase in fracture risk. The risk of fracture is inversely related to bone strength, which is a function of bone mineral density, bone microarchitecture and remodelling (NIH Consensus Development Panel, 2001). Bone mineral density is measured by dual X-ray absorptiometry (DXA). Factors that influence bone strength are age-related bone loss and hormonal status. It has recently been demonstrated that loss of trabecular bone can occur as early as the third decade in both men and women. However, it is not until middle age that loss of cortical bone begins for both sexes. Age-related bone loss is thought to be due to the reduced capacity of the kidney to hydroxylate vitamin D to its active form resulting in a low serum calcium and secondary hyperparathyroidism.

Hormonal related bone loss affects women more than men. With the onset of the menopause, the decline in serum levels of oestradiol and oestrone results in a mismatch between bone formation and resorption leading to progressive bone loss. The net resorption of bone leads to an increase in the level of extracellular calcium which

activates compensatory mechanism to prevent hypercalcaemia resulting in a net negative total body calcium.

In comparison, men do not experience an abrupt decline in sex hormones. Rather, there is a slow progressive decline in the bioavailability of testosterone and oestradiol due to the increase in sex hormone binding proteins (Drake et al., 2015).

Due to concerns over pharmacological replacement of oestrogen, selective oestrogen receptor modulators are licensed in the treatment of postmenopausal osteoporosis. Bisphosphonates are inorganic pyrophosphates that have a high affinity for hydroxyapatite. This forms a non-degradable barrier between osteoclast and Howship lacunae. The osteoclasts endocytose the bisphosphate leading to apoptosis.

Osteoporotic vertebral compression fractures can lead to significant morbidity due to acute or chronic pain and progressive kyphotic deformity resulting in biomechanical instability leading to falls risk or impairment of respiratory function. Therefore, screening for osteoporosis is recommend for women older than 65. For women younger than 65 or men older than 65, an analysis of individual risk factors may help predict the presence of osteoporosis. These risk factors include: female sex; White or Asian race; low body weight/body mass index; family history; early menopause; sedentary lifestyle; excessive alcohol; low calcium or vitamin D intake and inadequate sun exposure; certain medications (glucocorticoids or anticonvulsants); diseases such as rheumatoid arthritis and almost all systemic inflammatory diseases. Laboratory investigations include ESR, FBC, Ca, PO4, Alk Phos, Cr, and 24 h urinary Ca. DXA is considered the gold standard radiological investigation as it can predict fracture risk. Short tau inversion recovery (STIR) sequences on MRI scanning can help distinguish recent from long standing injuries.

Treatment of osteoporosis can be divided into non-pharmacologic and pharmacologic. Non-pharmacologic interventions include exercise and dietary modifications. Physical activity has been shown to reduce age-related bone mineral loss. A diet rich in dairy products and fish will supplement vitamin D intake. Pharmacologic therapies include bisphosphonates which reduced bone turnover in a dose-dependent manner and reduce fracture risk, hormone replacement therapy, and selective oestrogen receptor modulators.

Vertebroplasty and kyphoplasty

Vertebroplasty can be indicted in acute symptomatic osteoporotic compression fractures refractory to medical management. Under intravenous sedation with local anaesthetic or general anaesthesia. The patient is placed prone with bi-planar fluoroscopy or under CT guidance, a unilateral or bilateral approach via a small stab incision is made. An 11–13-gauge needle is passed to the anterior third or quarter of the vertebral body via a transpedicular or parapedicular route (the point of attachment of the pedicle to the vertebral body). Polymethyl methacrylate cement is then slowly injected until it approaches the posterior vertebral wall. If extraosseous cement is noted the procedure should be terminated immediately. Complications include pulmonary emboli from fat or cement, radicular pain neurological complications, and adjacent level fractures.

Kyphoplasty similarly is indicated for symptomatic osteoporotic compression fractures refractory to medical management and restoration of sagittal balance. The technique is the same except the needle is passed under the endplate at the centre of the vertebral body and a series of tools are used to create a working channel down which a bone tamp is passed. The tamp is expanded under fluoroscopic guidance with volume and pressure monitoring. Inflation is stopped when the height is restored or maximal volume/pressure is achieved in the balloon or the balloon comes within 1 mm of the cortical surface. The tamp is removed and Polymethyl methacrylate cement is then slowly injected into the cavity. Complications include pulmonary emboli from fat or cement, radicular pain, neurological complications, and adjacent level fractures.

Typical short- and long-term outcome measures for these procedures are pain scores (VAS), disability scores (ODI), complications (cement leakage, neurological injury), height of anterior vertebral body, kyphotic angle, adjacent level fractures, and length of stay. Both procedures are safe and effective with respect to all outcomes when compared to medical management. There was no difference noted in the incidence of adjacent level fracture between kyphoplasty and vertebroplasty. Both of these interventions reduced the incidence compared to conservative treatment. Kyphoplasty may have a slight advantage over vertebroplasty in restoration of the anterior vertebral height and kyphotic angle (Ma et al., 2012).

There is ongoing debate in the literature regarding the timing of vertebroplasty and kyphoplasty. The main indication for vertebroplasty is for pain control and therefore the optimum timing of vertebroplasty is uncertain with some authors suggesting that vertebroplasty can be safely and effectively performed at any time between 2 to 12 months (Nieuwenhuijse et al., 2012). As the indication for kyphoplasty is restoration of sagittal balance as well as pain control timing appears to be more important. Restoration of vertebral height is most effective in acute or subacute fractures and therefore it would appear that the accurate timing of the procedure is necessary (Crandall et al., 2004).

Controversy

Routine MRI for osteoporotic fractures

MRI may be used to assess if a fracture is acute or chronic. During the acute phase in fracture healing there may be a finding of haemorrhage and the normal fatty marrow can demonstrate significant marrow oedema that decreases over approximately three months (Brinckman et al., 2015; Piazzolla et al., 2015). This can be appreciated as a high signal intensity on T2 weighted sequences or the T1 fat suppression technique called STIR. Some recent studies have suggested that certain T1 and T2 characteristics of the acute fracture may help in predicting non-union (Tsujio et al., 2011; Takahashi et al., 2016). Other indications for using MRI in the setting of osteoporotic fractures would be if there is concern that the fracture may be a pathological fracture due to bony metastasis. This may be achieved by acquiring T1 postgadolinium and diffusion-weighted sequences (Pozzi et al., 2012).

Lumbar spinal disease

Christopher G. Kellett and Matthew J. Crocker

Introduction

Observations relating to degeneration of the lumbar spine date back to Hippocrates and Galen. It is only in the last century degenerative disc disease has become a recognized entity. In more recent years, advances in imaging and surgical technology have resulted in novel approaches to treatment, marking a renaissance in what is still an evolving field. Lumbar spinal disease is ubiquitous; it is prudent that the neurosurgeon develops a sound understanding of this challenging area.

Degenerative lumbar spinal disease

Key concepts

Three key concepts will be discussed: spinal function, the motion segment, and spinopelvic balance.

Spinal function

The spine has three principal biomechanical roles; namely load bearing, mobility, and protection of the neural elements.

Forces placed on the intervertebral disc are several times greater than the sum of the weight of body parts and supported objects. Regardless of loading pattern the healthy intervertebral disc and its hydrostatic properties, distributes load equally to the vertebral endplate. As in other diarthrodial joints, abnormal loading results in focal degeneration and pain, confirmed by discography (McNally et al., 1996).

The spinal musculature has a mechanical advantage; small changes in muscle length produce a large range of movement placing the spine under great stress. The ligamentous spine respects a tension-elongation relationship; with elongation tension increases, stability is associated with spinal tension and stiffness. There has been no conclusive evidence that translation or angular movement beyond the normal range of motion is associated with pain however anecdotally spondylolisthesis demonstrates that segmental instability results in pain.

Loss of integrity of supporting structures through the degenerative process frequently results in a mechanical and chemical insult to neural tissue. Examples include disc herniation, lumbar canal stenosis, and spondylolisthesis.

The motion segment

Schmorl and Junghanns (1971) were the first to describe the 'motion segment' consisting of two vertebrae, the intervening disc and the associated zygapophyseal (facet) joints. Segmental ligaments include longitudinal, flaval, and interspinous ligaments. The intrinsic segmental muscles (splenius, erector spinae, transversospinal) provide antagonizing actions and stability. 'The three-joint complex' was coined by Kirkaldy-Willis et al. (1978) highlighting the inextricable relationship between the intervertebral disc and facet joints. Degeneration of one component will lead to degeneration of the entire segment resulting in pain, deformity, and neural compromise. Panjabi (1992a, 1992b) describes the spine as a dynamic neuromuscular system with three subsystems (passive, active and neural with feedback subsystems) in equilibrium.

Spinopelvic balance

Optimal sagittal plane alignment allows the spine to support the weight of the body with minimal energy expenditure. Imbalance results in muscular fatigue, deformity, pain, and the psychosocial implications of kyphosis and deficient horizontal gaze. The relationship between the pelvis, spine, and overall sagittal balance is paramount when treating spinal disorders. The neurosurgeon will encounter many patients with 'failed' and 'flat back' syndrome. Obtaining full-length standing anteroposterior (AP) and lateral X-rays in these patients will allow measurement of spinopelvic geometry, reveal the magnitude of sagittal imbalance and the degree of correction required to restore balance. Discussion of spinopelvic parameters is beyond the scope of this chapter and the reader is referred to in Chapters 57 (spinal stability) and 66 (scoliosis)

Aetiology and pathophysiology

Eighty per cent (80%) of people experience an episode of low back pain in their lifetime, with 10% developing chronic pain. In the United Kingdom 8.3 million working days are lost per year secondary to musculoskeletal problems; patients are unlikely to return to work after two years of sick leave. The natural history of lumbar back pain is benign and in the majority, pain will resolve in 2–4 weeks and more than 90% are pain-free at 12 months. With the over-65 age group set to double over the next 25 years, back pain will have greater socioeconomic implications.

Degenerative disease has traditionally been linked to occupational repetitive loading. In addition, factors such as age, male gender, and smoking have been implicated. However, increasingly it is evident that genetic factors play a role. Familial degenerative disc disease is recognized and candidate-gene polymorphisms include those encoding collagen, Sox9, the vitamin D receptor metalloprotease-3, and interleukin-1.

The degenerative cascade

The degenerative process has three distinct phases (Kirkaldy-Willis et al., 1978). Instability occurs when degeneration exceeds structural changes conferring stabilization.

Firstly, dysfunction characterized by minor trauma or repetitive strain results in axial back pain secondary to segmental muscle fatigue, spasm, and inflammation. Disc degeneration manifests as circumferential annular tears and nuclear matrix changes then facet synovitis and cartilaginous degeneration occurs. Secondly instability characterized by internal disc disruption and resorption, facet capsule laxity, and subluxation. Thirdly stabilization characterized by osteophytosis and ankylosis reducing motion, thickening of the yellow ligament and circumferential encroachment with compromise of the neural elements.

Lumbar spondylosis

'Spondylosis' encompasses a group of pain disorders and clinical syndromes related to degeneration of the motion segment, the cardinal symptom being axial lower back pain. Neurological compromise and radicular pain may coexist.

Most patients with lumbar spondylosis describe non-specific back pain. A small group of patients (10–15%) present with pain related to disc or facet degeneration and instability. Degenerative findings on MRI are common in asymptomatic individuals however disc disease with associated Modic changes and significant facet degeneration is rare in younger patients. Certain clinical pointers may pinpoint specific pain generators and appropriate treatment.

Lumbar canal stenosis

Lumbar canal stenosis (LCS) and its clinical manifestations were first described in 1961 by Friedman. It affects approximately 1% of the population with patients undergoing surgery for this condition increasing eightfold over the last 30 years, predominantly in the over 65 age group. It is defined as any condition involving narrowing of the spinal canal or neural foramen. LCS may be classified as congenital (idiopathic or achondroplastic) and acquired (degenerative, spondylolytic, traumatic, or metabolic).

Congenital lumbar canal stenosis is rare and presents between 30 and 40 years of age. Degenerative lumbar canal stenosis is more common and presents predominantly in the over 60-year-old age group. The defining syndrome is neurogenic claudication: radicular leg pain, heaviness, numbness, or paraesthesia, which develops on standing and walking. The degree of radiological compression and severity of clinical symptoms reveals poor correlation. Risk factors for peripheral vascular disease should be sought; a careful history will usually differentiate vascular from neurogenic claudication.

Clinical features include back pain with associated radiation into the buttocks on walking and standing associated with heaviness and numbness. Relief of symptoms occurs with flexion of the lumbar spine and rest. Cauda equina syndrome is rare but patients may present with a chronic picture or coexisting acute disc herniation. Examination findings may be subtle and precipitated by exercise. Assessment of sagittal balance may reveal flexion of the knees and hyperextension of the hip to compensate for increased lumbar flexion.

Ligamentous thickening results in central encroachment. Shortening of the spinal column through loss of disc height and deformity causes buckling of the hypertrophied flavum, this is accentuated in lumbar extension. Olisthesis may coexist further reducing canal diameter and compromising neural content.

Claudication is hypothesized to be secondary to mechanical compression and vascular insufficiency. Longstanding compression of the cauda equina results in reduced cerebrospinal fluid (CSF) delivery, microvascular changes, and inflammation. Venous congestion impairs metabolism and nerve root arterioles lose the ability to vasodilate in response to increased metabolic demand during exercise.

In most patients, symptoms progress but a small percentage of patients improve with non-operative treatment.

Conservative management is reasonable in the presence of significant comorbidities, lack of radiological and clinical concordance, and mild or intermittent symptoms. Treatment options include non-steroidal anti-inflammatories, muscle relaxants, physiotherapy, postural education, and epidural steroid infiltration.

A direct comparison of patients undergoing surgical and conservative management of LCS is misleading due to lack of class 1 evidence and heterogeneity of the two groups. Despite this lack of evidence, it is generally accepted that surgery in patients experiencing moderate to severe symptoms is superior to non-operative management.

Progressive neurological deficit and sphincteric disturbance are absolute indications for surgery however this is rare. The surgical technique is dictated by the degree of compression, central or lateral compression, and coexisting deformity; options include laminectomy, selective decompression, laminoplasty, interspinous process distraction devices, decompression alone, or decompression and fusion (non-instrumented vs. instrumented). See **Figure 62.1**.

Laminectomy vs. selective decompression and laminoplasty

Central compression is treated surgically through laminectomy at the stenotic segment. This is favoured in severe stenosis, deformity, and when a wide lateral decompression is required. The greatest degree of compression is sublaminal where the flavum is thickest. In cases of moderate compression resection of the flavum may be performed through a unilateral approach (preserving the midline ligaments and contralateral muscles), laminotomy and an 'over-the-top' technique to decompress the contralateral canal. Moderate lateral recess and extraforaminal stenosis can be addressed using selective decompressive techniques such as laminotomy, medial facetectomy, and extraforaminal muscle splitting approaches.

Laminoplasty techniques have been described similar to those initially described in the cervical spine however, it is not commonplace in the treatment of LCS with increased operative time and no evidence to suggest benefit over other approaches.

Interspinous distraction devices

Interspinous distraction devices (ISD) require the insertion of a spacer through the interspinous ligament, maintaining the

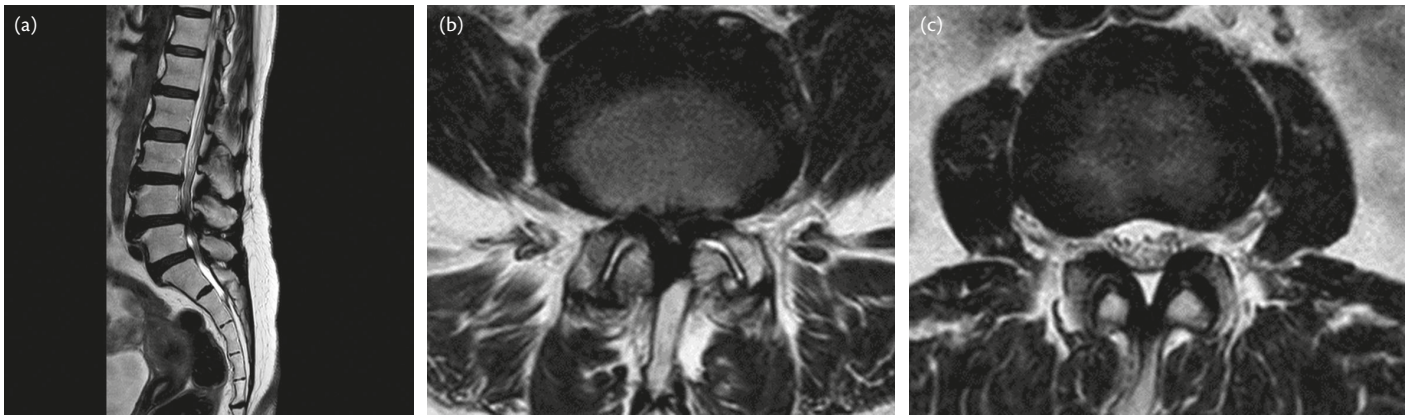

Fig. 62.1 T2 MRI. (A) Sagittal: L4/5 lumbar canal stenosis and degenerative spondylolisthesis; (B) Axial: crowding of the cauda equina secondary to a broad-based disc protrusion, facet and flaval hypertrophy; (C) Axial: non-stenotic level for comparison.

supraspinous ligament. This decreases intradiscal pressure, distracts the facets and neural foramen, unbuckles the flavum, and reduces abnormal segmental motion. They can be inserted at multiple levels, L4/5 being most common with a small S1 spinous process precluding placement at L5/S1. Contraindications include spondylolisthesis, tumours, trauma, unstable or high-grade degenerative spondylolisthesis, and osteoporosis.

Current evidence and NICE guidance (2010) suggest ISD devices are efficacious for carefully selected patients in the short and medium term, although failure may occur and further surgery may be needed. There are no major safety concerns. Therefore, these procedures may be used provided that normal arrangements are in place for clinical governance, consent and audit.

Decompression and fusion (instrumented vs. non-instrumented)

Combined decompression and fusion is recommended when there is evidence of segmental instability. This is somewhat theoretical and may be difficult to prove radiologically. It is generally accepted that fusion should be considered in cases of deformity, moderate to severe low back pain, recurrent and junctional stenosis, or when greater than 50% bilateral facetectomy is required for decompression.

Limited evidence suggests decompression and non-instrumented fusion in the context of degenerative spondylolisthesis results in significantly improved back and leg pain when comparing decompression alone. There is no evidence to suggest that instrumented fusion is superior to non-instrumented fusion in terms of clinical outcome however, instrumentation does result in higher rates of fusion. There is no evidence to suggest that interbody fusion (ALIF, PLIF, TLIF, and XLIF) improves overall outcome.

Lumbar disc herniation and cauda equina syndrome

Lumbar disc herniation (LDH) is focal displacement of disc material beyond the margin of the adjacent vertebral body. LDH and radiculopathy is the most common indication for spinal surgery. The prevalence of symptomatic LDH is approximately 3%, most commonly affecting the 30–50-year-old age group. LDH is associated with age related changes to the disc; traumatic herniation is uncommon. Occupational factors (frequent heavy lifting, twisting, and exposure to vibration) and genetic predisposition predispose to LDH. It is generally benign with most patients recovering within one month. Extruded and sequestered fragments have a greater tendency to completely resolve by six months, possibly due to engulfment by macrophages.

The location of the herniation determines which nerve root is involved (the nerve exiting or transiting the disc space, i.e. whether the protrusion is central, in the lateral recess, foraminal, or extraforaminal). LDH can be classified morphologically and whether the herniation is contained by or traverses the posterior longitudinal ligament, the following terms are used: a disc protrusion involves deformation of but not rupture of the annulus, an extruded disc breaches the annulus with nuclear continuity, a sequestered disc is a free nuclear fragment.

Radicular pain is likely secondary to a combination of mechanical and chemical irritation. Studies have suggested that radicular compression alone results in numbness but is not painful. Compression results in oligaemia, oedema, and inflammation. Reduced CSF and blood flow reduce nutritional supply and the ability to remove noxious chemicals.

A history of acute back pain may precede radicular symptoms. The possibility of a peripheral nerve lesion should be considered in cases of foot drop and disconcordant neurology.

Clinical features include dermatomal pain, paraesthesia, and numbness increased by sitting, standing, and Valsalva manoeuvres; myotomal weakness, hyporeflexia, a reduced range of motion; antalgic gait, pain on compression of the spine; a positive Lasegue sign, reversed Lasegue sign (upper lumbar compression), or crossed Lasegue sign (large discs).

MRI is the standard investigation, while high-resolution computed tomography (CT) or myelography can be used when MRI is contraindicated. Neurophysiology may help exclude peripheral nerve lesions.

In the absence of cauda equina syndrome or an acute foot drop treatment is normally conservative. Reassurance is the key, specifically a short period of bed rest (three days), optimal analgesia including anti-inflammatories followed by physiotherapy is utilized. Symptoms resolve over three months in the majority. Unrelenting severe sciatica with sensorimotor symptoms may take a different course and early surgery is reasonable. Epidural and transforaminal blockade with corticosteroid is an adjunct rather than a definitive treatment.

Absolute indications for surgery include severe paresis and cauda equina syndrome. Relative indications include non-responsive severe sciatica and persistent symptoms for greater than six weeks following optimal conservative management.

Operative techniques

Given the prevalence of asymptomatic disc herniation patient selection is paramount. Patients with concordant clinical findings unresponsive to optimal conservative management for a minimum of six weeks should be considered. Class 1 evidence supports improved short-term outcome with surgery. The efficacy of surgery in comparison to conservative treatment declines over time. Standard approaches are an interlaminar approach and lumbar microdiscectomy. Percutaneous techniques include endoscopic discectomy, chemonucleolysis, and automated percutaneous lumbar discectomy.

Interlaminar approach and microdiscectomy

The interlaminar approach uses a midline incision and bilateral or unilateral subperiosteal muscle strip to access the interlaminar space. The microdiscectomy approach is identical to the interlaminar approach. The patient is prone or placed in the lateral decubitus position with the affected side up. The standard technique used is similar to that described by Yasargil, Caspar, and Williams (**Box 62.1**).

Box 62.1 Lumbar microdiscectomy

- Following level identification a 1.5–2.5 cm incision is made just lateral to the spinous process corresponding to the disc space
- Incision of the lumbodorsal fascia lateral to supraspinatus ligament
- Subperiosteal muscle strip from the lamina
- Insertion of Williams or McCullough retractor
- Exposure of the inferior lamina: the operating microscope is brought in
- 4–5 mm high-speed burr may be used to thin the lamina and perform a medial facetectomy
- A curette may be used to detach flavum from the lamina or the flavum can be incised superficially with a number 15 blade and a Watson Cheyne dissector used to split the longitudinal flavel fibres
- A 2 or 3 mm Kerrison rongeur can then be introduced to remove the flavum and expose the epidural fat overlying the nerve root. To help identify the nerve root the pedicle can be probed with the Watson Cheyne dissector
- Once the nerve root has been delineated a nerve root retractor is introduced and gentle medial retraction is placed over the shoulder of the nerve root to expose the disc space
- Free fragments in the epidural space may be removed with a micropituitary rongeur
- Epidural veins are coagulated with bipolar on a low setting with short intermittent bursts
- The underlying posterior longitudinal ligament and annulus are incised with a number 15 blade
- Adequate discectomy is performed to decompress the nerve root
- The procedure is completed by performing a foraminotomy (removal of ligament and undercutting the superior articulating process of the facet joint)
- Haemostasis prior to closure is performed

Complications

- Recurrent disc herniation (5%)
- CSF leak
- Nerve root injury
- Discitis

Cauda equina syndrome

Cauda equina syndrome (CES) is rare with annual incidence between 1 in 33 000–100 000. CES is a major source of litigation in neurosurgical practice. It is characterized by a central or large paracentral disc herniation most commonly at L4/5 which impinges on the cauda equina, specifically, the centrally orientated sacral nerve roots. Smaller disc herniations may result in CES in the setting of a congenitally narrow canal. Presentation may be acute over hours or chronic in the context of lumbar canal stenosis.

It is important to distinguish complete from incomplete lesions according to the degree of bladder and anal sensorimotor involvement. It is hypothesized that the smaller diameter preganglionic and sensory fibres of the sacral nerves are more prone to damage from mechanical compression and inflammation.

Clinical features include severe lower back pain, bilateral radicular leg pain (pain may be absent with an inferiorly displaced sequestered L5/S1 disc fragment), disturbance of urinary function (altered urinary sensation and poor stream), myotomal weakness, and saddle and genital sensory disturbance.

Complete lesions have a poor prognosis and are defined by a neurogenic bladder (insensate and distended secondary to low tone and inability to contract and coordinate sphincter function leading to retention and overflow incontinence). Loss of anal sphincter tone resulting in faecal incontinence, complete saddle, and genital anaesthesia with loss of trigonal sensation and sexual dysfunction is usually a late finding.

The timing of surgery has generated great controversy; the clinician must be pragmatic and act in the best interest of the patient, in the absence of class 1 evidence. It stands to reason that the sooner the cauda equina is decompressed the more likely the chance of recovery. A meta-analysis of 322 patients by Ahn et al. (2000) demonstrated optimal outcome when decompression is performed within 48 hours of the onset of symptoms. Decompression as soon as possible and certainly within 24 hours of the onset of symptoms seems intuitive and is generally accepted.

The standard operative approach is a bilateral laminectomy. In experienced hands, a large disc fragment can be removed through a hemilaminectomy and medial facetectomy, or laminotomy and fenestration, the advantage being preservation of midline structures, less muscle atrophy, and proposed reduction in postlaminectomy back pain. See **Figure 62.2**.

Back pain

Eighty per cent (80%) of people experience an episode of back pain in their lifetime. The majority experience non-specific back pain (NSBP) and will have some degenerative changes on imaging. NSBP is a diagnosis of exclusion and lacks features suggestive of radicular compression or serious underlying pathology. Pain is usually diffuse and may radiate to the thigh. NSBP is a benign, self-limiting condition. Causes of specific back pain that should be excluded include neoplasia, inflammatory disorders, infection, trauma, degenerative disease, and deformity.

Management involves exclusion of serious pathology and a holistic approach addressing the patient's health beliefs, expectations, avoidance behaviour, employment issues, and potential secondary gains.

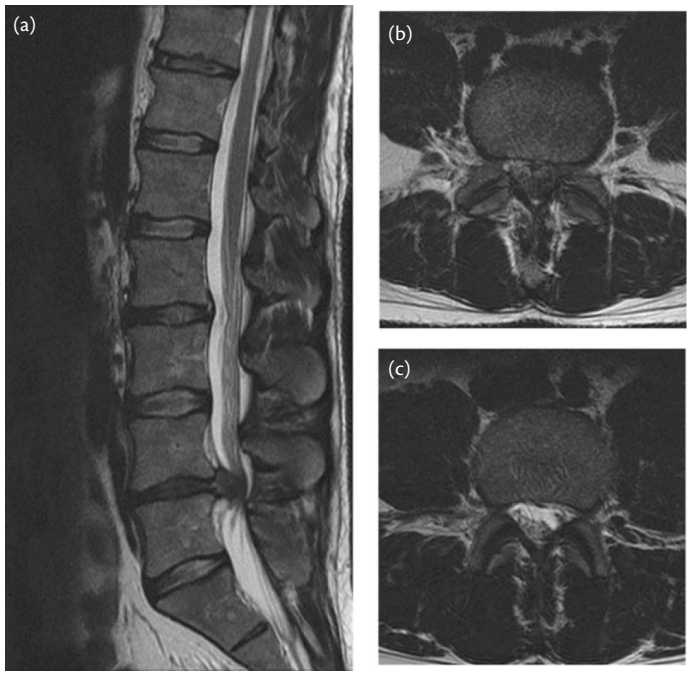

Fig. 62.2 (A) T2 sagittal: large L4/5-disc herniation and cauda equina compression; (B) T2 axial: complete obliteration of thecal CSF; (C) T2 axial: normal cross-section through lumbar canal for comparison.

Reassurance is paramount: by 12 weeks, 90% of individuals will be pain-free. Treatment is provided through a multidisciplinary approach and includes optimization of analgesia, referral to a pain specialist, regular exercise, physiotherapy, work conditioning programmes, and psychological evaluation if appropriate.

The disc, facet joints, and instability may be specific back pain generators that may respond to intervention

Lumbar disc disease

The lumbar disc supports most of the spinal load, acts as a highly efficient 'shock absorber' and withstands huge translational and rotatory forces. Mechanical failure occurs with age; a number of associated chemical and morphological changes are recognized including in the disc, loss of nuclear/annulus distinction and the ratio and distribution of type 1 to type 2 collagen changes, collagen cross-links break down which increases annular susceptibility to mechanical stress. Fissuring and deformation of the annulus, loss of sagittal/coronal disc height through deformation or resorption, nuclear matrix proteoglycan fragmentation, and disc dehydration all occur. There are reduced numbers of chondrocytes and an increased keratin/chondroitin sulphate ratio, neovascularization and neoinnervation by nerve fibres expressing substance P via hyperintensity zones, proinflammatory cytokines, increasing levels of lactate and decreased pH, which are all nociceptive.

In the vertebral end plate abnormal mechanical loading results in inflammation and Modic changes, calcification of the endplate occurs with reduction in blood supply and nutrient delivery. Increased susceptibility to mechanical stress occurs, which may be the basis for the development of Schmorl's nodes and limbus vertebrae.

Clinical features of disc disease include a deep central ache, pain referred to the anterior thigh or groin and exacerbation by loading the disc during flexion and when sitting for long periods.

MRI is the gold standard for the investigation of lumbar disc disease. In 1988 Modic classified endplate changes based on MRI signal characteristics (**Box 62.2**).

There has been renewed interest in Modic type 1 changes with infection being a potential aetiological factor for lower back pain. Albert et al. (2013) investigated the use of co-amoxiclav for 100 days in patients with back pain and Modic type 1 changes in a double-blind randomized control trial. Findings were encouraging and demonstrated a statistically significant improvement in disability indices in the antibiotic group versus the placebo group. See **Figure 62.3**.

Plain X-rays and CT are also of value demonstrating reduction in disc height, sclerosis, osteophytosis, and vacuum phenomenon. Lumbar disc stimulation may be used as an aid in selecting appropriate patients for fusion. Discs identified on MRI as potential pain generators are identified and injected. An MRI normal disc must be injected as a control during the study to ensure validity. In isolation,

Box 62.2 Modic changes

Type 1 (marrow oedema and inflammation)
- Low signal on T1 and high signal on T2

Type 2 (Fatty marrow transformation)
- High signal on T1 and T2

Type 3 (Subchondral bony sclerosis)
- Low signal on T1 and T2

Data from Modic MT, Steinberg PM, Ross JS, et al., Degenerative disk disease: assessment of changes in vertebral body marrow with MR imaging, *Radiology*, Volume 166, Issue 1, pp. 193–9, 1988 Radiological Society of North America.

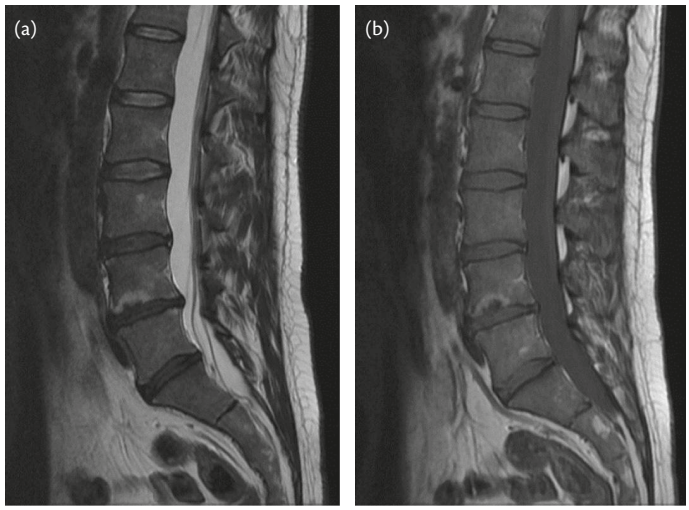

Fig. 62.3 (A) T2 sagittal MR and (B) T1 sagittal MR: type 2 Modic changes with associated Schmorl's node L4 inferior endplate.

there is poor correlation between symptoms and provocation discography. However, there is concordance with positive stimulation in the context of severe type 1 and 2 Modic changes. In addition, there is correlation between LBP and the severity of disc disruption described using the Dallas discogram scale. This is in keeping with the work by McNally et al. (1996) who demonstrated that discs with significant internal disruption transferring load solely to the annulus were painful.

Non-operative treatment options include optimal analgesia, referral to a pain specialist, physiotherapy, weight loss, regular exercise (core strengthening activities such as Pilates), and a trial of antibiotic therapy. Psychological assessment and counselling may also be appropriate.

Operative intervention is considered following failure of an adequate trial of conservative management. What constitutes an 'adequate' period of conservative management is open to interpretation and should not delay surgical intervention if it is felt that this is the best option for the patient.

Operative management of lumbar disc disease may include, non-instrumented fusion, instrumented fusion, disc arthroplasty, dynamic stabilization, intradiscal electrothermal therapy, or intradiscal delivery of biological agents and stem cell implantation.

Surgical management of lumbar disc disease

Non-instrumented fusion

Stand-alone non-instrumented fusion is rarely used today and a combination of 'bony' posterolateral fusion and pedicle screw (instrumented) fixation is recommended. In practice iliac crest is now rarely harvested secondary to the associated postoperative pain. Bone from the posterior elements and artificial bone substitute is now more commonly used. Posterolateral fusion is the gold standard procedure to which other non-fusion techniques are compared owing to its superior fusion rate and satisfactory clinical outcome (**Box 62.3**). The technique was first described in 1911 for the treatment of TB.

Posterior discectomy and interbody fusion can also be performed in combination with posterolateral fusion increasing fusion rates to almost 90% but with greater risk of neurological injury. There is no evidence to suggest anterior interbody fusion is superior to posterior approaches and has the additional risks of retrograde ejaculation and vascular injury.

Box 62.3 Posterolateral fusion: Key points

- Prone positioning with the lumbar spine in a neutral position
- Midline approach and wide subperiosteal muscle strip to expose the facet joints and transverse processes at the determined levels using fluoroscopy
- Decompression performed if necessary
- Decortication of the posterior elements as a fusion bed is achieved using a high-speed burr
- Posterior superior Iliac crest remains the graft of choice given its excellent osteogenic, osteoconductive, and osteoinductive properties. A combination of autologous bone chips harvested during decompression or bone graft substitute mixed with blood may also be used

Instrumented fusion techniques

Transpedicular fixation

Transpedicular fixation was introduced in the 1970s and has fast become the construct of choice because of its superior biomechanical stability over translaminar screws or laminar hook and clamp instrumentation (**Box 62.4**).

The technique affords the surgeon access to all three columns of the spine via the pedicle, the strongest bony structure in the spine. There is a steep learning curve but in experienced hands pedicle screws are associated with a low complication rate and, in comparison to non-instrumented fusion, provide superior fusion rates. Pedicle screws allow the surgeon to decompress widely if required without the risk of instability and the need for postoperative bracing.

Transpedicular screw fixation can be augmented with interbody fusion. Most commonly polyetheretherketone (PEEK) or carbon fibre cages are inserted following discectomy and preparation of the endplates. Iliac crest autograft and femoral ring allograft have also been described with good results. Interbody fusion can be achieved through posterior, posterolateral (transforaminal), lateral (extreme lateral) or anterior approaches. The advantages of interbody fusion are an increased fusion rate, restoration of alignment, and foraminal decompression through restoring disc space height, discectomy, and resection of endplate osteophytosis—see **Figure 62.4**.

The transforaminal approach (TLIF) involves resection of the facet and has the advantage of a unilateral approach, directly decompressing the segmental exiting and transiting nerve root with less neural retraction and blood loss. The extreme lateral approach (XLIF) is a minimally invasive transpsoas approach to the interspace with the patient in the lateral decubitus position. An interbody cage and lateral plate are used. Advantages are short operative time and minimal blood loss. This coupled with the ability to correct degenerative scoliosis make it an attractive option in older people. Intraoperative neurophysiology is mandated secondary to the risk of injury to the lumbar plexus. The L5/S1 interspace is not accessible secondary to obstruction by the ilium. The anterior approach (ALIF) has the advantage of preserving the posterior elements and maximal access and decompression with minimal risk to neural structures. Complications include increased risk of vascular injury and injury to the sympathetic chain resulting in retrograde ejaculation.

Box 62.4 Transpedicular screws: The Magerl technique

- Preoperative imaging and pedicle anatomy should be studied in detail. Vertebral anomalies may preclude screw placement (e.g. lumbar dysplasia and hypoplastic pedicles)
- The technique allows greater medialization and longer screw length than the Roy-Camille technique and therefore greater biomechanical strength
- With the patient prone and the lumbar spine in neutral alignment a midline approach and subperiosteal muscle strip is performed. A Wiltse paramidline muscle splitting technique can also be utilized which is less traumatic and results in less muscle atrophy and pain
- A wide exposure is performed to the transverse processes, allowing visualization of the pars and facet joint including the mamillary process. Care is taken to preserve facet joints at segments not involved in the fusion
- The entry point is at the intersection between a line bisecting the transverse process in the coronal plane and the inferolateral extent of the superior articulating facet in the sagittal plane
- This entry point allows a medial trajectory adjacent to the endplates
- A slightly lower entry point (lower one-third of the transverse process) and more superomedial trajectory is recommended for the upper screws of the construct so as not to impinge on the lower articulating facet of the caudal vertebrae not involved in the fusion
- The degree of medialization required increases from L1 to S1 from 15 to 30°. AP and lateral fluoroscopy should be used
- A laminotomy allows a probe to be inserted into the canal to palpate for medial breach as the screw is advanced
- Decortication as for non-instrumented fusion provides a bony fusion bed for autologous or substitute bone graft in the intertransverse trough
- Rods cut to length and contoured for lordosis are placed in-situ and secured with blockers screwed down on to the head of the screw and tightened. Polyaxiality of the screw head allows for ease of placement of the rod, regardless of angle
- Care should be taken not to trap muscle in the construct which leads to necrosis and pain

Complications

- Loss of purchase/pedicle fracture and screw breakout
- Screw misplacement
- Neurological injury
- Dural tear
- Adjacent level disease
- Vascular injury

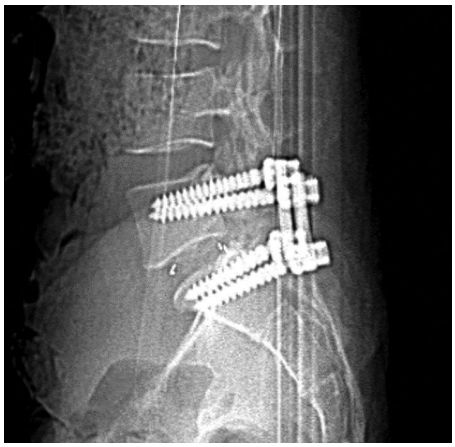

Fig. 62.4 Postoperative X-ray following posterior lumbar interbody fusion.

Disc arthroplasty

Fernstrom was the first to perform lumbar arthroplasty in the 1950s using the Fernstrom ball. The 1980s marked the development of the modern disc replacement with the SB Charité and ProDisc-L designs. The replacement is based on metal endplates sliding over a plastic ball-and-socket type core. The approach is retroperitoneal with associated complications as for ALIF. Contraindications include obesity, trauma, iatrogenic instability of the posterior elements, spondylolisthesis greater than grade 1 lytic pars osteoporosis, and trauma. Severe facet arthropathy is a relative contraindication. Level one evidence from FDA-regulated studies of Charité and ProDisc-L implants (Blumenthal et al., 2005; Zigler et al., 2007), reveals equivalent and, in some respects, superior clinical outcomes in the short to medium term when compared to fusion. David (2007) reports long-term clinical outcomes to be equivalent to fusion but with lower complication rates and a reduced incidence of adjacent segment disease. Lumbar disc arthroplasty is approved by NICE, clinicians are urged to publish their experiences. The longer-term outcome and life span of these implants is still not known.

Dynamic stabilization

Dynamic stabilization is based on off-loading the motion segment while maintaining the range of movement and reducing adjacent segment disease. Clinical outcome data remains modest and to date long-term follow-up does not exist.

Facet joint arthropathy

The facet joints support 20% of the spinal load. Segmental degeneration increases loading of the facets and arthropathy. Some evidence suggests that the more sagittal orientation of the lower lumbar facets and facet isotropy is associated with accelerated degeneration, instability, deformity, and pain. The pathological changes seen in facet degeneration include cartilaginous thinning and fibrillation, effusions, capsule laxity, joint subluxation osteophytosis, and synovial hypertrophy with cyst formation.

Facet arthropathy is best appreciated on CT. Weishaupt has devised a grading system to describe the severity of facet arthropathy based on CT and MR appearances. Single-photon emission computed tomography (SPECT) may aid in localizing active disease when MR and CT reveal multilevel degenerative changes. Facet effusions on MRI correlate with SPECT activity.

Clinical features include stiffness in the morning which improves with activity, pain is exacerbated on extension and twisting movements. Pain may be referred to the groin, buttock, or posterior thigh, and there may be localized paraspinal tenderness.

Conservative management including spinal injections performed by a pain specialist are the mainstay of treatment. Medial branch blockade (MBB) is superior to intra-articular injections. Injections should be performed on multiple occasions to increase diagnostic validity. There is some evidence to suggest that a positive response to MBB is predictive of a good response to radiofrequency ablation. Limited data suggests that radiofrequency ablation provides short- and long-term relief of facet mediated pain in selected patients.

Instability

'Instability' remains an enigmatic concept; it is the most controversial of the pain syndromes given the normal range of lumbar movement

and abnormal movement observed in asymptomatic individuals. It is more likely that abnormal movement results in abnormal loading of the annulus and vertebral endplate (pain generators) increasing demands on the spinal musculature and tendinous attachments, fatigue, and pain.

Clinical features include the back 'giving way', pain increased with sudden trivial movement and the back 'locking' and 'catching' on movement with associated muscle spasm

Anecdotal reports exist of lumbar back pain associated with instability demonstrated by abnormal translation and angulation on dynamic X-rays. Therapy is focused on improving core strength. Dynamic stabilization devices have been shown to alter the loading pattern which may explain their equivalent efficacy with fusion in the short term.

Injection therapy

Epidural Injections

Epidural corticosteroid injections are an effective adjunct for short-term relief of lumbar and radicular pain. A combination of steroid and short acting local anaesthesia is injected which address the inflammatory component of radicular pain. There is no evidence to suggest long-term efficacy. Lumbar epidural injections can be performed via an interlaminar approach above the level of interest or caudally via the sacral hiatus.

Indications for lumbar epidural injections include lumbar canal stenosis, multilevel involvement, non-specific pain, lumbar back pain with an acute annular tear and poor surgical candidates. Complications include abscess, arachnoiditis, epidural haematoma, CSF fistula, and paraparesis.

Selective nerve root block injections

Selective nerve root blockade is an effective diagnostic and therapeutic procedure used when there is lack of radiological and clinical concordance in determining or excluding a surgical target. In addition, they may be used for short-term pain relief in subacute radiculopathy in the absence of a neurological deficit. Periprocedural imaging (CT is used at the authors' institute) is essential to enter the 'safe triangle' inferior to the pedicle and superolateral to the nerve root. Complications include an increase in pain, nerve root damage, permanent neurological deficit, CSF fistula, and abscess.

Spondylolisthesis

The Greek word 'olisthanein' means to slip, and Killian coined the term 'spondylolisthesis' in 1854. Spondylolysis indicates a defect in the pars interarticularis which may lead to spondylolisthesis. Spondyloptosis refers to severe slippage and complete malalignment of the vertebral bodies. The disease was first described by the Belgian obstetrician Herbinaux in 1782, while in 1976 Wiltse, Newman, and MacNab proposed their widely accepted aetiological classification (Box 62.5).

The Meyerding classification published in 1932 describes the degree of slippage where grade 1 is 1–25%, grade 2 is 26–50%, grade 3 is 51–75%, grade 4 is 76–100%, and grade 5 is spondyloptosis.

Box 62.5 Spondylolisthesis

- **Isthmic Most common at L5/S1**
  - **Type A**—Defect in pars
  - **Type B** —Healed defect with elongation of pars
  - **Type C**—Acute bilateral fracture
- **Degenerative Most common at L4/5**
  - Disc and facet degeneration
- **Dysplasia**
  - Dysplasia of L5/S1 junction
    - Wedging of small dysplastic L5
    - Dome-shaped upper S1 vertebral border
    - Horizontal orientation of L5/S1 facets
    - Mimics isthmic type
- **Traumatic**
  - Aihara classification
- **Pathological**
  - Metabolic bone disease
  - Connective tissue disease
  - Infection
  - Neoplasia

Isthmic spondylolisthesis (spondylolysis)

The pars interarticularis acts as a conduit connecting the neural arch to the vertebral body via the pedicle. If disconnected the vertebral body and the superior spine have the potential to drift away from the corresponding inferior articulating process and superior articulating facet of the vertebral body below. Given the enormous stress placed on the pars it is surprisingly one of the weakest bony structures in the spine.

The pars defect develops in late childhood and becomes established in adolescence or early adulthood. It most commonly occurs at the L5/S1 segment. The proposed aetiology is repeated mechanical stress resulting in fatigue and fracture of the inferomedial cortex of the pars with superolateral propagation. Isthmic fatigue fractures are well recognized in athletes and heal with conservative management. Non-union leads to the type A form with fibrous tissue spanning the fracture. Remodelling, elongation, and union results in the type B form. Less than 20% of patients with spondylolisthesis progress and develop symptoms. The isthmic type has a greater propensity to slip than the degenerative type. Some authors believe slip angle (the angle defined by the intersection of two lines drawn from the superior endplate of S1 and inferior endplate of L5) predicts progression. Clinical observation with standing lateral X-rays is recommended.

The clinical features include dull central back pain at the level of the slip exacerbated by exercise, a bony step-off at the level of the slip, increased lumbar lordosis, flattened buttocks, a waddling gait disturbance, posterior thigh pain, tightening, and spasms of the hamstrings, radicular pain (L5 most commonly secondary to compression by the isthmic fibrocartilaginous mass) but central compression, neurogenic symptoms, and cauda equina syndrome are rare. Phalen-Dixon sign presents with sciatic crisis, hamstring spasm, gait, and postural abnormality in the young patient; weakness of the extensor hallucis longus or ankle dorsiflexion are rare.

Management

Treatment options include conservative management such as optimal pain management including referral to a pain specialist, restriction of physical activity, bracing, and physiotherapy. Indications for surgical management include severe pain despite an adequate trial of conservative measures, progressive neurological deficit, and progressive slip and a high slip angle.

Surgical options include direct repair of the pars defect with a pars screw, autologous bone graft to the defect site, radical decompression of nerve roots followed by posterolateral (instrumented or non-instrumented) or interbody fusion, or wiring of the transverse processes and non-instrumented fusion with autologous bone graft.

In cases of significant radicular symptoms, decompression as described by Gill involves removal of the loose posterior elements, the hypertrophic fibrocartilaginous mass, and total facetectomy. Fusion following decompression of isthmic spondylolisthesis is recommended. Caragee (1997) reports a higher rate of pseudarthrosis and worse outcomes with decompression alone. It is controversial as to whether instrumentation in addition to fusion improves outcome but obviates the need for postoperative bracing.

In the absence of radicular symptoms decompression is not necessary and fusion can be performed through a midline approach or using the Wiltse technique: following a midline skin and fascial incision, bilateral paraspinal fascial incisions are made overlying the groove produced by multifidus medially and longissimus laterally. Using a combination of muscle splitting and sharp dissection, this plane allows access to the pars, transverse processes, and facet joints for fusion and instrumentation.

Instrumented fusion can be achieved through pedicle screw fixation or interbody fusion. Both techniques are equivalent in terms of outcome and do not reduce the rate of pseudarthrosis. Some authors believe that fusion improves radicular symptoms secondary to reduced instability and radicular irritation. Pedicle screw fixation has the additional advantage of enabling reduction of the spondylolisthesis. It is purported that reduction improves the rate of fusion but is associated with a higher rate of nerve root injury. See Figure 62.5.

Degenerative spondylolisthesis

Degenerative spondylolisthesis is seen in the middle aged and elderly population secondary to degenerative disc disease which puts additional strain on the facet joints. It is more common in females and patients of African descent. It occurs most frequently at L4/5, this may be related to the sagittal orientation of the L4/5 facets in comparison to the coronal orientation of the L5/S1 facets which resist anterior translation. Presentation is similar to that of lumbar canal stenosis and radicular pain resulting from compression of the L5 nerve roots by the slipped inferior articulating process, hypertrophied facet, and a rolling broad-based disc. Cauda equina syndrome is rare but may present subacutely with a coexisting acute disc herniation. The natural history suggests that this is a relatively benign condition, progression rates are as low as 25% with slippage rarely progressing beyond one Meyerding grade.

Non-operative treatment involves effective pain management and physiotherapy. Epidural or perineural blockade may be of use when radicular symptoms exist. Surgical management is considered in symptomatic patients following an adequate trial of optimal conservative measures. Several studies suggest superior functional and pain outcomes in surgical versus medically treated patients. See Figure 62.6.

Fig. 62.5 A and B sagittal T2 MRI. (A) Hypoplastic L5 and grade 1 isthmic olisthesis; (B) L5 isthmolysis clearly demonstrated.

The decision to decompress alone or decompress and fuse in the context of a degenerative spondylolisthesis remains controversial and should be based on individual factors such as age, comorbidities, bone quality, back pain suggestive of instability, dynamic radiographs, degree of slip, and intraoperative findings of segmental instability.

Spinal synovial cysts

These relatively rare cysts are associated with spondylosis and are most commonly an incidental finding. They most commonly occur at L4/5 but are also found in the cervicothoracic spine. It is hypothesized that abnormal movement results in myxoid degeneration and synovial hypertrophy.

Histologically, the cyst wall may or may not be lined by synovium (ganglion cyst); however, this is a purely academic point. Presentation is usually radicular in nature with small cysts causing compression in the subarticular space. Occasionally there may be an acute deterioration secondary to haemorrhage into the cyst and rarely cauda equina syndrome. They may spontaneously regress.

These cysts can usually be differentiated from other lesions according to their MR characteristics and location. The differential diagnosis includes nerve sheath tumours, a herniated disc fragment, or intradural disc fragment, a meningeal cyst, arachnoid herniation, perineural cyst, or metastatic deposit.

It is important that these cysts are recognized as they may inadvertently be drained during the surgical approach and erroneously be diagnosed as a herniated disc fragment. MR characteristics can vary according to the cyst composition and whether haemorrhage is present. Calcification of the cyst wall appears low intensity on T1 and T2, haemorrhage is hyperintense on T1. The cyst may clearly communicate with the facet joint space which differentiates it from neural associated cysts. On contrast injection the cysts may display peripheral enhancement.

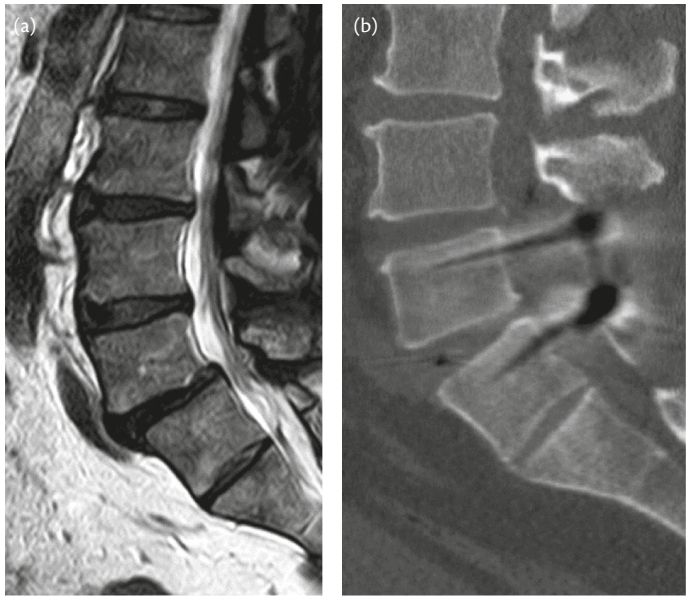

Fig. 62.6 (A) T2 sagittal MR showing a grade 1 spondylolisthesis; (B) postoperative CT in the same patient shows reduction of spondylolisthesis following posterior interbody fusion.

Management

The existing literature consists of small case series. Following an adequate trial of conservative management including optimal analgesia, facet, and targeted perineural injections, surgery is considered. The standard approach is open cyst extirpation and foraminotomy +/– fusion. The risk of recurrence is approximately 2% with decompression alone. Fusion is associated with a lower rate of recurrence and should be considered in patients who have clinical or radiological evidence of segmental instability. Minimally invasive resection and aspiration has been described but with an increased recurrence rate. See Figure 62.7.

Spinal meningeal cysts

These rare CSF containing thin walled cysts may exist as diverticulae of arachnoid, dura, or the nerve root sheath within the lumbar spine and are usually incidental findings on MRI. They can be classified according to Nabor (see Box 62.6).

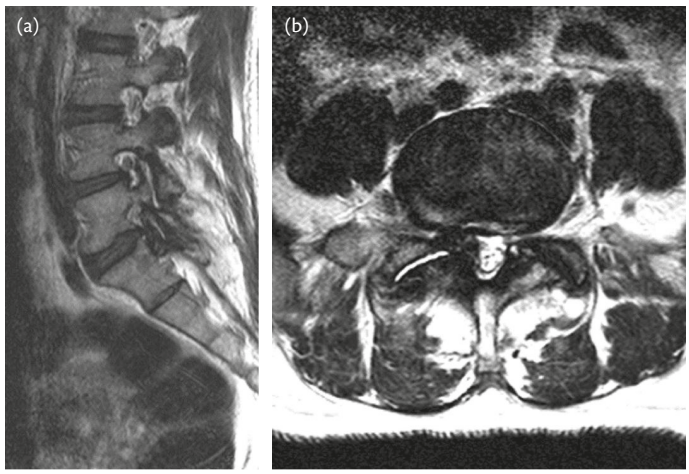

Fig. 62.7 T2 MRI sagittal (A) and axial (B) images showing right L5/S1 lateral recess stenosis secondary to a synovial cyst.

Box 62.6 Spinal meningeal cysts

- Type 1—Extradural meningeal cyst without neural tissue
  - Type 1a—Extradural spinal arachnoid cyst
  - Type 1b—Sacral meningocele
- Type 2—Extradural meningeal cyst containing neural tissue (Perineural/Tarlov cysts)
- Type 3—Intradural arachnoid cysts

Source data from Nabors MW, Pait TG, Byrd EB et-al. Updated assessment and current classification of spinal meningeal cysts. *J. Neurosurg.* 1988;68 (3): 366-77.

Tarlov cysts (Nabor type 2)

The estimated prevalence is between 5% and 9% of the population with most cysts being an incidental finding arising most commonly in association with the S2 and S3 nerve roots. There is often remodelling of the sacrum. The aetiology is unknown but is likely to incomplete obliteration of the perineural space and CSF pulsatility. They arise between the endo- and perineurium at the junction of the nerve root and the dorsal root ganglion (DRG) encompassing or invading the nerve root with compressed nerve fibres forming part of the cyst wall. There is a potential communication with the subarachnoid space in comparison to meningeal diverticulae which occur proximal to the DRG and communicate freely with the subarachnoid space. Examination with CT myelography reveals late or no filling whereas other meningeal cysts fill early.

Rarely cysts can exert mass effect and present with pain which is exacerbated by Valsalva manoeuvres. Sacral insufficiency fractures have been described secondary to scalloping of the sacrum.

While normally asymptomatic, clinical features can include progressive sacral radicular pain, numbness, and paraesthesia, poorly localized sacral, perineal, or rectal pain, and bowel, bladder, and sexual dysfunction.

Non-surgical management involves optimal pain management. Anecdotal reports suggest CSF drainage provides temporary relief of symptoms. Rarely, surgery is considered in patients with progressive symptoms despite optimal pain management. There are case reports describing CT guided injection with fibrin sealant and lumbo-peritoneal or cysto-subarachnoid shunting with good results. Definitive management involves sacral laminectomy, cyst fenestration/resection and closure with a sacrospinalis myocutaneous flap. Intraoperative electrophysiology is recommended.

Sacroiliac disease

The sacroiliac (SI) joint is a synovial and fibrous joint between the ilium and sacrum which transfers weight from the axial to appendicular skeleton. Movement involves minor rotatory and gliding movements. Ligamentous laxity commonly results in SI related pain during pregnancy. Sacroiliitis is the manifestation of a wide range of diseases and may mimic lumbar spine pathology. Common symptoms include lower back, buttock, and thigh pain, exacerbated by sitting for long periods. The New York criterion offers a grading system based on the degree of sclerosis and ankylosis on plain X-ray. Stigmata of systemic disease should be sought during history and

examination. The diagnosis is obtained through positive provocative distraction and compression manoeuvres on examination and pathognomonic changes on plain X-ray. The pattern of involvement offers clues to the underlying aetiology (symmetrical and bilateral, asymmetrical and bilateral, or unilateral). The differential includes the inflammatory athritides, infection, and neoplasia.

Management involves treatment of the underlying aetiology, effective pain management, SI joint injections, and physiotherapy. Arthrodesis is considered in patients with progressive and incapacitating pain resistant to an adequate trial of optimal conservative therapy.

Coccydynia

Coccydynia refers to pain around the region of the coccyx. It is exacerbated by sitting for long periods and on rising from a sitting position. The exact incidence is unknown, but risk factors appear to be obesity and female sex. It is sufficiently rare in males to warrant further investigation for serious underlying pathology. There is pinpoint tenderness on examination. Rectal examination allows assessment of coccygeal range of movement which may be hypo or hypermobile.

Aetiologies include osteoarthritis, local trauma, hypermobility, Infection, pelvic inflammatory disorders/chronic infection, and neoplasia (local primary bone tumours, nerve sheath tumours, direct spread from pelvic tumours or metastatic disease). Ninety per cent (90%) of cases resolve with conservative treatment. This involves non-steroidal anti-inflammatory drugs (NSAIDs), lumbar supports which encourage lordosis and specially designed cushions to reduce pressure on the area. Manipulation may reveal a dislocated coccyx and prove therapeutic.

Other options include local corticosteroid injections, caudal epidural corticosteroid injections, sympathetic blockade, or coccygectomy (variable success and should only be considered once conservative measures have been exhausted).

Failed back syndrome and management of postoperative complications

'Failed back syndrome' refers to a patient population who fail to improve to a satisfactory degree following spinal surgery. The term does not imply negligence, more that the patient has persistent pain beyond what is expected, and that this may be incapacitating and prevent return to work. When a poor surgical outcome is encountered, three questions should be asked: Was this the correct operation? For example, decompression alone in a patient with degenerative spondylolisthesis experiencing increasing back pain postoperatively. Was it the correct diagnosis? For example, performing lumbar surgery in the context of hip and knee pathology or cervical surgery in the context of shoulder pathology or coexisting ulnar or median nerve neuropathy. Medical conditions such as diabetes, vasculitis, and nutritional deficiency resulting in neurological dysfunction should always be borne in mind. Finally, was this the correct management for this particular patient? For example, it is important to assess the patient's level of motivation, expectations, psychological well-being, and be aware of potential secondary gains and litigation.

This algorithm may aid in reflective practice, however, there will be occasions when poor outcomes are beyond the control of the clinician. Recurrent or ongoing axial and radicular pain may be due to residual compression (retained disc and osteophytes), recurrent disc herniation, adjacent segment disease, peridural scar formation and fibrosis, postoperative discitis (infective and aseptic), pseudomeningocele formation, epidural haematoma, arachnoiditis, permanent nerve root injury, and operative damage following retraction or inadvertent durotomy, conjoined nerve roots (compression at an adjacent level to that operated), progressive spondylosis and instability, failure to appreciate sagittal imbalance resulting in muscular fatigue and deformity, coexisting myofascial syndrome, and complex regional pain syndrome.

It is important to ascertain the nature of pain. Burning pain is characteristic of neuropathic pain secondary to nerve damage and includes complex regional pain syndrome. This type of pain is best treated with neuropathic agents and referral to a pain specialist. Neuromodulation in the form of spinal cord stimulation may also be considered.

Sagittal imbalance (flat back/lumbar kyphosis) is corrected through the action of the back extensors and increased pelvic tilt resulting in pain and fatigue. Pain can be incapacitating, and deformity can have psychosocial implications secondary to poor self-image and deficient horizontal gaze. Correction of fixed deformity can be achieved through aggressive surgical techniques, such as the Smith–Peterson osteotomy and pedicle subtraction osteotomy.

Inadvertent durotomy and pseudomeningocele

Durotomy is a common occurrence with an incidence of approximately 15%. There is a strong association with revision surgery. In itself, it rarely results in morbidity however, there are several possible complications that may ensue including nerve root or cauda equina injury (contusion or laceration), persistent CSF leak (pseudomeningocele or CSF fistula), meningitis, arachnoiditis, and chronic headache.

It is more common during revision surgery owing to the formation of scar tissue and loss of identifiable tissue planes. The dura may be extremely thin in older people with chronic stenosis predisposing to injury. The underlying pathology may result in the dura or nerve root sleeve lying in an unexpected location. Accidental slippage of instruments and an obscured fold of dura caught in the Kerrison are common causes. The surgeon should be careful to round off any bony spikes left by the Kerrison as this can be a source of delayed CSF leak.

Management involves microscopic primary repair (e.g. with 5/0 Prolene or staples). Care should be taken to avoid lacerating or encompassing nerve roots in the suture line. If the durotomy is small, herniation of nerve roots makes it difficult to close the dura. In this case the durotomy should be lengthened and a cottonoid used to protect the nerve roots during the closure. If the durotomy is anterior the dura can be opened dorsally and an intradural repair made. Occasionally it is impossible to close the dura if the nerve root sleeve is involved or there is a large defect and closure may entrap the cauda equina. In this scenario the patient's blood, fat, or muscle can be used as graft material. The use of layered Surgicel, a crushed

muscle patty and coagulated blood, or a fibrin sealant such as Tisseel is favoured by the author.

Postoperative orders include a period of flat bed rest of usually 3–5 days. If the dural opening is small and the arachnoid remains intact with no CSF leak, then it is reasonable not to impose a period of bed rest following primary repair. The use of wound and lumbar drains is controversial and is essentially down to the surgeon's preference. Thromboembolic prophylaxis is prudent for patients on bed rest.

A contained CSF collection is termed a pseudomeningocele. Tense collections may lead to wound breakdown, CSF fistula, and infection. Symptoms include low pressure headache, back pain, and radicular symptoms. MR imaging is an essential investigation. If seroma or infection are suspected, then needle aspiration is warranted and the sample sent for MC&S. CSF can be distinguished from seroma using the beta-2 transferrin biomarker. A trial of lumbar drainage is reasonable with symptomatic pseudomeningocele. Definitive repair requires open repair as described earlier (+/– lumbar drainage). MR (fat suppression sequences), MR, CT, and digital subtraction myelography are useful when repair fails and the site of durotomy is difficult to identify. In recurrent cases plastics consultation for consideration of flap reconstruction is recommended.

Postoperative discitis

This is a rare event with an incidence of approximately 1%. Eighty per cent (80%) of cases present within the first month of surgery. Risk factors include older people, diabetes, immunosuppression, and concomitant systemic infection.

Clinical features include moderate to severe back pain and spasm, fever, a limited range of movement and point tenderness but radicular symptoms are rare and few patients will have an associated wound infection.

There are reports of aseptic or chemical discitis following surgery. The clinician should be guided by infective blood markers such as white cell count (WCC) (neutrophilia), CRP, and erythrocyte sedimentation rate (ESR) in addition to positive imaging findings. MR appearances suggestive of infection include enhancing prevertebral and epidural collections in association with disc enhancement and endplate oedema.

Blood cultures should be obtained. Needle biopsy of the disc in question provides positive microbiology in approximately 40% of cases. *Staphylococcus epidermidis* and *aureus* are most commonly implicated along with Gram-negative species and *Streptococcus*. Anaerobes, TB, and fungi are less common. Infective parameters should be followed weekly until stabilized or normal.

Positive cultures guide therapy. Intravenous (IV) antibiotics with antistaphylococcal action are administered for a minimum of 6 weeks (this can be performed in the community in some cases). If infective indices have responded a change to oral therapy (e.g. Flucloxacillin and fusidic acid) may be instituted for a further prolonged period advised by microbiology. Prior to termination of treatment a further enhanced MRI scan may be performed for comparison. In resistant cases discectomy and washout is considered. This can be performed through open or minimally invasive approaches.

Outcomes are variable according to the literature. Approximately 80% show a significant improvement in back pain, this is similar to the outcome following lumbar disc surgery.

Adhesive arachnoiditis

Arachnoiditis involves all three layers of the meninges. Inflammation results in clumping of the nerve roots. It is proposed that the adhesive process reduces blood and CSF flow to the nerve roots in addition to mechanical insult from tethering. Enhancement on MR suggests an acute process exists which should prompt further investigation and surveillance particularly if there is uncertainty regarding the underlying aetiology. Three patterns are observed on MRI namely central adhesion and the development of central cords, adherence of the nerve roots to the theca giving the appearance of an empty thecal sac and CSF is replaced by inflammatory tissue (block and 'dripping candle wax' sign on CT myelography).

It is occasionally associated with degenerative disease, and in this context is usually an incidental finding. Arachnoiditis secondary to trauma is commonly associated with the formation of syringes. The risk factors for developing arachnoiditis are inadvertent durotomy and CSF leak, the presence of blood products in the thecal sac, infection, trauma, spinal anaesthesia, previous use of oil-based contrast agents, and neoplasia.

Radicular pain related to arachnoiditis carries a poor prognosis. Treatment is aimed at symptomatic relief through a comprehensive pain management regime, physiotherapy, and psychological support. The results of surgery are disappointing and involve removal of constrictive extradural scar tissue and foraminotomies if felt beneficial.

Management of recurrent lumbar disc herniation

The strict definition of a recurrent LDH is the recurrence of pain following a minimum pain-free period of 6 months secondary to an ipsi- or contralateral disc herniation at a previously operated level. The rate of recurrence is reported as between 5% and 12%. The differential diagnosis includes progressive perineural fibrosis and arachnoiditis.

Pre- and postcontrast MR imaging of the lumbar spine provides valuable diagnostic information. Perineural scarring enhances as opposed to herniated nucleus pulposus and clues such as retraction of the theca and nerve root towards the lesion suggests fibrosis and conversely thecal displacement indicates a recurrent herniated fragment. There is no evidence to suggest whether conservative sequestrectomy or annulus incision and more aggressive discectomy at the primary operation affects recurrence rate.

A careful history should be taken and the nature of the pain clarified. Pain of a diffuse burning nature suggests neuropathic pain and does not respond to surgery. As a proposed hypothesis perineural fibrosis may result in constriction of the nerve root, chronic ischaemia, and nerve damage.

The risks of durotomy with reoperation are as great as 20% with additional increased risk of neural injury. Some authors would therefore advocate a more aggressive approach involving facetectomy ipsilateral to the disc herniation approaching from lateral and using virgin tissue planes to work medially towards the disc herniation

and area of nerve root impingement. This approach mandates instrumented fusion +/– interbody fusion with claims that this also reduces the risk of further recurrence.

The systematic review by Dower et al. (2016) concludes that there is no evidence to suggest routine fusion in the management of recurrent LDH results in improved outcome. Therefore, a pragmatic and individualized approach is recommended, if there are clinical or radiological features of segmental instability, then fusion should be considered. Likewise, intraoperatively, if fibrosis is extensive and facetectomy is considered, the surgeon should be prepared to fuse the segment.

Experience with endoscopic and minimally invasive surgery (MIS) in the spine is evolving with approaches such as endoscopic transforaminal lumbar discectomy, MIS transforaminal lumbar interbody fusion and percutaneous pedicle screw fixation. It will prove interesting to follow the long-term durability of these techniques in the future.

Degenerative spondylolisthesis with radicular symptoms: Decompression alone versus decompression and fusion (instrumented versus non-instrumented)

Progression of spondylolisthesis following decompression alone has been reported to be as great as 50% with recurrence of symptoms. Preoperative flexion-extension lateral lumbar spine X-rays do not predict instability but may occasionally demonstrate abnormal translation (greater than 4 mm). The meta-analysis by Mardjetko (1994) reported improved clinical outcomes with decompression and fusion (instrumented and non-instrumented) versus decompression alone. The meta-analysis and systematic review by Gibson and Waddell (2005), confirmed improved fusion rates, minimally superior clinical outcomes, and a higher complication with instrumentation versus non-instrumented fusion. The Spine Patient Outcomes Research Trial (SPORT) found no significant difference in outcome when comparing the various different fusion techniques.

Spinal tumours

John Brecknell and Boon Leong Quah

Diversity

For the spinal neurosurgeon, the range of pathologies, clinical presentations and required surgical techniques included within the management of spinal neoplasia is vast, from benign lesions unchanged over a decade of observation to malignant disease that progresses over a few hours to paraplegia, and from the finest microsurgery to instrumentation over multiple spinal segments. This chapter could have a broader remit still but excludes the management of non-neoplastic masses of the spine. It will also exclude aspects of the management of spinal tumours specific to childhood.

This diversity can be rationalized to a degree by dividing spinal tumours into two broad groups: those that arise within the thecal sac and those that arise extradurally. There are very few that coexist in both compartments. The former largely represent the expression of the various types of brain tumour below the foramen magnum and are chiefly pathologically benign conditions. The latter are dominated by metastatic malignancy as well as including those tumours that have arisen from the connective and haematological tissues of the spine.

Common ground presentation

Despite the variety, there is some common ground particularly around clinical presentation and investigation. The clinical method which elucidates these aspects of each case does so before a patient with a spinal tumour receives a diagnosis.

Pain

Patients with a spinal tumour most frequently present with pain. When this is experienced locally it is the result of the effect of the tumour on nociceptors within the spine. This effect is mediated by a multitude of mechanisms including direct mechanical deformation, venous congestion, and pathological fractures of the vertebrae. Such pain is usually persistent and progressive, reflecting tumoural growth. Pain may be worse at night and in recumbency and this phenomenon is usually attributed to exacerbation of venous congestion by the distension of the epidural venous plexus, which occurs on lying down. Sudden exacerbations of pain, with a shift to worsening in erect postures and on movement, may suggest a pathological fracture.

Pain may also be experienced at a distance from the tumour and represent the compression of neural elements of the spine. Compression of one or more roots, either by tumour or distorted spinal elements is a relatively common cause of radiating pain and compression of the cauda equina can result in neurogenic claudication. Damage to the spinal cord can result in a burning dysaesthetic central neuropathic pain. While this is perhaps most associated with tumours of the spinal cord itself, it can also result from the damage caused to the spinal cord by external compression such as that from metastases.

Some 80–90% of patients with metastatic spinal cord compression have pain as their earliest symptom and 95% have pain at the point of presentation (Cole and Patchell, 2008). Over three-quarters of primary bone tumours of the spine present with pain, and about a half with no other symptoms. The authors of a large series of 438 patients attributed the majority of this local pain to tumour expansion within bone, but pathological fracture and root compression contributed (Dang et al., 2015). Just over half of patients with intradural tumours present with pain (Wu et al., 2014) but this rises to a clear majority of over 80% for tumours below the conus.

Neurological deficit

The other important symptom group arises from the dysfunction of compromised neural elements of the spine, among which the spinal cord is perhaps the most important. Although pressure on the cord can directly damage axons and lead to demyelination it seems to do most of its damage by vascular mechanisms—initially congestion and oedema from venous compression and later ischaemia and infarction from arterial insufficiency (Baptiste and Fehlings, 2006).

While metastatic spinal cord compression as a clinical syndrome is defined by neurological deficit, among all patients presenting with spinal tumours, about half have a neurological deficit, regardless of the type of tumour. Weakness, sensory deficit, loss of balance, and incontinence are reported at decreasing frequency.

Other presentations

While spinal deformity may result from the musculoskeletal destruction caused by metastases or primary bone tumours, it is rare as a dominant or isolated presenting feature. Scoliosis as the presentation of intramedullary tumours is rare but described in children.

It should also be noted that spinal tumours may be discovered incidentally. All spinal practitioners in the MR era will be aware of the common finding of vertebral haemangiomata. A pre-MR series based on pathological or plain radiological studies provided prevalence estimates for this benign vascular tumour of about 10% (Fox and Onofrio, 1993) and more recent studies of MR for other reasons have provided estimates as high as 27% in Iran (Barzin and Maleki, 2009). Series of primary bone tumours (4%, Dang et al., 2015) and intradural extramedullary tumours (4/18, Marchetti et al., 2013), have been reported including a small proportion of incidental cases. It seems as though tumours of the spinal cord itself are rarely discovered incidentally (0/89, Li et al., 2014). Metastatic spinal tumours are often discovered during the staging workup after primary diagnosis at a stage when they are asymptomatic if not entirely incidental

Differential diagnosis

Spinal pain is 'an almost universal human condition' (Hall, 2014) and a quarter of US adults, for example, report having had at least a day of back pain over the past 3 months. The lifetime prevalence of back pain may be as high as 80% and the vast majority is not attributable to any definable abnormality (Srinivas et al., 2012). It is easy then for the occasional patient with a spinal tumour, with an incidence several orders of magnitude lower than this, to be missed. Perhaps for this reason, the median time from symptom onset to diagnosis is as long as 25 months (Manzano et al., 2008) for the usually benign group of intradural tumours and even 200 days for spine metastasis presenting without a previous primary diagnosis (Quraishi et al., 2014).

There is a broad range of other pathological processes that can affect the spine and present with pain and neurological dysfunction. Infective processes can cause spinal destruction, which threatens the spinal cord and can also infiltrate the epidural space. Insufficiency fractures secondary to osteoporosis may be hard to tell apart from those secondary to tumour although the former rarely cause neurological deficit. Degenerative spine disease often presents with axial spinal pain and myelopathy, similar to extradural tumours, or with radicular pain, as may intradural extramedullary tumours. The absence of pain usually distinguishes the many neurological causes of myelopathy from tumoural causes.

Imaging

Since it became widely available in the 1990s, magnetic resonance imaging (MRI) has become the imaging modality of choice for the investigation of spinal pain and neurological deficit. While a strong case can be made for limiting the application of MRI to patients with the common complaint of spinal pain on the grounds of healthcare economics or medicalizing a normal human experience (Srinivas et al., 2012), for patients with red flags or 6 weeks of new pain it represents a non-invasive investigation without which the potentially serious diagnosis of a spinal tumour will not be made.

MRI with and without gadolinium enhancement is the modality of choice in the workup of a patient with a suspected spinal tumour. MRI provides excellent resolution of all spinal compartments, and provides enough information to differentiate blood and cystic fluid, enhancing solid tumour and spinal cord. It is particularly important to establish from the available imaging in which anatomical compartment the tumour lies and this can be achieved by the analysis of the relationship of the tumour to cord and dura (**Fig. 63.1**). Where metastatic spinal cord compression is suspected, whole spine MR within 24 hours is the gold standard.

Where MR is contraindicated, computed tomography (CT) myelography (**Fig. 63.2**) can be utilized. CT of the spine complements MR as the imaging modality of choice in assessment of bony structures, and is therefore invaluable in the imaging of the bony spine eroded or destroyed by tumour and the visualization of pathological fractures. It is also utilized in the planning of instrumentation in cases with bony collapse and instability. CT of chest, abdomen, and pelvis is widely utilized in the search for other metastatic deposits and the primary tumour and nuclear medicine bone scans also have a role in screening for other bony metastases. CT is the principle imaging modality for the guidance of percutaneous biopsies of spinal tumours, although it is unusual for this approach to be taken for intradural lesions

Plain X-ray alone is insensitive in the detection of spinal tumours and its role should be limited in contemporary practice to determining spinal level intraoperatively and the postoperative imaging of instrumentation. For highly vascular tumours such as haemangioblastoma, vertebral haemangioma, and renal metastasis, digital subtraction angiography (DSA) may prove an important investigation in identifying the spinal level of feeding vessels and imaging abnormal vasculature. It can be extended to embolization to reduce intraoperative blood loss. Ultrasound is limited to the paediatric population and intraoperative localization.

Modalities of treatment

The immediate management of patients with spinal tumours includes analgesia, the institution of antithromboembolic prophylaxis and immobilization where necessary. The instability of tumoural spinal destruction is rarely as dramatic as that following trauma and the institution of bed rest will usually suffice. Dexamethasone is a synthetic glucocorticoid with an anti-inflammatory effect that can help with analgesia and allow neurological improvement. For some haematological tumours it can have an antitumour effect affording a rapid biological decompression of the spinal cord. The rapid introduction of dexamethasone can improve the ambulatory outcome of patients with metastatic spinal cord compression (Sorensen et al., 1994) and is universally instituted prior to surgical intervention for spinal tumours with a view to improving neurological outcome through a neuroprotective effect.

Surgery

For most patients discovered to have a spinal tumour, a spinal surgical opinion is sought regarding the role of surgical intervention for diagnosis, symptomatic relief, improving prognosis, or even for cure. For some, particularly those with widespread malignancy and very limited prognosis, surgery may have nothing to offer but for many patients with intradural tumours, surgery will represent the central component of their therapy.

A sagittal image demonstrating the tumour with reference to the sacrum is a prerequisite for the planning of surgery for tumours in

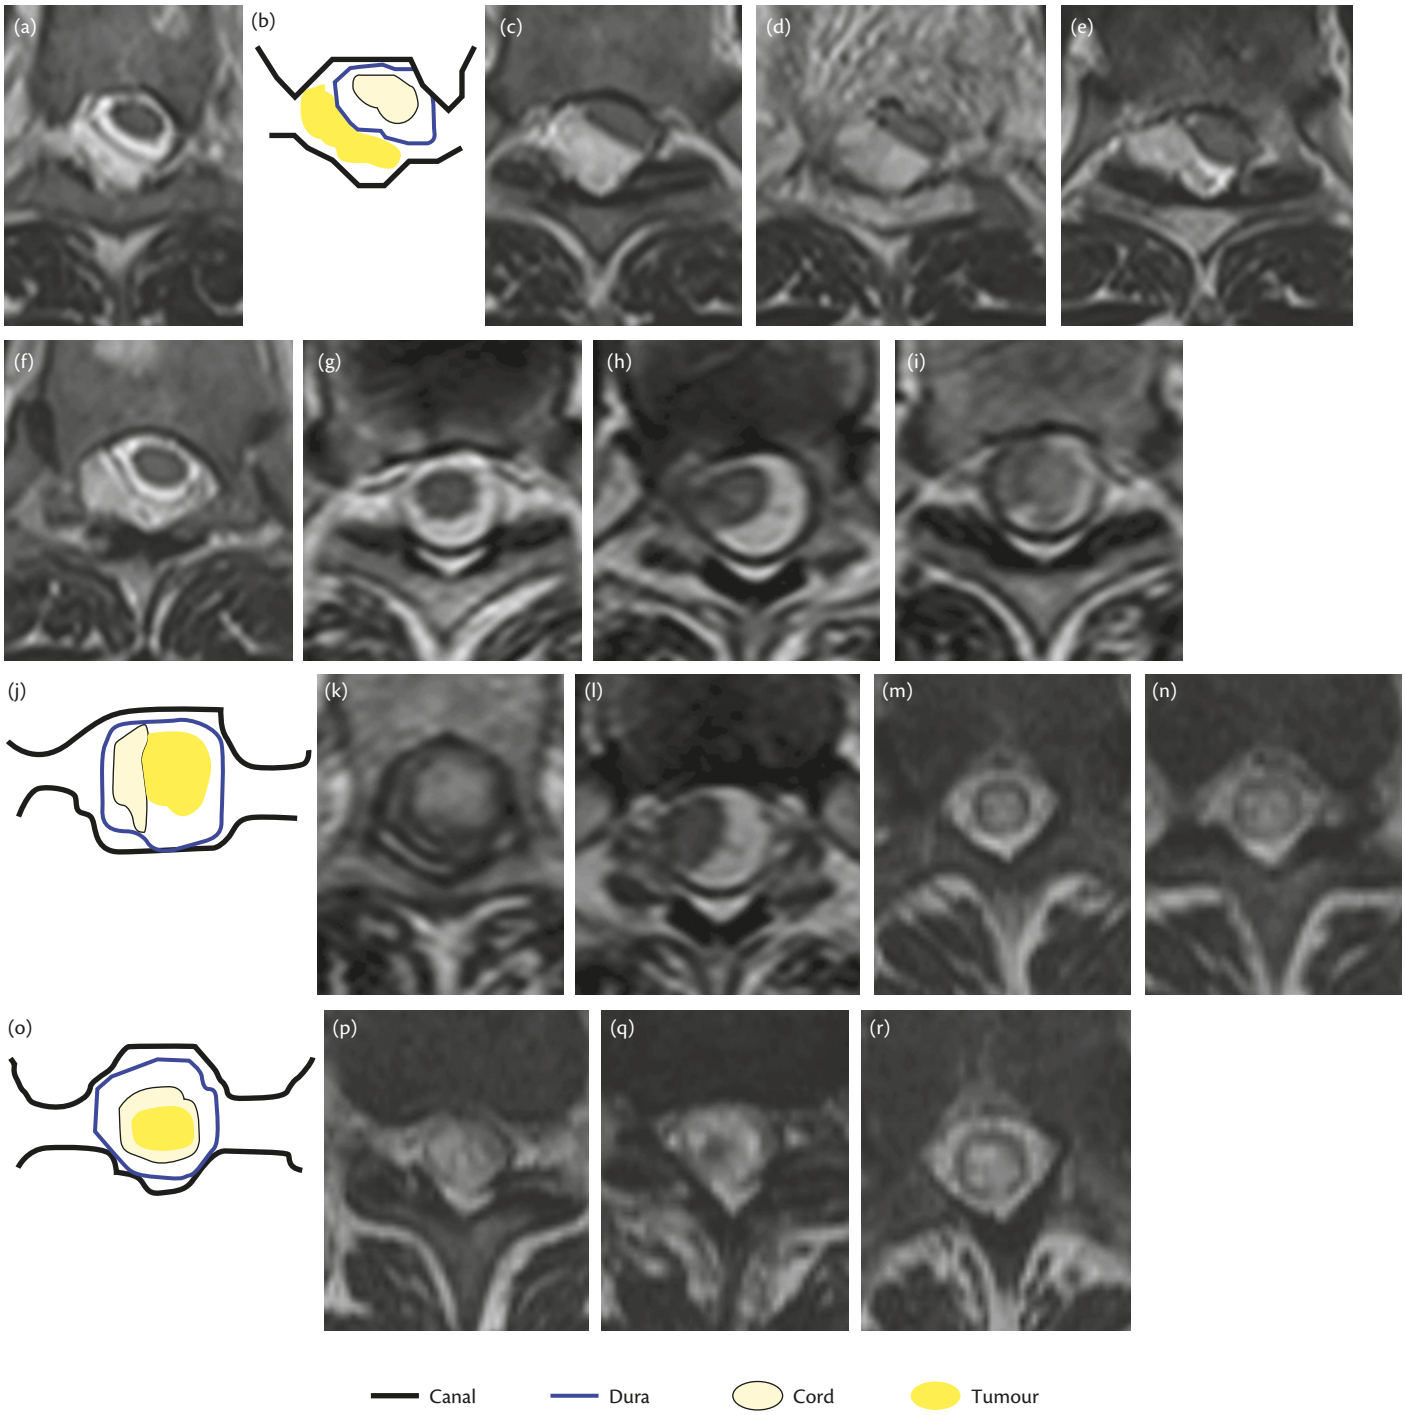

Fig. 63.1 These images show how serial axial images can help determine the compartment in which a spinal tumour lies by noting its relationship to the cord and the dura; extradural (A–F), intradural extramedullary (G–L), or intramedullary (M–R).

the sacral, lumbar, and thoracic spine. The occiput can be used as a point of reference for tumours in the cervical and uppermost thoracic spine. These preoperative images allow an image intensifier to be used intraoperatively to localize the tumour and plan a suitable incision. Careful positioning to avoid pressure damage to skin, peripheral nerves, and the face is essential. The use of a single dose of antibiotic (e.g. Cefuroxime 750 mg) on induction as prophylaxis against infection is reasonable. If a low molecular weight heparin has been introduced preoperatively for venous thromboembolism (VTE) prophylaxis in light of reduced mobility, this may be withheld for 24 hours pre- and postoperatively to reduce intraoperative bleeding and the risk of postoperative haematoma. Graduated compression stockings and intermittent calf compression are frequently used intraoperatively.

Intraspinal access

Laminectomy is the standard surgical approach employed for resection of tumours from the spinal canal. Although it affords good

Fig. 63.2 CT myelogram of a thoracic intradural, extramedullary tumour (schwannoma).

access to the canal, both intra- and extradurally, problems with postoperative pain and postlaminectomy kyphosis, especially in paediatric patients, have led some to explore alternative access procedures including laminoplasty, hemilaminectomy (Fig. 63.3), and the techniques of minimally invasive spinal surgery. Hemilaminectomy has also been applied to the decompression of the spinal cord in metastatic spinal cord compression (MSCC) without worsening stability as an alternative to the larger instrumented approaches, described next (Fig. 63.3; see also Millward et al., 2015).

Larger tumours with lateral extension may require removal of the facet joint and pedicle for adequate exposure and total resection. Although ventral access procedures have been employed for spinal tumour resection, the ventral aspect of both extra- and intradural compartments can be accessed dorsally and dorsolaterally without excessive retraction of the cord.

Intradural access

If intraoperative ultrasound imaging is available, it is advisable to check that the exposure allows access to both tumour poles prior to opening the dura. A longitudinal durotomy is usually employed. The arachnoid is then incised before the tumour is identified. The dentate ligament may be divided to allow access to tumours arising ventrally to the cord. Solid extramedullary tumours are debulked with the aid of an ultrasonic aspirator and cystic tumours drained before the peripheral tumour is dissected under microscopic control from the surrounding structures. Nerve sheath tumours with a single nerve root of origin may be able to be excised completely by division of that root above and below the tumour and surprisingly little disability usually results. When, however multiple roots, or a particularly large motor root are involved, the surgeon may elect instead to attempt to dissect tumour from root or to leave a small volume of tumour attached to each intact root. While many intradural extramedullary tumours have a good plain between them and surrounding structures and can be curatively resected, others may be densely adherent, and myxopapillary ependymomas are particularly notable in this regard.

Intramedullary access

Once the cord is exposed, the identification of the normal structures under microscopic vision aids in orientation. A large tumour or swollen cord distorts the normal anatomy and in such cases the midline dorsal vein and posterior median sulcus which guide a dorsal, midline myelotomy and the dorsal roots and posterolateral sulcus which provide the landmarks for entry through the dorsal root entry zone may be particularly difficult to identify. Once exposed, the tumour is internally debulked with an ultrasonic aspirator and a biopsy is sent for frozen section. Assessment of the interface between tumour and cord at an early stage should guide the extent of resection, and this decision may also be guided by the on-table pathology result, and intraoperative electrophysiological monitoring. While ependymomas can usually be completely resected (Fig. 63.4), astrocytomas are often less distinct from the cord.

Instrumentation

The resection of tumours from the spinal skeleton can be achieved through any number of approaches, chosen to give the best access to pathology. Neurosurgery has long been familiar with anterior approaches to the cervical spine, but the widespread application

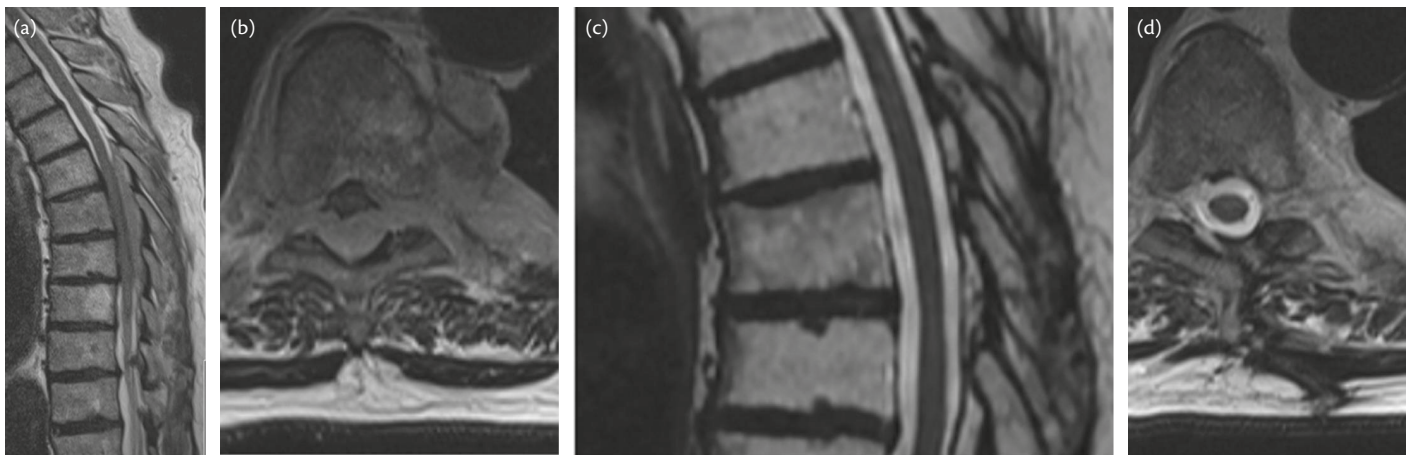

Fig. 63.3 Thoracic lymphoma. A 74-year-old man presented with progressive paraparesis and leg pain. Midsagittal T2-weighted (A) and axial gadolinium-enhanced T1-weighted (B) MRI scans demonstrating an extradural enhancing mass lesion. He had a hemilaminectomy for biopsy and decompression. Postoperative sagittal (C) and axial (D) MRI images are shown.

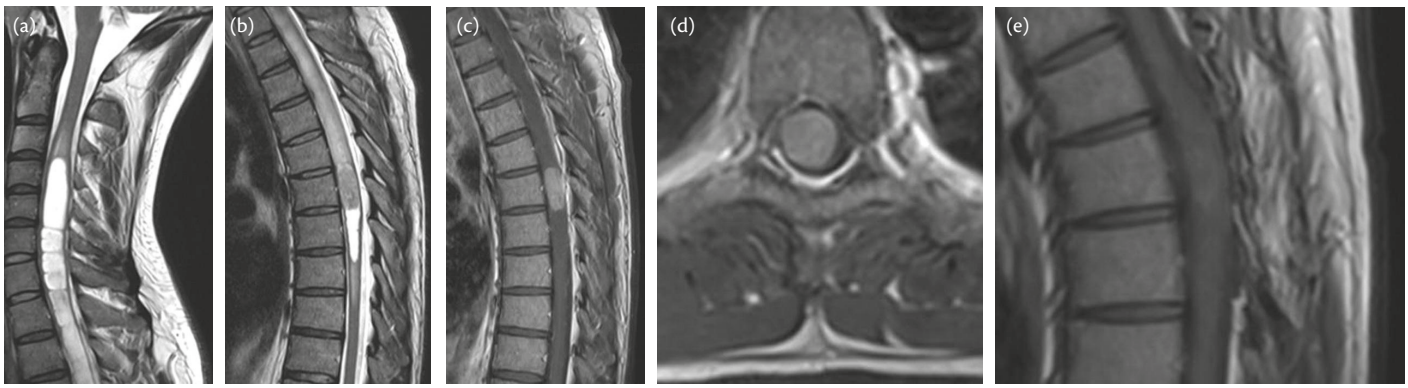

Fig. 63.4 A 30-year-old gentleman presenting with progressive paraparesis and diagnosed with an ependymoma (WHO grade 2). Note the enhancing tumour near the caudal end of the syrinx (A–D); (E) shows the MRI 4 years postresection. The patient recovered with good neurological outcome.

of trans- and extracavitary approaches to the thoracic and lumbar spines has changed the approach to tumours within the vertebral body (Young et al., 1980; *cf.* Patchell et al., 2005). Not only can destructive tumours reduce the mechanical integrity of the spine, so may the resections employed to treat them. Surgeons involved in the treatment of spinal tumours should have access to the full range of anteriorly and dorsally applied instrumentation in order to restore stability to the spine.

Over recent years there has perhaps been a shift towards posterior approaches to both metastatic spinal tumours and primary bone tumours. The contemporary generation of pedicle screw-based instrumentation allows the spine to be stabilized over a disease segment without the need for a weight-bearing element to be placed anteriorly. Minimally invasive spine surgery has been applied to both the decompression and stabilization of the spine affected by tumour (Ziari et al., 2012) again allowing a purely dorsal approach. Even total or *en-bloc* vertebrectomy, applied to solitary radiotherapy- and chemotherapy-resistant metastases, such as those from renal cell carcinoma, chordoma, and other bone tumours, can be performed through a purely dorsal surgical approach.

Surgery for spinal tumours is associated with significant risks. Table 63.1 by no means provides an exhaustive list, but rather highlights the main potential complications. These risks should be clearly emphasized during patient counselling, minimized as far as possible, and clearly explained during discussion with the patient.

Percutaneous vertebral augmentation

The percutaneous transpedicular injection of bone cement either directly into the marrow space of the vertebral body (vertebroplasty) or into a space performed by expansion of a balloon within the vertebra (kyphoplasty) are well established as options for the treatment of pain following osteoporotic vertebral collapse. Such procedures are also useful in the treatment of patients with painful vertebral metastases and myeloma deposits. Vertebroplasty can be employed

Table 63.1 Complications related to surgery for spinal tumours

Complications		
General	**Benign tumours**	**Malignant tumours**
Bleeding	DSA + embolization useful in certain tumours (e.g. haemangioblastoma, metastatic renal cell carcinoma). On the whole, surgery for malignant tumours poses a higher risk of intraoperative blood loss	
Infection	Risk increased with concomitant use of steroids, extremes of age, and other comorbidities such as diabetes mellitus	
CSF fistula +/– pseudomeningocele	Intervention only if clinically symptomatic. Surgical options include lumbar drain, surgical repair	
Tethered cord	May be reduced with pial sutures, whereas duraplasty has not been shown to be protective	
Syringomyelia	Risk increased with cord tethering at site of surgery Excision of tumour and re-establishing CSF flow usually results in decreased size, or even resolution of preoperative syrinx	
Vascular compromise	Risk increased with preoperative DSA +/– embolization procedures	
Permanent neurological worsening including tetraplegia and paraplegia	Approximately 20% of patients will experience permanent motor, sensory, sphincteric (or a combination) dysfunction; <4% risk of delayed, postoperative myelopathy. Dorsal column dysfunction seen in almost all patients with intramedullary tumours approached through a dorsal myelotomy. Useful techniques such as spinal cord monitoring give the surgeon additional information in order to reduce these risks	
Tumour recurrence	Very low in completely resected tumours. However, incompletely resected myxopapillary ependymoma is an exception	Malignant tumours almost always recur
Tumour seeding	Very rare	At site of biopsy, especially in sarcomas. The tissue surrounding the biopsy needle path should be removed during definitive sarcoma surgery
Spinal deformity	More of an issue in paediatric cases due to neurological disability caused by tumour, or following surgery	

effectively and safely, even in the presence of epidural soft tissue, for the treatment of painful metastases (Sun et al., 2014).

Oncological treatment

Despite recent evidence to support the role of surgery in the treatment of metastatic spinal cord compression, radiotherapy remains the principle modality of treatment for the majority of patients suffering from this oncological emergency. Radiotherapy is also employed in the treatment of unresectable and recurrent intradural tumours with, perhaps, modest results. For chordoma and chondrosarcoma proton beam therapy may be of benefit, where it is available.

Focused radiation, employed for over 60 years for cranial tumours through stereotactic radiosurgery, has also been applied to the spine. As a treatment for enlarging intradural extramedullary tumours, radiosurgery can achieve radiological stabilization, neurological preservation, and even improvement with the risk of cord radionecrosis rarely arising (Marchetti et al., 2013). It may have a more durable effect than conventional radiotherapy in the treatment of spine metastases and has additional benefits of efficacy in radioresistant disease and relapse after conventional radiotherapy (Gerszten et al., 2009). Chemotherapy has a limited role in the treatment of spinal tumours but for haematological malignancies, particularly lymphoma, when they affect the spine, may be curative.

Rehabilitation

Patients with spinal tumours are often understandably distressed through the course of their treatment and if pain is not appropriately managed, these patients are at risk of psychological and psychiatric disturbances such as depression, anxiety, and fatigue (Jones et al., 2003). Spinal neurorehabilitation is an integral part of management, and maximal benefits are gained with early commencement of a tailored programme at a specialized centre. Rehabilitation has also been shown to improve depression (Ruff et al., 2007).

Tumour group specifics

Intramedullary spinal cord tumours

Intramedullary spinal cord tumours (IMSCT) are rare and comprise less than 4% of central nervous system tumours and 30% of intradural spinal neoplasms. The most common tumour types are ependymomas and astrocytomas. The former outnumbers the latter in most case series with a suggestion that astrocytomas predominate in the younger age group, with ependymomas being more frequently encountered with increasing age (Manzano et al., 2008). Haemangioblastomas are less frequent, and rarer still are other miscellaneous developmental tumours and cysts such as lipomas and dermoid, epidermoid, and neurenteric cysts. Features of the more common IMSCTs are listed in Table 63.2.

It is important to note that while resection of intramedullary spinal cord tumours is compatible with both good oncological prognosis and long-term ambulation, myelotomy itself is not without morbidity. In a recently reported series of 278 patients, 61% had a worsened neurological status postoperatively, permanently so in about 20% (Klekamp, 2013).

Intradural, extramedullary spinal tumours

Intradural, extramedullary spinal tumours (IDEMs) are over twice as common as IMSCTs but still rare, accounting for 70% of the incidence of intradural tumours—between 0.8 and 1.3 per 100 000 population/year. The most common of the IDEMs are nerve sheath tumours (Fig. 63.5), followed by meningiomas and myxopapillary ependymomas (Traul et al., 2007). These tumours are usually benign and solitary; other features are listed in Table 63.3. The full range of tumours arising in this anatomical compartment is broad and includes metastatic tumours, paragangliomas, epidermoid, and dermoid cysts, lipomas, and teratomas.

Surgery is mainly indicated for progressively enlarging, symptomatic tumours. Some schwannomas, meningiomas and developmental lesions do not progress, and surveillance alone is adequate, thereby avoiding the potential surgical risks. However, the myxopapillary ependymoma behaves differently and deserves special mention.

Myxopapillary ependymoma

Myxopapillary ependymomas are almost entirely confined to the lumbar spine and usually solitary. Due to its unique location, symptoms are usually attributable to dysfunction of the conus or cauda equina. These tumours may fill the entire lumbosacral spinal canal (Fig. 63.6). Although classified as 'benign'—they are WHO grade 1 tumours—the myxopapillary ependymoma behaves aggressively with a propensity for recurrence and CSF dissemination that usually translates to multiple surgeries in the patient's lifetime (Boström et al., 2011). It may scallop bone as well as erode through dura and become densely adherent to the nerve roots of the cauda equina. The treatment of choice is complete surgical excision. Incidental, small, asymptomatic tumours may be operated on early as the chance of curative and complete excision is good at this stage reducing the risk of dissemination and progression to irresectability is reduced. In practice, an *en-bloc* excision is sometimes difficult to achieve as the tumour capsule is thin and the tumour itself is usually soft. The filum terminale should be identified early in the course of surgery, and this may be facilitated by using a nerve stimulator and EMG electrodes in the external anal sphincter.

Primary bony tumours of the spine

Primary tumours of the bony spine are again, rare, with vertebral metastases being much more common. The pathological diversity is wide and these tumours demonstrate a bimodal age distribution, affecting both young and older people. Tumours with connective tissue components as cells of origin and therefore belonging to the sarcoma group, can be classified into two broad categories, either malignant (Table 63.4) or benign (Table 63.5). Their management is the province of the supraregional specialty unit.

Malignant bone tumours

The chordoma (Figs. 63.8 and 63.9) is the most common adult primary malignant spinal bone tumour and is typically a midline tumour, found to occur commonly in the axis and lumbosacral regions. They are slowly growing but destructive lesions, with a particularly high rate of recurrence following piecemeal resection. Radical, complete, *en-bloc* resection without violation of the tumour has been shown to significantly reduce the rate of recurrence and improve survival (Fuchs et al., 2005).

The osteosarcoma is the most common primary spine sarcoma and has an especially poor prognosis (Sansur et al., 2007). Risk factors in the development of osteosarcoma include Paget's disease and

Table 63.2 Features of ependymomas, astrocytomas, and haemangioblastomas

			Tumour type					
			Ependymoma		**Astrocytoma**		**Haemangioblastoma**	
MRI features	T1WI		Variable		Hypointense		Iso- to hypointense	
	T2WI		Hypointense		Hyperintense		Iso- to hyperintense (enlarged feeding and draining vessels may be visualized)	
	Location		Central		More eccentric		Usually superficial	
	Enhancement		Homogenous		Heterogenous (none with LGG; intense in pilocytic astrocytomas and HGG)		Intense	
	Margins		Generally distinct		Poorly defined		Distinct nodule	
	Syringomyelia/Cyst		Often associated		Less common (pilocytic astrocytomas may have an associated cyst)		Very commonly associated with a cyst	
Potential for GTR			Yes		Less common		Yes	
Histology	Subtypes (commonest in bold)	WHO Grade	Subependymoma (rare) Ependymoma Anaplastic ependymoma	1 2 3	Pilocytic astrocytoma (rare) LG astrocytoma Anaplastic astrocytoma Glioblastoma	1 2 3 4	Haemangioblastoma	1
	Microscopic features of commonest subtype		Sheets of uniform cells with oval nuclei and fine cytoplasmic processes Perivascular pseudorosettes Mitoses rare/absent		Well differentiated neoplastic astrocytes within microcystic tumour matrix (No necrosis or microvascular proliferation) Mitoses: Ki-67/MIB-1 <4%		Two main components: endothelial cells and pericytes; large, vacuolated stromal cells containing lipid Rosenthal fibres in cyst and syrinx walls Mitoses usually absent (MIB-1: 0–2%)	
	Immunohistochemistry		GFAP, S-100 protein, Vimentin		GFAP Vimentin (more consistent in higher grade)		Stromal cells lack endothelial cell markers (negative in RCC) but are positive for D2–40 Ab and inhibin-A (positive in RCC), Vimentin, VEGF	
Syndromic associations			NF2 (chromosome 22q12)		NF1 (chromosome 17q11) TP53 germline mutations / Li-Fraumeni syndrome Ollier's disease		VHL (chromosome 3p25)	

Abbreviations: T1WI, T1-weighted imaging; T2WI, T2-weighted imaging; LGG, low-grade glioma; HGG, high-grade gliomas; NF1, neurofibromatosis type 1; NF2, neurofibromatosis type 2; VHL, Von Hippel-Lindau syndrome; GTR, gross total resection; Immuno, immunohistochemistry; VEGF, vascular endothelial growth factor; GFAP, glial fibrillary acid protein; RCC, renal cell carcinoma; Ab, antibody; Ollier's disease also known as inherited multiple enchondromatosis type 1.

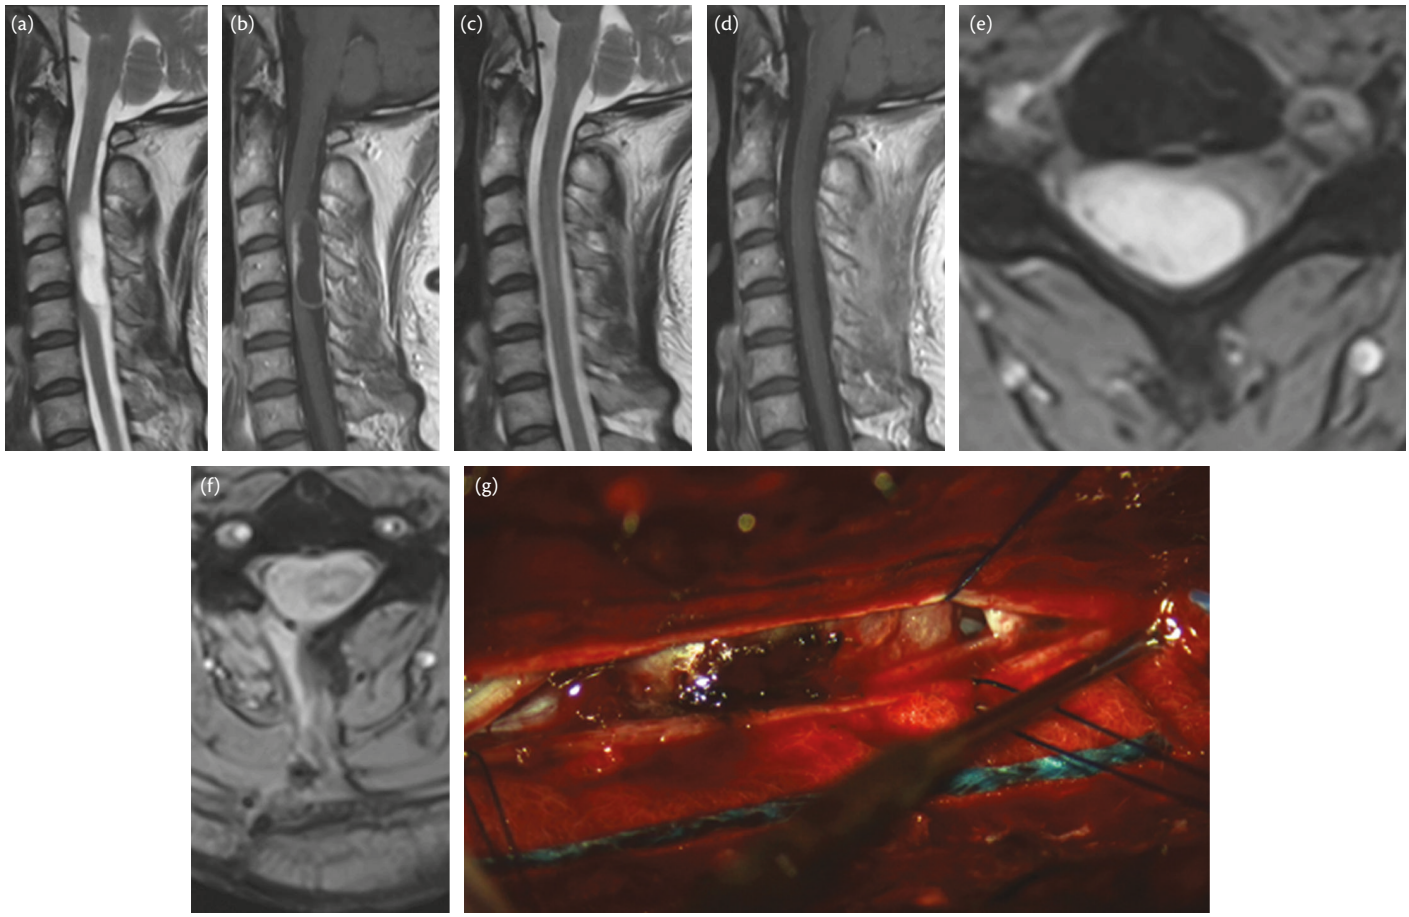

Fig. 63.5 MR images to illustrate the resection of a cervical schwannoma through a unilateral, parasagittal approach and hemilaminectomy (A–F). The postoperative image is also shown (G).

radiotherapy. Unfortunately, *en-bloc* resection is rarely achievable and despite all treatment options, the management of primary spinal osteosarcomas is palliative.

Chondrosarcoma (Fig. 63.10) has a characteristic radiological appearance including moth eaten osteolytic areas and 'rings and arcs' of calcification within the tumour matrix, which are best appreciated on CT. Extraosseous and epidural extension is common, and MR is the modality of choice in demonstrating this. Fortunately, majority of chondrosarcomas are low grade. Wide, *en-bloc* surgical resection is associated with prolonged survival and recurrence free interval, in contrast to debulking procedures (Quiriny and Gebhart, 2008).

Multiple myeloma and plasmacytoma

Multiple myeloma (MM) is a systemic haematological malignancy characterized by proliferation of monoclonal plasma cells (Fig. 63.11). It represents about 1% of all cancers worldwide and an incidence of about 5.5 per 100 000 (Ferlay et al., 2013) and is a disorder of older people with a median age at presentation of 70. Plasmacytomas are discreet, solitary lesions that are histologically identical to MM but without the systemic manifestations.

The vertebral column represents the commonest site of bony involvement. The management of symptomatic cord compression in MM remains an area of controversy. In the setting of soft tissue related cord compression, urgent local radiotherapy is the treatment of choice. Generally, surgery is reserved for symptomatic MM patients with evidence of bony or structurally related cord compression and consolidated by radiotherapy. However, Rao et al. (2006) have suggested that radiotherapy alone is an effective form of palliative treatment without surgery after reviewing a cohort of patients with MM of the cervical spine with both clinical and radiological features of instability. The bone density in this condition is notoriously low which can compromise the use of instrumentation.

Haemangioma

Vertebral haemangiomas are benign tumours and are the most common primary spinal tumours (Figs. 63.12 and 63.13). They are usually incidental lesions found on imaging; MRI characteristically demonstrates high signal on both T1- and T2-weighted imaging and these appearances allow a diagnosis to be made without the need for biopsy. Vertebral haemangiomas are rarely symptomatic, but a small proportion of these tumours may expand the bone and cause pathological fractures, or extend into the epidural space and compress neural structures. Larger lesions demonstrate the characteristic 'honeycomb' appearance or 'corduroy sign' on sagittal and coronal CT, which are prominent vertical striations of thickened trabecular bone. Treatment options for symptomatic lesions include surgical excision, vertebroplasty, endovascular embolization, and radiotherapy.

Table 63.3 Features of nerve sheath tumours, meningiomas, and myxopapillary ependymomas

			Tumour type					
			Nerve sheath tumours		**Meningioma**		**Myxopapillary ependymoma**	
MRI features	T1WI		Hyperintense		Isointense		Hypointense	
	T2WI		Hyperintense		Isointense to Hyperintense		Hyperintense	
	Location		Affecting sensory nerve root(s) Even distribution in spinal canal		Dural based; posterior / postero-lateral; Thoracic		Almost exclusively affecting filum terminale	
	Enhancement		Heterogenous		Homogenous; 'Dural tail'		Homogenous	
	Margins		Distinct		Distinct		Distinct	
	Oedema		None		Variable		Often associated	
	Cystic change		Common		None		Not uncommon; also areas of haemorrhage	
Surgical pearls	Relationship to arachnoid		Both layers of arachnoid (similar to cranial counterpart) must be opened		Clear arachnoid plane between tumour and spinal cord		Arachnoid needs to be opened to expose the tumour, which is in turn surrounded by a thin capsule	
	Surgical removal		Piecemeal. Sacrifice of sensory nerve root of origin		Piecemeal or *en-bloc* excision. Cautery or excision of overlying dura		En-bloc, total excision	
Histology	Subtypes (common in bold)	WHO Grade	Schwannoma Neurofibroma	1 1	Benign Atypical (rare) Malignant (rare)	1 2 3	Myxopapillary ependymoma	1
	Microscopic features of commonest subtype		Composed entirely of neoplastic Schwann cells in two patterns: Antoni A (cellular; spindle shaped cells, dense pericellular reticulin arranged in intertwining fascicles; characteristic Verocay bodies), Antoni B (less cellular; cells loosely arranged in myxoid stroma with scanty surrounding reticulin)		Variable, depending on subtype and grade. Common subtypes: meningothelial, psammomatous Mitotic rate (Ki–67 index) usually <4% Reticulin pattern rarely as dense as schwannoma		Encapsulated tumour; not infiltrative Clusters of tumour cells with round, monomorphic nuclei characteristically arranged in papillary pattern, enveloped in abundant mucin / myxoid stromal cores. Mitosis and necrosis rare	
	Immunohistochem		S-100: strong and diffuse expression GFAP: focal, infrequent staining Collagen IV and laminin positive: found in surface basal lamina that is present in all schwannomas		EMA, Vimentin: positive S-100 variable Cytokeratins: focal GFAP negative		GFAP, S-100, Vimentin: positive Cytokeratins: absent	
Syndromic associations			NF2 (chromosome 22q12) Carney's complex (17q23-q24) (melanotic schwannomas)		NF2 (chromosome 22q12) Previous radiotherapy Castleman's syndrome (chordoid type)		NF2 (chromosome 22q12)	

Abbreviations: T1WI, T1-weighted imaging; T2WI, T2-weighted imaging; NF1, neurofibromatosis type 1; NF2, neurofibromatosis type 2; GTR, gross total resection; GFAP, glial fibrillary acid protein; EMA, epithelial membrane antigen; Immunohistochem, immunohistochemistry.

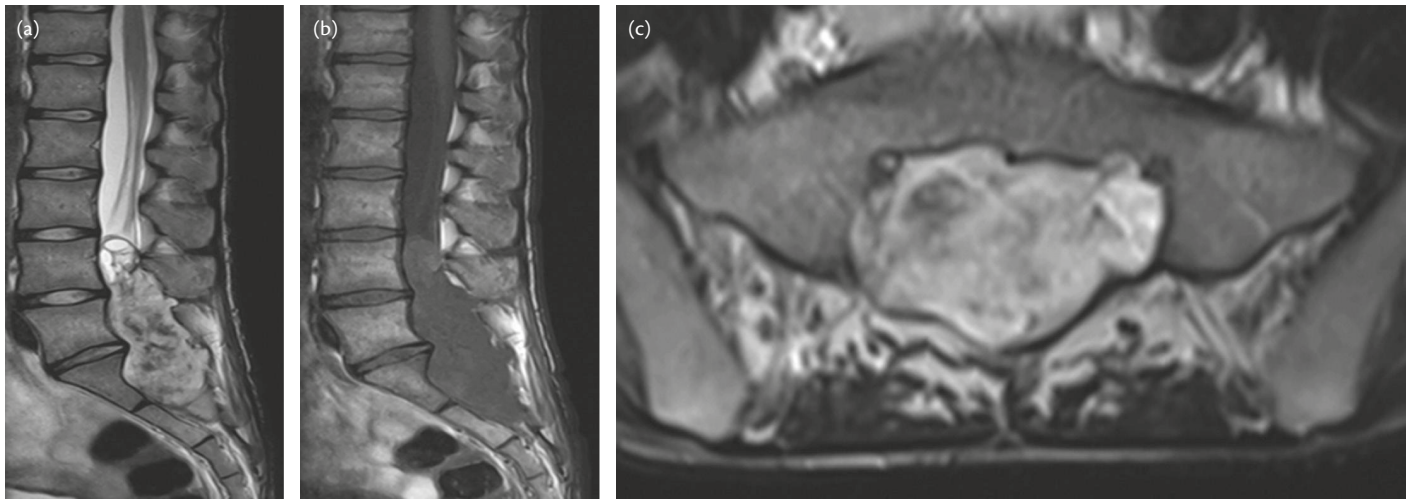

Fig. 63.6 Late presenting myxopapillary ependymoma with destruction of the posterior elements and scalloping of the sacral body (A, B). The caudal nerve rootlets and dura have been invaded by tumour, limiting resection. The wound was closed over a directly placed spinal drain as direct closure of the dura was impossible (C).

Spinal metastases

Among the various significant clinical entities described in this chapter, spinal metastatic malignancy is by far the most common. The spine is the most common osseous site for metastatic deposits and 40% of patients dying from cancer have spinal disease on autopsy. It is inevitable that a rise in the incidence of metastatic spinal disease will accompany the increase in survival of patients with cancer, which has accompanied more effective treatment of this group of pathologies (Sciubba et al., 2010). The commonest sources of spinal metastases are from cancers of the lung, breast (Fig. 63.14) and prostate but renal cell carcinoma, gastrointestinal malignancy, and melanoma are also common. Myeloma deposits may indeed be metastatic but have been considered here with primary tumours of bone.

When the growing tumour invades the epidural space or causes pathological fracture of a vertebral body the spinal cord can become compressed and when neurological function develops, the oncological emergency of MSCC results. Sudden onset deficits may represent cord infarction and carry a relatively poor prognosis compared to gradual onset deficit. There is an established diagnosis of malignancy in most patients but up to 20% of spine metastases represent the first presentation of the patient's disease (Cahill, 1996). The investigation of this patient group should include a myeloma screen, prostate-specific antigen in men, examination of the breasts in women and a screening CT of the chest, abdomen, and pelvis.

The spinal surgeon is often called upon to make decisions about the appropriateness of surgical intervention for MSCC. A decision is often needed promptly to facilitate rapid institution of therapy,

Table 63.4 Malignant primary osseous spine tumours

Tumour type	Age (yrs)	Location in spine	Origin	Clinical presentation	Median survival (mths)	5-year survival (%)	Metastasis	Management
Chordoma	60s	Sacrum (if occurs in C-spine, had predilection for C2)	Notochordal remnants	Pain, deformity, neurological deficit	74	50–85	Uncommon	Wide margins, *en-bloc* surgical resection, radiotherapy (insensitive to chemo)
Osteosarcoma	Two peaks: 10–30 and 50s	Sacrum, posterior elements	Bone		11	18–41	Pulmonary mets common. Malignant degeneration in Paget's disease and following radiotherapy	Wide margins, *en-bloc* surgical resection, chemo, radiotherapy (often purely palliative)
Chondrosarcoma	50s	Thoracic, posterior elements	Cartilage		26	40	Uncommon. Malignant degeneration of osteochondroma	Surgical resection (Insensitive to chemo and radiotherapy)
Ewing's sarcoma	10–30 (teens)	Sacrum, posterior elements	Small, round, blue-cell tumour		37	55–73	Commonly to lungs and bone. Rarely epidural	Surgery, chemo, radiotherapy

Table 63.5 Benign primary osseous spine tumour

Type	Age (years)	Location	Clinical presentation	Malignant degeneration	Management	Recurrence rate (%)
Haemangioma	Any age	Thoracic, body	Incidental	No	Surgical excision and/or radiotherapy for symptomatic lesions	(Low)
Osteoid osteoma	10–20	Lumbar, body	Night pain relieved by salicylates, NSAIDs <2 cm	No	Surgical excision	<4.5
Osteoblastoma	10–30	Lumbar, body	Non-specific pain; >2 cm	Yes	Surgical excision	<15
Aneurysmal bone cyst See Fig. 63.7	<20	Thoracolumbar, posterior elements	Pain, deformity, neurological deficit	No	Complete curettage and excision. High recurrence rate with incomplete excision	<30
Giant cell tumour	20–40	Sacral, body	Aggressive. High recurrence rates	Not reported. However, post-op radiotherapy associated with 10% radiation induced sarcoma	Surgical excision with wide margins. Radiotherapy not associated with improved outcomes	<40 (increased with incomplete resection and intralesional margins)
(Osteo)chondroma	30–40	C2, Posterior elements	Neurological deficits rare. Scoliosis	Yes (to chondrosarcoma)	Complete surgical excision	Paucity of data
Chondroblastoma	Adolescence	Not applicable due to rarity	Pain, neurological deficits	Not reported	Complete surgical excision. High recurrence with incomplete excision	24–100

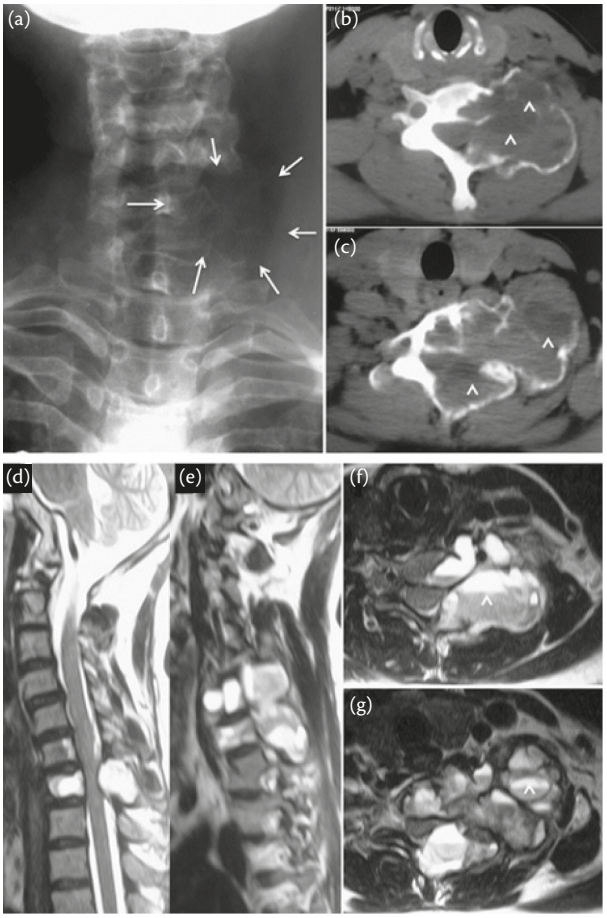

Fig. 63.7 A 47-year-old female patient with neck pain with pathological diagnosis of aneurysmal bone cyst. (A) Anteroposterior X-ray lytic destructive lesion at the left side of C6–C7 vertebra (arrows). (B, C) Fluid–fluid levels (arrowheads) demonstrated in the multilocular expansile lesion involving both the body and posterior elements on consecutive computed tomography images. Magnetic resonance imaging of the same patient. (D, E) Sagittal and (F, G) axial T2-weighted images demonstrate multiple fluid–fluid levels representing haemorrhagic elements at various ages (arrowheads).

whether it commence with surgery or radiotherapy, and should when possible be made in consultation with an oncologist familiar with the patient's case and with sight of MR imaging. Many factors need to be considered and these may be considered in four groups (Fig. 63.15). Oncological factors include the radio- and chemosensitivity of the malignancy and the patient's stage and prognosis. Neurological factors include the symptoms and deficits of neurological compression, and the presence of a radiologically compressive lesion which explains them. A complete cord lesion lasting longer than 24 hours is extremely unlikely to improve following decompression. Biomechanical factors revolve around the effect of the tumour on the structure of the spine. Mechanical pain and deformity may be indications for surgical stabilization, but the integrity of adjacent levels is required to capture spinal elements with instrumentation. Additional CT scanning may be helpful in providing this information but a patient with compromise of long segments of the spine is unlikely to become a surgical candidate. Patient factors are of primary importance and include performance status, comorbidity, age (Chi et al., 2009), and patient wishes.

Various authors such as Tokuhashi et al. (2005) have formalized consideration of some of these factors into scoring systems. They are based on actuarial survival tables to provide a guide to prognosis and can contribute to the decision-making process. The numbers should not be used blindly however and do not replace the need for careful discussion with oncologist and patient. Sciubba et al. (2010) have recommended surgical decompression and stabilization in patients with bony cord compression, rapid neurological decline, evidence of instability, radioresistant tumours, and recurrent tumours despite radiotherapy.

Controversy

There is no doubt that Patchell's landmark study, published in 2005, changed practice regarding the application of surgery to MSCC. A previous randomized controlled trial of laminectomy and

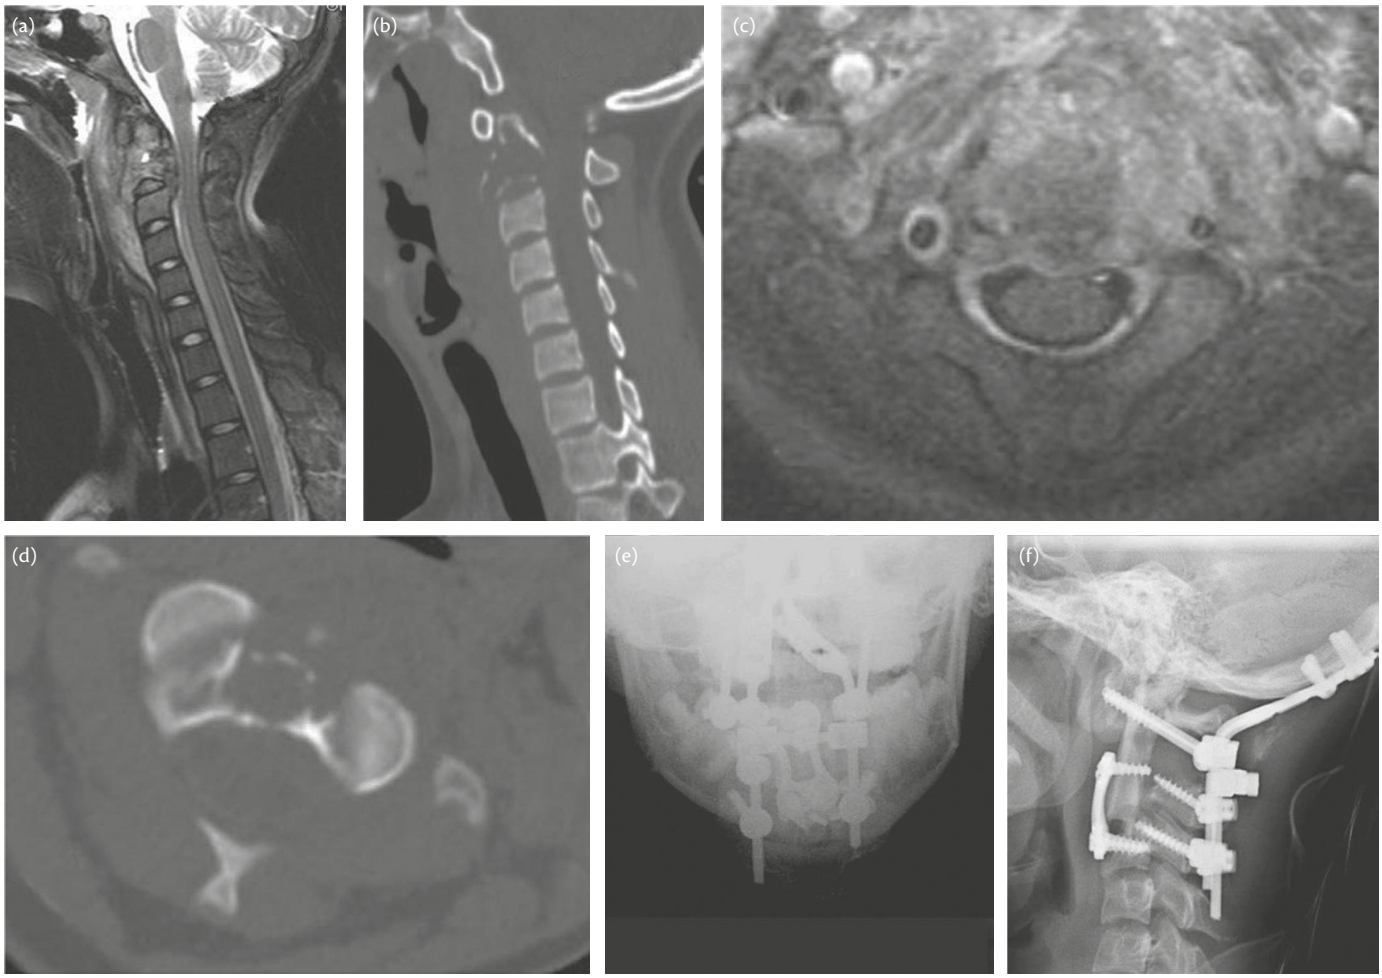

Fig. 63.8 Chordoma. Preoperative sagittal T2-weighted MRI (A) shows extensive destruction of the C2 vertebral body with prevertebral extension from the clivus to C5 (arrow). Preoperative sagittal CT reconstruction (B) shows an expansile lesion involving C2 vertebral body (arrow). Preoperative axial T2-weighted MRI (C) with gadolinium contrast enhancement shows extensive infiltration of the C2 vertebral body with tumour surrounding the vertebral arteries (arrow). Preoperative axial CT (D) shows bony involvement of C2 vertebral body (arrow). Radical extended transoral-transmandibular resection followed by posterior element resection, instrumentation, and fusion was undertaken. Postoperative anteroposterior (E) and lateral (F) radiographs were performed after total C2 resection, instrumentation, and fusion (see Walcott et al., 2012).

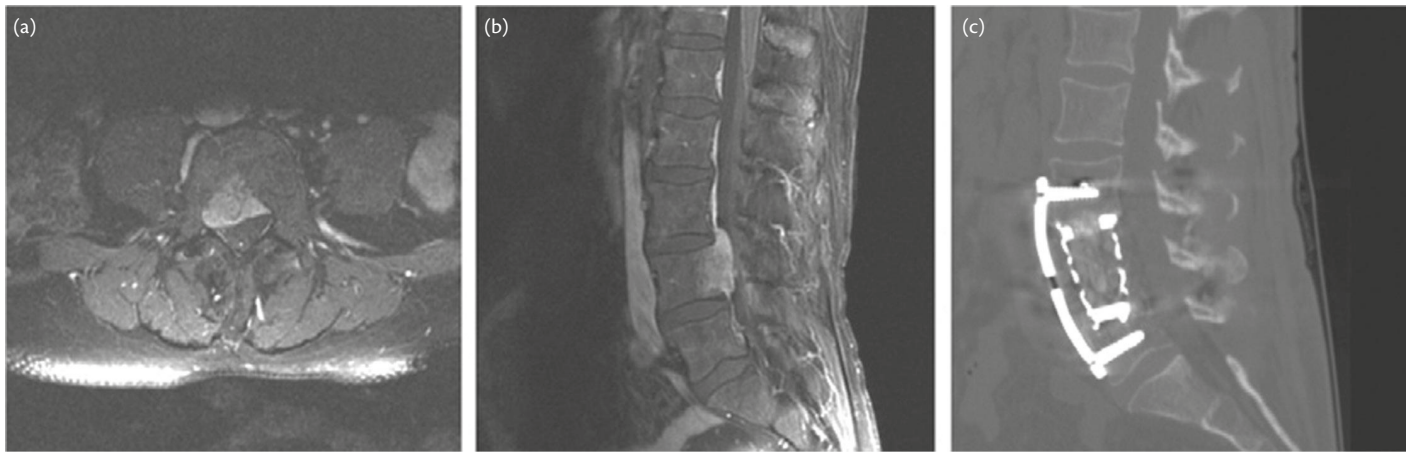

Fig. 63.9 CT and magnetic resonance images of lumbar chordoma preoperative axial magnetic resonance images of lumbar chordoma (left); preoperative sagittal magnetic resonance images of lumbar chordoma (middle); and postoperative lateral radiographs (right) (see Ozaki et al., 2002).

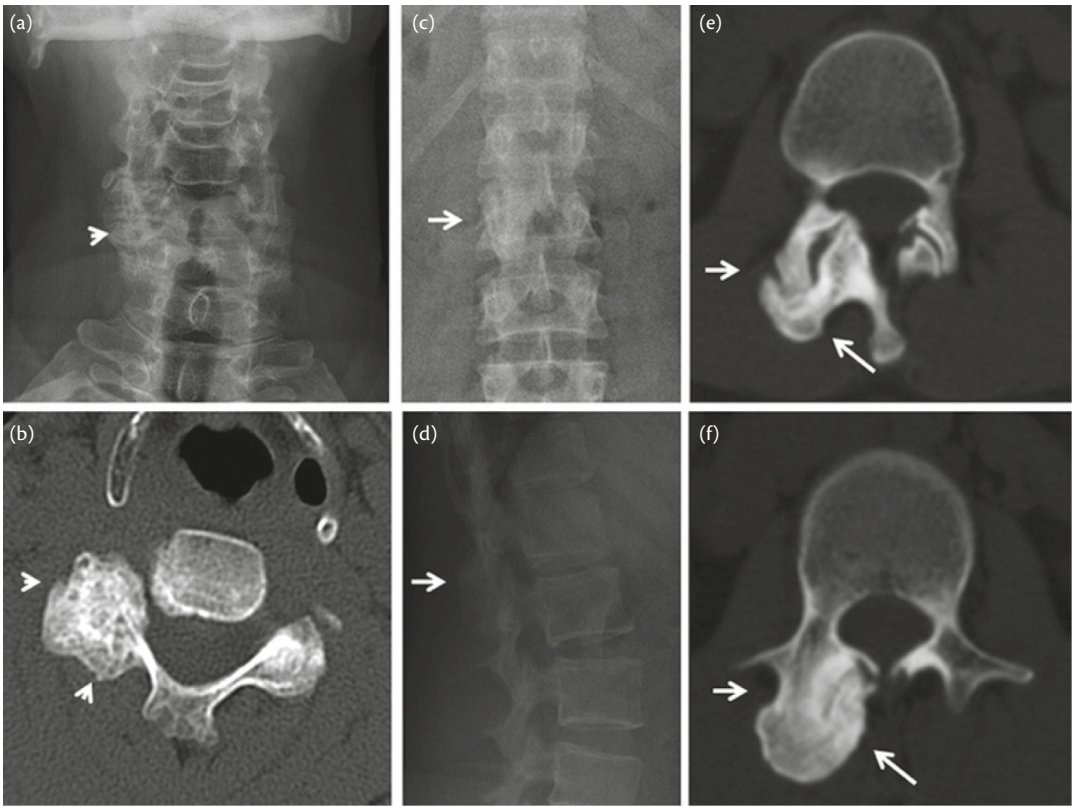

Fig. 63.10 Two different patients with osteochondromas of the spine. First patient: a 45-year-old man with an osteochondroma originating from the right C5–C6 facet joint. (A) Anteroposterior (AP) cervical X-ray; (B) axial computed tomography (CT) scan demonstrates a well-defined bone forming a tumour with lobulated contours (arrowheads). Second patient: a 36-year-old woman with back pain. (C, D) AP and lateral X-rays; (E, F) axial CT scan shows similar imaging findings at the right superior articular process of L2 vertebra (arrows) (see Anderson and Smith, 2013).

Fig. 63.11 Multiple myeloma. Sagittal images of the lumbar spine in (A) T1-weighted and (B) T2-weighted, show similar, variegated areas of abnormal signal intensity throughout the marrow of the lower thoracic and lumbar spine.

radiotherapy compared with radiotherapy alone as a treatment for MSCC had found no difference in neurological outcome between the groups (Young et al., 1980). A contemporary estimate of laminectomy morbidity of 10% together with awareness of the inefficacy of laminectomy at treating ventral cord compression from vertebral body collapse led to a surgical approach to MSCC being abandoned in favour of radiotherapy alone. Radiotherapy is efficacious in the treatment of MSCC and, for example, in one large study (Maranzano and Latini, 1995), all but 2 of 109 walkers retained the ability and of 82 patients who had lost the ability to walk but had some preserved power, 60% recovered ambulation.

Patchell et al. (2005) reported a randomized controlled trial of 101 patients with MSCC with 50 patients randomized to receive surgery followed by radiotherapy and 51 to receive radiotherapy alone. The trial was stopped early after an interim analysis. The primary outcome was ambulation and 84% of the surgical group were able to walk after treatment compared to 57% after radiotherapy alone. The study also showed a significant advantage of surgery in terms of duration of ambulation, recovery of ambulation for those patients who had lost the ability to walk preoperatively, post-treatment continence, and survival. While the evidence appears to be overwhelmingly in support of the statement that surgical treatment of MSCC has more to offer patients than radiotherapy alone, it is not unbalanced in the literature and in a larger but retrospective matched pair analysis, no significant benefit of surgery over radiotherapy alone was demonstrated (Rades et al., 2010).

If we accept that surgery does have a potential benefit over radiotherapy alone, this is not to say that all patients with MSCC should

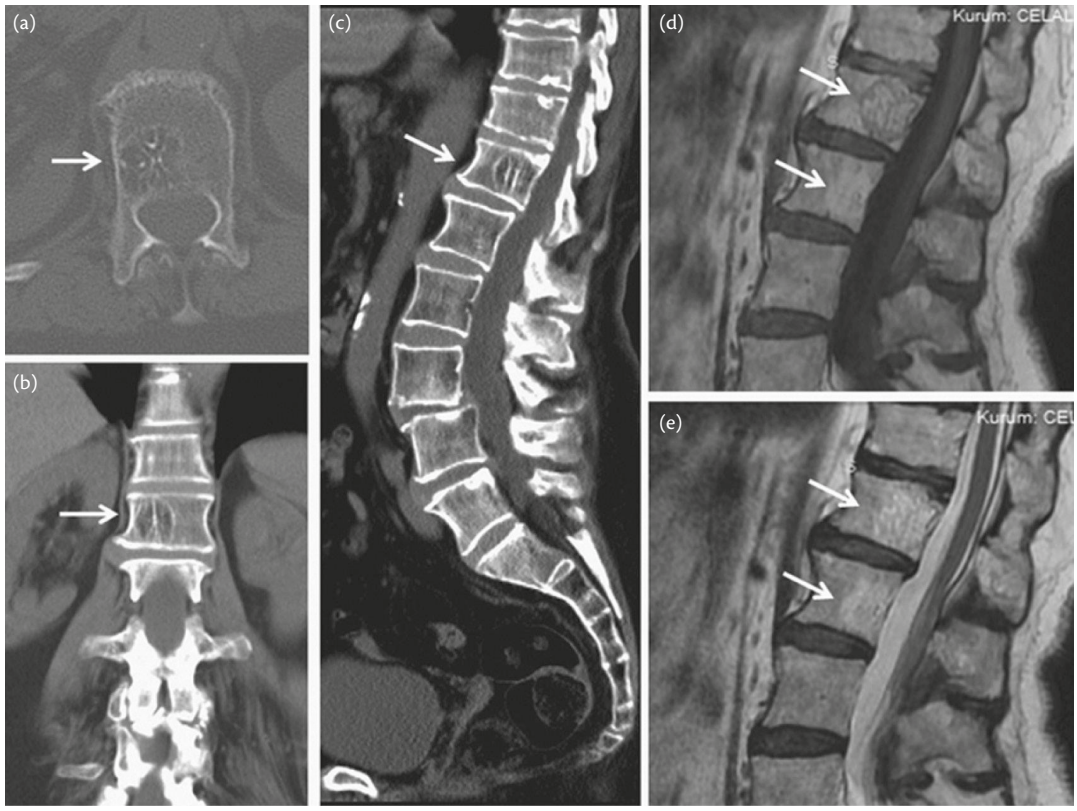

Fig. 63.12 Haemangioma. (A) Axial computed tomography (CT) scan image showing multiple punctate areas of sclerosis creating the white polka-dot sign. (B) Coronal and (C) sagittal reconstructed CT images displaying prominent vertical trabecula of corpus of the D12 vertebra resembling a honeycomb and forming the 'corduroy' sign. (D) Sagittal T1-weighted and (E) sagittal T2-weighted magnetic resonance images demonstrating two haemangiomas at the D12 and L1 vertebrae with high signal intensity (arrows).

be treated surgically. In the index study (Patchell et al., 2005), it took over 10 years to recruit the 101 patients from 7 neuro-oncology centres. This should perhaps be considered as surprising for a condition with an incidence of 5–8/100 000 (Loblaw et al., 2003) and suggests selection bias, and therefore that the treatment may be applicable to a small subgroup of patients with MSCC. Among 903 patients referred acutely for treatment for MSCC in a region of Norway during an 18-month period, only 58 (6.4%) were treated surgically (Zaikova et al., 2011).

It is thus likely then that the patients to whom the studies on the surgical treatment of MSCC apply represent a small subgroup. Anterior thoracolumbar spinal decompression and reconstruction is major surgery with reported complication rates as high as 52% and mortality as high as 13% (Dunning et al., 2012) and perhaps poorly

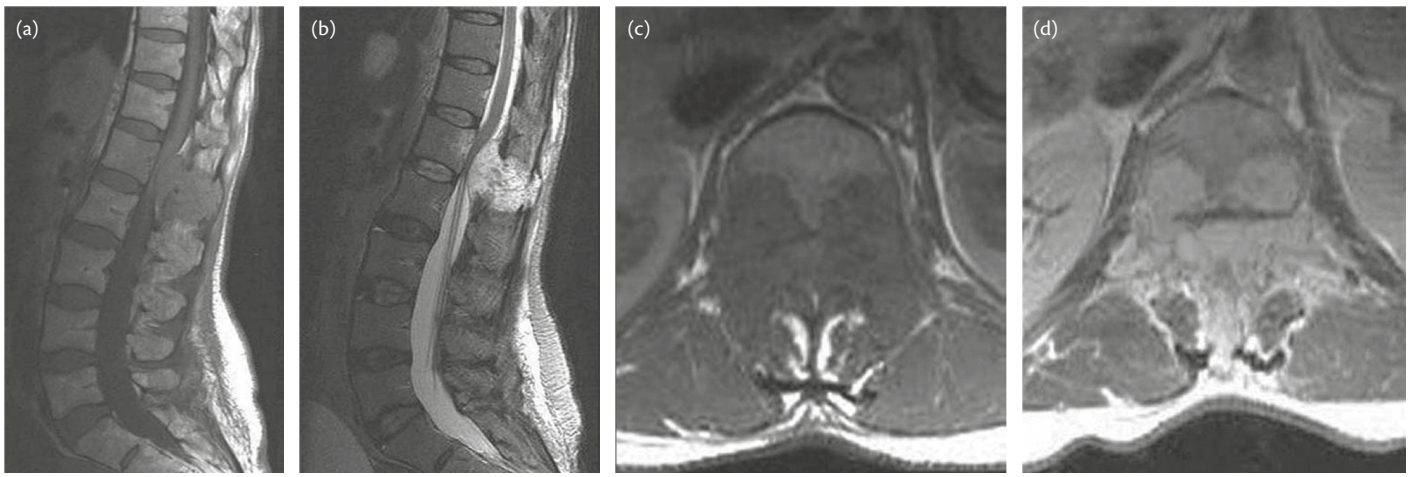

Fig. 63.13 Haemangioma. Exophytic mass affecting posterior aspect of vertebral bodies and posterior elements is shown on T1 (A) and T2 (B) sagittal MRI (arrows). Axial MRI before (C) and after (D) contrast show intense enhancement of the haemangioma with substantial compression of the thecal sac (arrows).

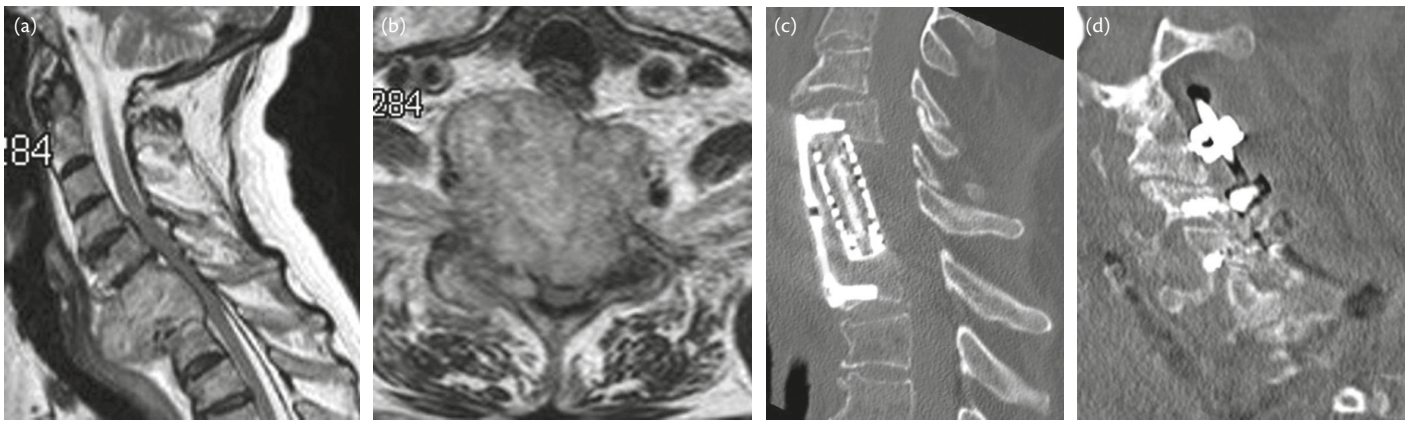

Fig. 63.14 This patient presented with progressive difficulty ambulating over a few days. They were found to have a destructive cervical lesion with cord compression on MRI, the patient was diagnosed with metastatic breast cancer at this primary presentation. She underwent a two-level vertebrectomy, followed by a posterior approach for instrumentation from C4 to T1.

suited to patients in the terminal phase of their disease. Recovery from anterior spinal surgery can be expected to last 3 months with persistent restriction of physical activity advised for as long as 6 months and symptomatic improvement possible over 18 months postoperatively (RNOH, 2018). Taken as a whole, patients with MSCC have a poor prognosis and in a population-based study, 74% had died within 3 months of admission (McLinton and Hutchison, 2006). For those patients with prognoses at or close to the anticipated rehabilitation period for the procedure, surgery is extremely unlikely to be of benefit. It is also worth noting that a subgroup analysis of the Patchell study demonstrated that the beneficial effect of surgery over radiotherapy alone is lost for patients above the age of 65 (Chi et al., 2009).

Those involved in the surgical treatment of MSCC should, while aware of the potential benefit that such therapy can bring to their patients, expect it to be applicable to only a very small proportion of patients with the condition.

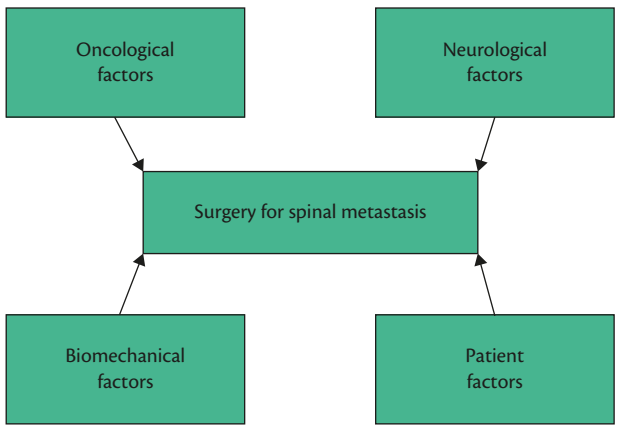

Fig. 63.15 Illustration of the many factors to be considered when advising a patient with spinal metastatic malignancy about surgical intervention.

Vascular lesions of the spinal cord

Daniel Walsh

The normal vascular anatomy of the spinal cord

Arterial supply

The spinal cord is irrigated by perforating arteries which arise from a single ventral arterial axis—the anterior spinal artery (ASA)—and two dorsal arterial axes—the posterior spinal arteries (PSA). Branches of the radicular arteries reach the cord by following the dorsal and ventral roots. The anterior axis lies within the ventral spinal cleft and forms from a series of radiculomedullary arteries, while the posterior form from radiculopial vessels.

Embryogenesis

These ventral and dorsal axes themselves develop *in-utero* as paired metameric arteries. From the sixth week to the fourth month of intrauterine life fusion occurs of the anterior metameric pairs ultimately forming the ASA. Simultaneously *desegmentation* occurs with involution of many metameric arteries. Of 62 metameric vessels (31 dorsal and 31 ventral) 4–8 remain ventrally and 10–20 persist dorsally (Lasjaunias et al., 2001).

The anterior spinal axis is established first and the posterior axes mature later at approximately 15–20 weeks of fetal development. Failure of fusion accounts for the occasional fenestrations seen in the ASA.

There is great variability in the degree to which anterior metameric arteries regress, but two relatively constant remnants are named.

The artery of the lumbar enlargement (also known as the artery of *Adamkiewicz* or *arteria radciularis magna*) most often arises from the left side. In 75% of cases it arises between T9 and T12. When it arises outside of that area there is usually a second large, persisting metameric artery to be found cranially or caudally.

The artery of the cervical enlargement is reliably identified entering the C5/6 level and arises from thyrocervical and costocervical trunks. Variation is again frequent, and its direct origin from the subclavian artery has also been described (Miller, 1993).

The radicular arteries

The intrinsic supply is derived from extrinsic supply formed by each radicular artery. They reliably give radiculospinal and radiculomeningeal branches. At each level, the radiculospinal branch may divide into anterior and posterior branches entering the spinal canal with the corresponding nerve roots.

This extrinsic arterial supply is relatively well collateralized, particularly in the cervical region. Occlusion of the costocervical artery is relatively unlikely to result in anterior spinal infarction, as the deep and ascending cervical arteries will collateralize the anterior spinal axis.

The radiculomeningeal branches supply the nerve root's dural sheath and contents but do not reach the spinal cord. It is from these arteries that spinal dural arteriovenous fistulae recruit arterial supply. It is the radiculospinal branches that contribute to the intrinsic supply of the cord and from which spinal cord arteriovenous malformations and perimedullary arteriovenous fistulas recruit supply.

Arriving at the cord each radiculospinal artery contributes to the posterior and/or anterior axes via radiculopial or radiculomedullary arteries, respectively (**Fig. 64.1**).

Radiculopial arteries

The terminal branches of the radicular arteries, reaching the pia via the spinal root, form PSA. Those branches reaching the cord are termed *radiculopial* arteries and they invade the cord from the pial surface and supply the peripheral parts of the cord with a watershed region at the interface between the white and grey matter. Small branches from radiculopial and radiculomedullary systems run on the pial surface and encircle the cord. These are referred to as *vasa coronae.* These give perforating vessels into the superficial white matter of the cord as well as forming a superficial anastomosis with the anterior circulation.

Radiculomedullary arteries

The anterior axis irrigates most of the anterior grey matter of the spinal cord via radial branches of the radiculomedullary vessels as well as the anterior part of the posterior grey matter and elements of the anterior, lateral, and posterior white columns. Each radiculomedullary artery contributes a superior and inferior ramus to form the anterior arterial axis. *Sulco-commissural* arteries penetrate the cord via the ventral commissure in turn giving rise to the radially directed perforating vessels, which irrigate the cord.

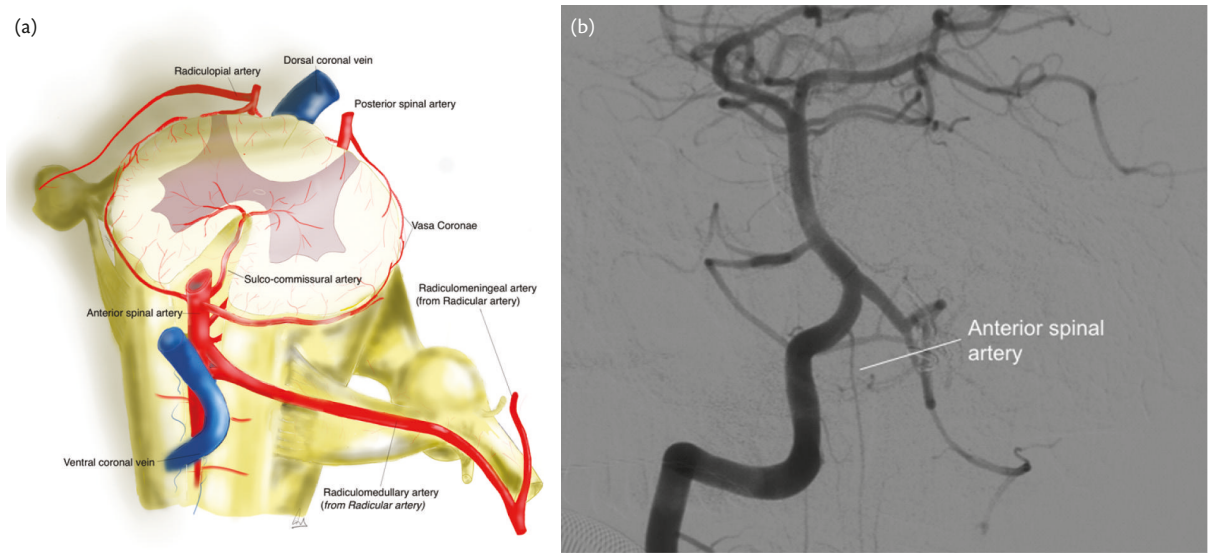

Fig. 64.1 (A) Line drawing of anterior and posterior arterial axes; (B) spinal angiogram (right vertebral artery injection).

Arterial anastomoses and the 'conus basket'

The vasa coronae and radial perforating vessels form longitudinal and segmental anastomoses along the cord. The relative contributions by the radiculopial and radiculomedullary systems vary. The cervical cord is evenly served while radiculopial vessels irrigate the thoracic cord proportionally more and less reliably although the well-known vulnerability of the thoracic cord to ischaemia may also be a function of its venous drainage as discussed next. The lumbosacral segments rely mainly on the central radiculomedullary system (Hassler, 1966).

There is an especially well-developed anastomotic channel between anterior and posterior arterial axes at the level of the conus medullaris. This is referred to as the *conus basket* (Lasjaunias et al., 2001). The ASA tapers as it runs down the anterior surface of the conus and one to two branches join it to the PSA (Martirosyan et al., 2015). The artery of the filum terminale is the terminal continuation of the anterior axis below the conus.

Venous drainage

The cord blood drains primarily via a dorsally and ventrally located coronal venous plexus each draining venous capillary networks along the length of the cord. Thron described larger veins traversing the thoracic cord particularly and facilitating communication between ventral and dorsal collectors. This results in relatively redundant venous drainage capacity in the thoracic cord perhaps rendering it vulnerable to congestion (Thron, 1988).

Spinal angiography

Catheter spinal angiography remains the gold standard for the assessment of structural vascular pathology. Sequential catheterization of each segmental arterial supply to the cord together with examination of the circle of Willis and medial sacral arteries is required. Access is usually via the femoral arteries, but brachial access may facilitate examination of the thoracic and cervical segments in the presence of severe aortoiliac disease.

A full angiographic interrogation of the cord is therefore a relatively prolonged process and may require staging or general anaesthesia to ensure the patient remains comfortable and still throughout. Physiological movement (e.g. respiration and peristalsis) may degrade imaging and are more easily controlled under general anaesthesia. Staging of the examination also allows the radiation exposure to be fractionated and the contrast load aliquoted.

At our institution specific cross-sectional imaging in the form of MR spinal angiography or CT angiography is utilized to allow targeting of catheter spinal angiography (Zampakis et al., 2006; Amarouche et al., 2015).

Neurological complications of spinal angiography are rare in experienced hands despite its technically demanding nature and that it is carried out far less frequently than cerebral angiography (Chen and Gailloud, 2011). Non-neurological complications that have been described included vascular injury, retroperitoneal haematoma, pulmonary oedema, and contrast sensitivity.

The intrinsic vessels of the cord are usually straightforward to distinguish on angiography. The veins are characteristically sinusoidal and centrally located while the arteries are straighter and the radiculomedullary vessels terminate in a characteristic 'hair-pin' morphology.

Spontaneous spinal haemorrhage

Spontaneous epidural spinal haemorrhage (SESH)

Spontaneous spinal epidural haemorrhages that are not associated with structural vascular lesions are usually the result of anticoagulant use. Such haemorrhage is responsible for up to 11.8% of non-traumatic spinal cord injury (Citterio et al., 2004). It is not presently known how the introduction of novel oral anticoagulants (NOACs) will affect its incidence.

In a systematic review of 553 reported patients with spontaneous central nervous system (CNS) haemorrhage, SESH patients were significantly younger. Some 88% underwent surgical decompression

with death and good recoveries each accounting for 21% of outcomes in an admittedly small cohort. The same authors conducted a post-mortem examination which did not identify any different cellular inflammatory responses from traumatic spinal cord injuries and suggest therefore that lessons in spinal cord protection learned from trauma can be usefully applied in SESH (Furlan et al., 2012).

Spinal aneurysm and spinal subarachnoid haemorrhage

Between 0.6 and 1% of intracranial subarachnoid haemorrhage may be caused by spinal pathology and in most of these cases a spinal vascular malformation or cavernoma is the culprit. Isolated saccular aneurysms of spinal arteries are exceptionally rare causes of subarachnoid haemorrhage (Handa et al., 1992; Massand et al., 2005).

Aneurysms of the PSAs appear to be rarer and more likely to be idiopathic. ASA aneurysms have been reported in association with mycotic infection, rheumatoid arthritis, fibromuscular dysplasia, and Behcet's disease. Most aneurysms reported have been successfully surgically treated. One case in a patient with Behcet's disease involuted with expectant management (Geibprasert et al., 2010).

There are case reports of spinal subarachnoid haemorrhage occurring in association with a variety of intradural tumours most commonly schwannomas, ependymomas, and haemangioblastomas.

Ischaemic myelopathy

Spinal cord infarction is rare and typically complicates aortic surgery or severe atherosclerotic aortic disease. Maintaining spinal cord blood flow greater than 10 ml/100 g/min (Gharagozloo et al., 1998) markedly reduces cord ischaemia during aortic cross clamping and this has led to interest in manipulating intrathecal cerebrospinal fluid pressure to potentiate the spinal cord perfusion pressure (SCPP). Animal experimental models demonstrated significant improvement in SCPP if CSF drainage was carried out before cross clamping (McCullough et al., 1988) and some have adopted it during repair of thoraco-abdominal aneurysms.

Chronic ischaemic myelopathy is most commonly encountered when caused by an arteriovenous fistula. Arterialization of the venous drainage from the cord is believed to sufficiently impair gas-transfer across the cord such that cell injury and eventually death is the result. Spinal dural arteriovenous fistula is the usual culprit but spinal vascular malformations with different architectures may also produce ischaemia.

Signs and symptoms of ischaemic myelopathy

The onset of symptoms is often insidious and delay in diagnosis common. In this author's personal series of spinal dural arteriovenous fistula (SDAVF) the median duration of symptoms before diagnosis is 18 months. Patients are more frequently male (1:1.5 ratio) and in the sixth and seventh decades of their life.

Motor and sensory symptoms tend to develop in tandem. Patients describe altered sensation and frequently a sensation of 'something crawling under the skin'. A sensory level in the later stages will be discerned. Sensory alteration typically begins distally and ascends to affect the trunk. Pain may occur mimicking lumbar radiculopathy and symptoms often deteriorate with exertion (Jellema et al., 2003). Gait disturbance has been reported to develop in between 20 to 69% of patients (Atkinson et al., 2001). Mixed upper- and lower-motor neurone findings as well as impairment of proprioception are typical. Sphincteric and sexual functions are frequently affected and are the symptoms least likely to recover after successful treatment.

A high index of clinical suspicion is necessary to prompt timely investigation and treatment. Arteriovenous shunts producing cervical cord ischaemia are relatively rare and, in our experience, more likely to be caused by Cognard type V cranial dural arteriovenous fistulae. A thorough angiographic examination of the circle of Willis and the external carotid circulation is therefore necessary in such a case.

Investigation

The appearances of cord ischaemia alone are compatible with a wide range of differential diagnoses. Where no structural vascular abnormality can be identified it is appropriate to screen for potential neuro-inflammatory and neoplastic causes and the investigation of these lies outside the scope of this chapter.

MR usually suggests the diagnosis with congestion of the cord manifesting with apparent increased volume. The middle and lower thoracic segments are affected most often and oedema of the conus medullaris observed in most cases (Muralidharan et al., 2013). There is centrally increased T2 signal and a ring of relatively low intensity peripherally thought to reflect the presence of deoxygenated blood in cord capillaries (Gilbertson et al., 1976). Where there is an associated arteriovenous shunt, the dilated coronal venous plexuses may be seen on the cord as multiple small flow voids. When prominent these make the MR appearance of a spinal dural arteriovenous fistula pathognomic (**Fig. 64.2**A). Pial shunts may mimic this appearance too although these tend to be given away by the presence of more dense conglomerations of arterialized vessels near the surface of the cord.

MR and CT angiography have both been used to characterize the architecture of spinal dural arteriovenous fistulae. Time-resolved imaging contrast kinetics MR angiography is used in our department to estimate the level of the fistula and targeted catheter angiography is carried out at that level and the immediately adjacent segments to confirm the presence of the fistula and determine if there are significant metameric arteries nearby. It does not provide particularly useful information on the architecture of polyfistulous lesions or parenchymal arteriovenous malformations in which cases catheter angiography is preferred as the index vascular imaging (Amarouche et al., 2015).

Two-dimensional (2D) angiotomography is helpful when planning surgery to lesions with complex architectures. Cross-sectional images are acquired during microcatheter angiography and allow resolution of the arterial and venous phases of the malformation while relating that to the nervous and bony structures. An example is shown in **Figure 64.3**B where the relationship of the spinal vascular malformation to the conus medullaris is better demonstrated than on axial MR or conventional angiography. This facilitated planning of the surgical approach in the illustrative case where the anatomy of the scoliotic spine was complex.

Spinal vascular malformations

In this section we will examine structural vascular malformations in more detail considering their angio-architectures, classification, and

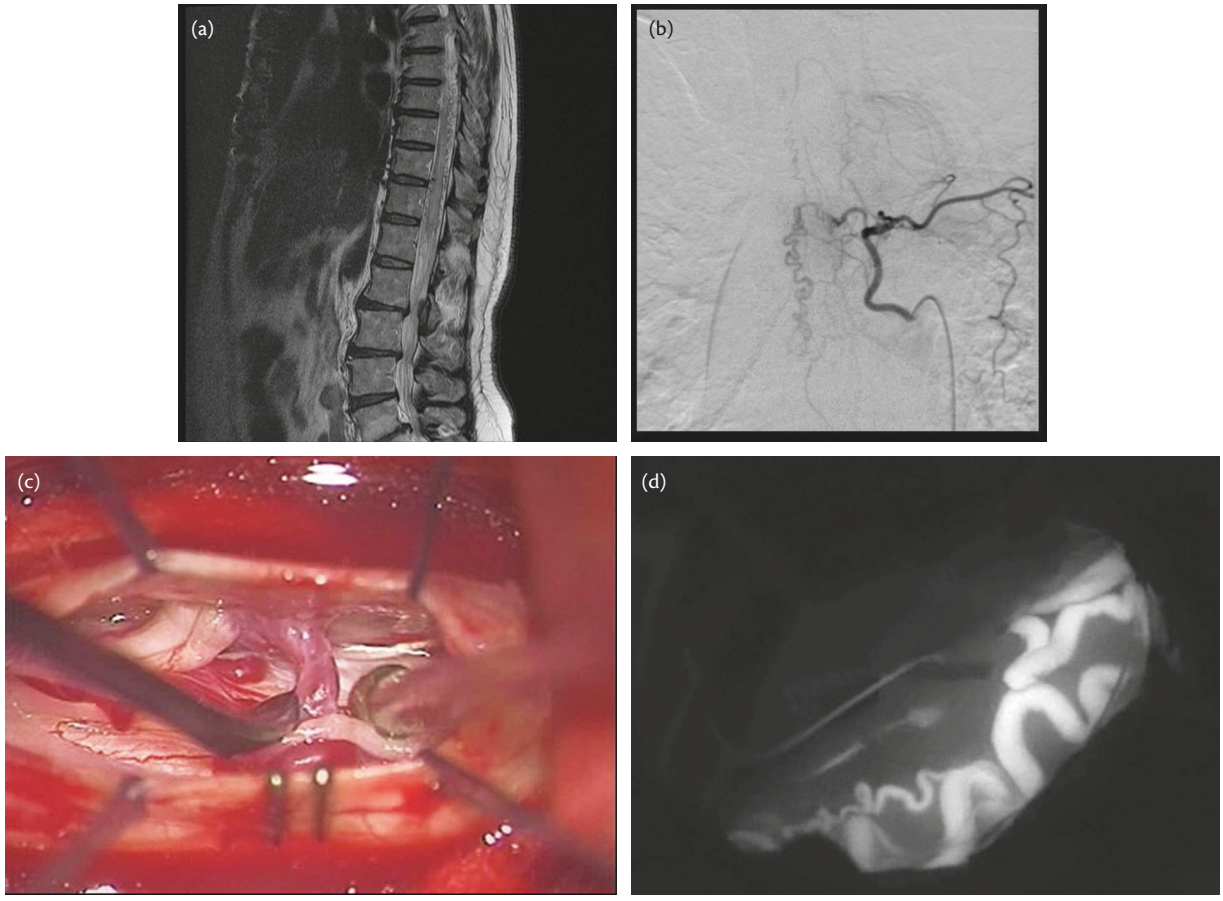

Fig. 64.2 (A) MRI of patient with spinal dural arteriovenous fistula (SDAVF); (B) angiographic appearance of SDAVF; (C) fistulous vessel draining from dural leaflet to coronal venous plexus of cord; (D) ICG-videoangiogram illustrating arterialization of dorsal coronal vein.

clinical associations. Understanding the architecture of a spinal vascular malformation (SVM) is an important step towards treating it.

Classification systems

Classification systems have proliferated over the years and the subject is intimidating when first approached. In truth there is still no universally agreed system of describing SVM and one regularly encounters lesions where there is some disagreement as to the correct terminology. Surgeons have historically tended to favour anatomically based systems while radiologists concentrate on the haemodynamics and aetiology of the arteriovenous shunt.

Essentially what one requires of a classification system are the answers to three questions:

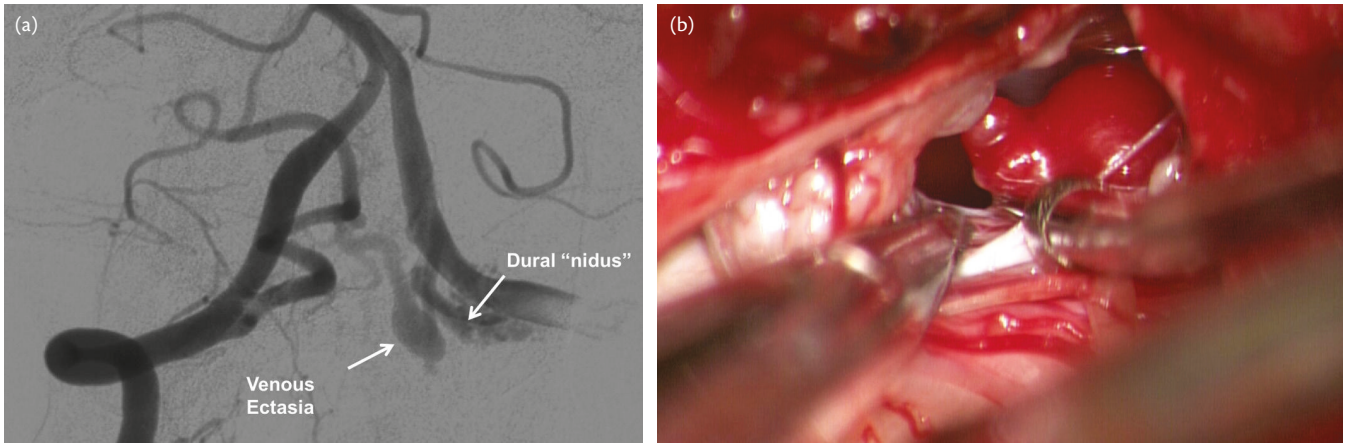

Fig. 64.3 (A) Cervical dural arteriovenous fistula with venous ectasia. This lesion presented after subarachnoid haemorrhage. (B) The venous aneurysm seen via a far-lateral approach.

1. Where is the arteriovenous shunt occurring?
2. How may I reach it?
3. Need I look for coincident pathology?

In 2002 the Hospital Bicêtre proposed a system of attractive simplicity broadly classifying spinal malformations into arteriovenous malformations and arteriovenous fistulae (Rodesch et al., 2002). They proposed assigning arteriovenous fistula (AVFs) and arteriovenous malformation (AVMs) to one of three categories, determined by their pathogenesis:

Group 1: **Genetic hereditary lesions** (e.g. associated with hereditary haemorrhagic telangiectasia)

Group 2: Genetic non-hereditary lesions which share a metameric connection. Hitherto a spinal vascular malformation affecting a variety of tissue types within one metameric segment was referred to as a *juvenile* or *metameric* AVM. Where all the tissues within the metamere were affected it was termed *Cobb's syndrome*. They may be a relatively common cause of myelopathy in CLOVES syndrome (Alomari et al., 2011). Categorization of craniofacial vascular malformations into the *cerebrofacial metameric arteriovenous syndromes (CAMS 1–3)* allows their description according to the metamere affected rather than relying on eponyms such as Wyburn-Mason syndrome or Bonnet-Dechaume-Blanc syndrome. The same system may be applied to the spinal metameres describing SAM types 1 to 31 according to the metamere affected. Polymetameric variants are possible (Bhattacharya et al., 2001).

Group 3: Solitary lesions. It is proposed that lesions in this group may represent the incomplete expression of type 1 and 2 lesions however it could also include acquired lesions meaning that the vast majority of spinal vascular malformations will fall into this latter group. It is useful to subcategorize this group accepting that the type III lesions formerly known as *juvenile* or *metameric* AVMs belong to the Bicêtre Group 2 and that there will be instances where Type IV lesions belong in Group 1 or 2 (e.g. in the *Ras*-opathy described as capillary malformation-AVM syndrome; Eerola et al., 2003; Thiex et al., 2010).

Such a system is useful because it prompts one to consider potential associated lesions with malformation of uncommon architecture or which involve more than one tissue type. For example, recognizing a group 1 lesion should prompt referral for genetic counselling and discussion with the patient regarding the potential pulmonary and central nervous system complications of hereditary haemorrhagic telangectasia (HHT). As originally described paraspinal and dural malformations are excluded, drawing criticism for making the system of limited practical application (Rodesch et al., 2002). We find it practical to include these lesions in the third group. Many paraspinal AVMs might be thought of as incomplete expressions of metameric lesions. There are examples of acquired perimedullary as well as spinal dural fistulae, and they sit comfortably together in the third group.

A system categorizing SVM into groups I-IV has endured through the years and it may be most correctly thought of as an evolving entity contributed to by a large group of clinician-scientists from France, Britain, and the United States. For that reason, some authors refer to an American–British–French connection when describing it (Black, 2006).

Box 64.1 Adapted Bicêtre Classification of Spinal Vascular Malformations

Group 1

Genetic hereditary lesions (e.g. associated with hereditary haemorrhagic telangectasia)

Group 2

Genetic Non-hereditary lesions which share a metameric connection—spinal arteriovenous metameric syndrome (SAMS)

Group 3

Solitary lesions which are acquired or represent incomplete manifestations of group 1 or 2

Paraspinal vascular malformation

Spinal dural arteriovenous fistula

- **a)** Solitary fistula
- **b)** Polyfistulous

Intramedullary AVM

Perimedullary fistula

- **a)** Solitary simple fistula, minimal venous dilation
- **b)** One to two feeding arteries, moderate venous enlargement +/– venous pouch at site of fistula
- **c)** Giant polyfistulous lesions

Reproduced with permission from Rodesch, Georges; Hurth, Michel, Classification of Spinal Cord Arteriovenous Shunts: Proposal for a Reappraisal—The Bicêtre Experience with 155 Consecutive Patients Treated between 1981 and 1999, *Neurosurgery*, Volume 51, Issue 2, pp. 374–80, Copyright © 2002 Oxford University Press and the Congress of Neurological Surgeons (CNS).

Merland proposed a useful subdivision (Gueguen et al., 1987) of the perimedullary fistulae described first by Djindjian (Djindjian et al., 1977). Heros suggested perimedullary fistulae be treated as a discrete Type IV lesion (Heros et al., 1986) while others describe them as fistulous AVMs (fistulous spinal cord arteriovenous malformations or SCAVM) because they are usually supplied mainly by the radiculomedullary arteries, considered part of the intrinsic cord blood supply.

It is perhaps best not to cling tightly to one nomenclature. Subdivisions emerge and lesions once believed distinct are discovered to have more in common than was previously understood. The remainder of this chapter utilizes the adaptation of the Bicêtre system described earlier (**Box 64.1**). The American–British–French system is summarized in **Table 64.1**. Thorough appreciation of the angio-architecture is possibly more important than the nomenclature one then applies.

Extradural (paraspinal) vascular malformations

These are rare lesions with drainage exclusively into the epidural venous plexus. These have been reported occurring autonomously (Willinsky, 1993), as a complication of trauma (Johnson et al., 1990) or in neurofibromatosis type 1 (Deans et al., 1982; Benndorf et al., 2000). These may also constitute an incomplete expression of a genetic, non-hereditary malformation as suggested by the Bicêtre group (see earlier).

Asymptomatic paraspinal malformations are occasionally encountered incidentally on cross-sectional imaging. Depending on the degree of venous engorgement they may produce symptoms when they compress the thecal sac or the nerve roots. **Figure 64.4** illustrates a paraspinal AVF presenting with a severe lumbar

Table 64.1 American–British–French classification of spinal vascular malformations

Type I	Spinal dural arteriovenous fistula • Solitary fistula • Polyfistulous
Type II	Intramedullary AVM
Type III	Juvenile or Metameric AVM (SAMS)
Type IV	Perimedullary fistula • Solitary simple fistula, minimal venous dilation • 1–2 feeding arteries, moderate venous enlargement +/– venous pouch at site of fistula • Giant polyfistulous lesions

radiculopathy. Embolization of the fistula resulted in rapid and complete resolution of the pain. Reversible myelopathy has also been reported (Willinsky, 1993).

These lesions may also present with spontaneous extradural haematomas particularly in children (Lonjon et al., 1997; Sivakumaran et al., 2016). Such haematomas are thought to result from vascular malformations in 3–18% of cases (Kubo et al., 1984; Graziani et al., 1994).

Treatment is by endovascular or surgical means and based on published case reports outcomes are usually good for symptomatic lesions.

Spinal dural arteriovenous fistulae

SDAVF account for 70–85% of vascular malformations presenting in clinical practice (Merland et al., 1980; Symon et al., 1984) and occur up to five times more frequently in males. Symptoms typically develop after the fifth decade of life. This is in contrast to other varieties of SVM which present earlier in life, usually the third and fourth decades (Djindjian et al., 1977; Rosenblum et al., 1987). SDAVF are believed to be acquired lesions although their pathogenesis is not understood.

The most common location of the fistula is in the thoracic spine. In our series this accounts for 68.5% of cases. Cervical and sacral lesions are rare accounting for less than 5% each and lumbar cases constitute 21%. Multiple fistulae have an estimated incidence of 2% (Krings et al., 2004).

Fistulation occurs within the dural leaflet near the exiting spinal nerve root. This is near where a vein normally drains blood from the radiculomeningeal artery supplying the nerve sheath and its contents. This vein becomes arterialized and is readily recognized as it penetrates the dura just caudal to the exiting nerve root. The vein typically enters directly beneath the vertebral pedicle. Careful inspection of the inside of the dura as the vein pierces it will reveal prominent arteries within feeding the fistula. Disconnection of the vein at this point will obliterate the arteriovenous shunt. Excision of the dura itself is not required to treat the fistula.

The arterialized vein connects directly to the coronal venous plexus causing congestion as described in the section on ischaemic myelopathy. Subarachnoid haemorrhage from spinal dural arteriovenous fistulae is extremely rare but has been most often reported in association with fistulae of the cervical canal. Cases of haemorrhage from lumbar and thoracic fistula have also been seen (Koch et al., 2004). Venous aneurysm and varicosity appear common in such instances.

Microsurgical treatment

The fistula is typically exposed intradurally via a (hemi)laminectomy or laminotomy. Tubular retraction systems and fibreoptic lighting allow minimally invasive approaches to be employed. The fistulous vein is identified entering the dura, diathermied, and then cut with fulguration of dura around the entry point. Extradural diathermy (or embolization) of arterial feeding vessels alone may result in transient improvement but are bound to result in the recruitment of other dural arterial vessels and recurrence of the fistula.

While arterialized the veins of the dorsal coronal plexus are engorged and slightly pink. When the shunt is closed these veins collapse and the pia-arachnoid around them becomes crenulated. This change is not always obvious to the naked eye in relatively low-flow arteriovenous shunts. Microdoppler examination (Iacopino et al., 2001) or indocyanine green videoangiography (ICG-VA) may be used to confirm normalization of flow in the vein. ICG-VA is also useful in detecting metameric vessels and distinguishing them from arterialized veins (Walsh et al., 2013). **Figures 64.2**A–D illustrate the change in flow observed on ICG-VA as the fistula is occluded.

Currently microsurgical division of the fistula is the criterion standard. A recent meta-analysis of the English Language literature

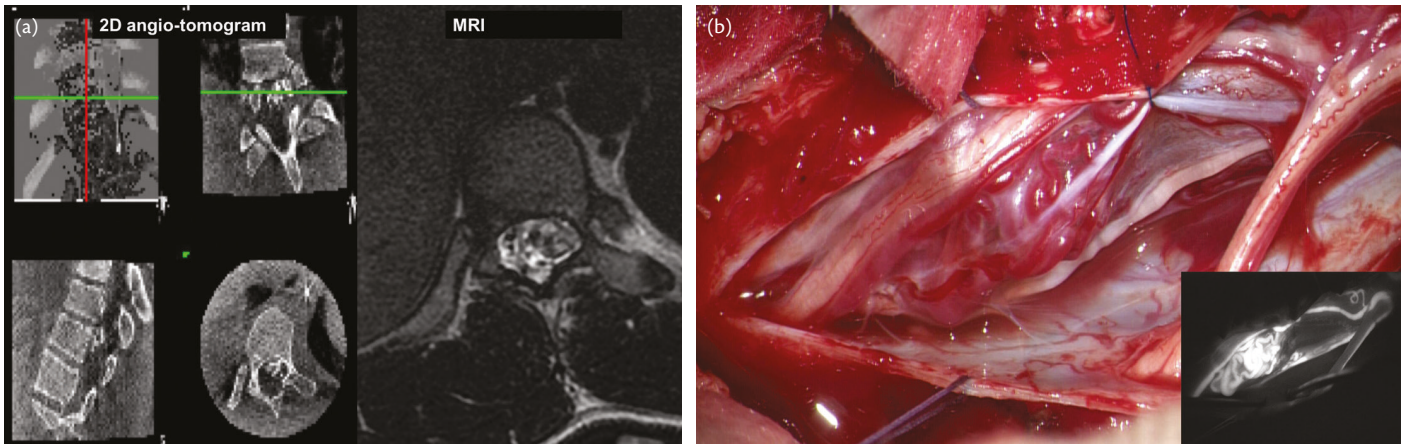

Fig. 64.4 (A) Two-dimensional (2D) angiotomograms demonstrating a compact intramedullary AVM at ventrolateral surface of conus; (B) operative view after costotransversecomy.

from 2004 onwards included 35 studies with 1112 patients. Surgery obliterated 96.6% (94.8–97.8% 95% CI) of fistulae. Endovascular treatment with N-butyl-cyanoacrylate (NBCA) glue or Onyx obliterated 72.2% (95% CI 68.1–75.9%). Late recurrence of the fistula was significantly more likely with endovascular treatment (Bakker et al., 2015).

Procedural complication rates also compare favourably. In the meta-analysis conducted by Steinmetz and colleagues a rate of 1.9% was reported for surgery and 3.7% for endovascular treatment. Both treatments are relatively safe and most morbidity minor. The 'point' disconnection possible at operation means there is little risk to the coronal vein itself.

A significant risk in surgical treatment is that the incorrect spinal level be approached. This risk is mitigated by the careful use of fluoroscopy. The deposition of an endovascular coil (Britz et al., 2004) or glue (Timo Krings et al., 2010) in the radiculomeningeal vessel aids identification of the level intraoperatively.

Endovascular treatment

To effect cure an embolic agent must reach the proximal part of the draining vein piercing the dura, replicating the 'point' disconnection of the arteriovenous shunt described earlier. Particle and coil embolization of arterial supply of the arterial inflow alone will not produce a lasting result. Liquid embolic agents such as Onyx or NCBA penetrate to the draining vein effectively when delivered transarterially. If, on control angiography, the agent has not reached the draining vein then further treatment will be required. This further procedure should not be delayed in hopes the fistula will spontaneously thrombose despite a patent draining vein. Further clinical deterioration has been described in such cases (Andres et al., 2008).

Cure rates are significantly lower than with surgical division. Some authors advocate a tentative attempt at embolization at the time of diagnostic angiography. Such a protocol should inform the patient of the small risk of retrograde coronal vein thrombosis which can result in neurological deterioration.

Treatment outcomes for SDAVF

The outcome from endovascular and surgical treatments of SDAVF are similar so long as the arteriovenous shunt is abolished. Aminoff and Logue (1974) graded deficits in the patients gait and control of micturition (Table 64.2) and this system is still commonly used to report treatment outcomes.

In a series of 154 patients treated surgically 45% of patients reported improved lower extremity strength at discharge. Some 12% reported improvement in sensation and 15% in sphincter control, while 17% reported worsened sphincter control at discharge. The majority of patients were unchanged in the short term by treatment. Utilizing the combined Aminoff-Logue gait and micturition scores as a composite index of disability, 45% of patients were found to have improved at a mean duration of follow-up of 31 months, while 34% remained at their preoperative baseline (Bakker et al., 2015). Sphincter dysfunction has an unfavourable prognosis. Steinmetz found approximately 33% of patients reported any improvement in sphincter function with 11% worsened in the longer term despite 89% of patients improving or stabilizing overall (Steinmetz et al., 2004).

Table 64.2 Aminoff-Logue grading system

Grade	Definition
Gait	
0	Normal
1	Leg weakness, abnormal gait, or stance without limitation of activity
2	Restricted activity
3	Requires one stick or similar support
4	Requires crutches or two sticks to walk
5	Unable to stand, bed-bound, or in a wheelchair
Micturition	
0	Normal
1	Hesitancy, frequency, or urgency
2	Occasional incontinence or retention
3	Permanent urinary incontinence or retention

Intramedullary arteriovenous malformations

Spinal cord arteriovenous malformations (SCAVM) are formed by shunts from the intrinsic arterial supply of the cord to its venous drainage. Some distinguish the *glomus* (or *nidal*) variety from *fistulous* AVM. Glomus (nidal) AVMs have a discrete nidus deep to the pia and are architecturally homologous to cerebral AVMs. These may be described as compact, diffuse, or of mixed types. We will consider fistulous lesions as a separate entity—perimedullary fistula (PMAVF). This distinction in the literature is confusing but illustrates the difficulty sometimes in appreciating a nidus when there is congestion of the various veno-venous and other physiological anastomoses in the cord.

These lesions may also be subdivided into 'high' and 'low' flow lesions. High-flow lesions are characterized by the remodelling of vessels: hypertrophy of arteries, and development of aneurysms and venous pouches. They are more often seen in children and patients with HHT. In their review of 155 patients, Rodesch and colleagues noted 31.6% incidence of arterial aneurysm (Rodesch et al., 2002).

Such vascular stress is associated with an increase in intramedullary or subarachnoid haemorrhage. They may also present with ischaemic myelopathy or symptoms resulting from neural compression by dilated vessels. Neuropathic pain is reported in about 30% of patients.

The natural history of incidentally discovered lesions is not known with any certainty. A pooled analysis of studies containing greater than three cases suggested an annual haemorrhage rate of 4% with approximately half these lesions first presenting with a haemorrhage. These same data showed partial treatment mitigated the risk somewhat with a recurrent rate of haemorrhage for partially treated lesions of 2–3% across all modalities (Gross and Du, 2013a).

Endovascular treatment

Endovascular treatment has an important place in the management of these lesions especially those fed primarily from the ASA. The

goals of treatment may be subtly different to cerebral AVM and there is some evidence that partial treatment may not only alleviate symptoms of ischaemia, mass-effect but may also favourably affect risk of haemorrhage. Onyx or NCBA glue are the most commonly used liquid embolic agents at present when trying to effect nidal penetration. Coils may be used to treat venous pouches, ectasia, and aneurysms.

Given considerable variation in the angio-architectures being treated, treatment outcomes vary and clearly the operator must exercise a great deal of judgement during each procedure to avoid inadvertent migration of embolic materials with resultant ischaemic injury.

In 16 studies containing 104 patients, 33% of treatments with liquid embolic agents resulted in complete obliteration of the shunt (Gross and Du, 2013a). Despite this Aminoff-Logue gait and micturition scores were similar to surgical outcomes at ten years. No re-haemorrhages were recorded in the follow-up periods. Recanalization was significantly more likely after poly-vinyl-alcohol (PVA) particle embolization (17%) compared to Onyx or NCBA glue (0–11%).

Microsurgery

Surgical extirpation is an effective treatment in selected cases, but the morbidity is determined mainly by the location of the malformation and the difficulty accessing it. Spetzler has suggested compact AVMs of the conus medullaris be considered a distinct subtype peculiarly amenable to surgical treatment (Spetzler et al., 2002).

The principles of surgical excision are similar to operating on the cranial homologue but certain nuances of technique merit comment. Firstly, as relatively low-flow lesions they may be advantageously approached from the venous side without the same fear of haemorrhage or congestion in the cord. Secondly excessive pial dissection may be avoided and elements of the shunt are divided 'in-situ' rather than attempting complete extirpation of every component of the malformation. When surgery follows endovascular embolization, it is not necessary to excise completely embolized elements of the malformation when it requires further disturbance of nervous tissue.

Most lesions are approached posteriorly or posterolaterally. Again, we have found 2D angiotomography helpful as an aid to planning the surgical approach and routinely make use of intraoperative neurophysiological monitoring, particularly of Delta waves and motor evoked potentials to detect alterations in the motor tracts anteriorly (**Fig. 64.4**A).

In Gross's analysis extirpation was achieved in 78% of cases. Long-term Aminoff-Logue gait scores were improved or stable in 93% and micturition scores the same or better in 94%. Many of these patients had significant disability however at the preoperative baseline and treatment was prompted by symptoms (Gross and Du, 2013a).

Radiosurgery

Spinal arteriovenous malformations are of such a volume as to be attractive for radiosurgical treatment. They pose challenges not encountered with their cerebral counterparts. Targeting the selected volume with highly conformal radiation while accounting for excursion of the target with respiratory movement is facilitated by modern image guidance systems.

Sinclair et al. reported their experience of treating 15 intradural AVMs using the CyberKnife™ platform. Concerned to avoid cord toxicity treatment was delivered in two to five sessions. Only one malformation was obliterated at a mean of 27.9 months of follow-up. The short follow-up of these lesions limited the conclusions that may be drawn regarding efficacy (Sinclair et al., 2006). Hida et al. reported a 10-year experience with ten patients using LINAC. Complete obliteration was not observed in any patient but with a median of 49 months follow-up, no subsequent haemorrhage was observed nor any radiation toxicity (Hida et al., 2003).

Spinal cord tolerances for radiation are still being explored. The chances of complete obliteration appear very low at present but given that partial treatment can improve outcome with other modalities, radiosurgery for these lesions merits further investigation.

Perimedullary fistula

Perimedullary arteriovenous fistulae (PMAVF) are direct communications between intrinsic arteries on the cord surface with the venous drainage. Usually arising from the anterior arterial axis, radiculopial fistulae are also occasionally encountered. They may be subclassified according to the number of arterial feeders, flow, and size (see **Box 64.1** and **Table 64.1**). In the literature they are sometimes referred to as pial arteriovenous fistulae or fistulous spinal cord AVM (SCAVM).

Most PMAVFs present with ischaemic myelopathy but haemorrhage occurs in about 32% distinguishing their clinical course from SDAVF (Gross and Du, 2013b). They may occur as isolated lesions or in association with genetic disease, for example, HHT (perimedullary macrofistulae) or CM-AVM *Ras*-opathy.

Again, reliable data on natural history are lacking since most of these uncommon lesions are discovered when symptomatic. Data on treatment is limited to relatively small case series although the published results are encouraging with obliteration rates of 93% for type A lesions and 71% for type C. Microsurgical and endovascular treatment are the mainstays of management. Type C lesions are particularly suitable for endovascular treatment as hypertrophied feeding arteries facilitate navigation. Type A and B lesions may be addressed by endovascular, surgical, or combined techniques. At our institution we have usually found PMAVF suitable for surgical treatment where endovascular treatment was not feasible (Amarouche et al., 2015).

There is little experience with radiosurgery in the literature. There is one case reported treated with CyberKnife without any outcome data. It is possible some of the Stanford series (CyberKnife) were fistulous AVMs but detail on all the architectures treated is not provided. We have treated one mid-thoracic, type A PMAVF with CyberKnife without any effect at 18 months' follow-up.

Spinal cavernoma

It may reasonably be argued that cavernomas do not belong in a discussion about vascular cord lesions. They are low-pressure, angiographically occult lesions unless associated with a deep venous anomaly (DVA). The natural history of all cavernomas is poorly understood and this is particularly the case with the rare spinal cavernomas.

The literature consists mostly of operated case series. Treatment is recommended when lesions are symptomatic. The definition of haemorrhage is problematical however in a lesion characterized by slow egress of blood products into surrounding tissues. Should overt haemorrhage be considered a less favourable predictor of subsequent disability than symptomatic microhaemorrhages?

Intramedullary cavernoma

A recent meta-analysis identified 40 studies meeting criteria for analysis and including 632 patients (Badhiwala et al., 2014). Some 376 patients had outcome data reported. The thoracic cord was the most common location accounting for 55.2% of lesions reported followed by the cervical cord (38%), cervicothoracic segments (2.4%), lumbar (2.1%), conus (1.7%), and thoracolumbar (0.6%). The annual rate of haemorrhage was 2.1%. Cerebral cavernomas and multiple cavernomas coexist in approximately 50% of cases.

The authors conclude that surgical intervention for symptomatic lesions is supported by the data. Patients who presented acutely had treatment outcomes superior to those with chronic symptoms. More than 80% of patients undergoing surgery had improved or stable symptoms at final follow-up although early postoperative deterioration was common (27%). While intervention was associated with superior outcomes it should be noted that only 10% of patients in these studies were managed conservatively.

Extradural cavernoma

Extradural spinal cavernomas are rare and occasionally require surgical attention. Purely intraosseous lesions are probably the most common but rarely become symptomatic. Epidural lesions can produce radicular pain and/or myelopathy dependent on their size and location. Surgical resection yields good results in 92% of patients (Mühmer et al., 2014).

Radiosurgery and spinal cavernoma

Surgical extirpation remains the standard of care when intervention is warranted. A single case report describes apparently successful treatment of a paraspinal cavernoma after surgery was abandoned because of bleeding (Sohn et al., 2009). Treatment of an intramedullary, mid-thoracic cavernoma has been described but with only 6 months of follow-up taken as evidence of effect (Martin et al., 2012) there remains little evidence to support such an application.

Spinal cerebrospinal fluid dynamics

Graham Flint

Pathophysiology

The column of CSF within the posterior fossa and spinal canal is subject to arterial pressure waves, about 70 times each minute, generating a 'to-and-fro' movement. It is also subject to venous pressure waves, which are less frequent and irregular in their timing but of greater amplitude, brought on by any Valsalva-like manoeuvre. Venous waves move significant volumes of fluid between the intracranial and intraspinal compartments. During any Valsalva-like manoeuvre the net flow of CSF is from the spinal theca into the head. At the end of Valsalva fluid returns to the spinal canal, distending the thecal sac once more as spinal epidural veins collapse down.

Fluid dynamics are somewhat different if there is a partial obstruction to flow at the craniovertebral junction. Fluid will still flow freely into the head, during coughing, straining, and so on. but will not flow back as readily. Instead, an extra volume of CSF is trapped, temporarily, within the head and, before it is absorbed via the arachnoid granulations, there occurs a period lasting for several seconds, during which the intracranial pressure is high. An accurate history of such pressure dissociation headaches will reveal that they develop not at the time of coughing or straining but immediately afterwards. Likewise, such headaches come on after the affected individual gets up from bending over.

Arterial pressure waves may also exert undesirable effects, if there is obstruction to free movement of CSF along the spinal canal. With normal anatomy the CSF systolic pressure wave is dissipated along the entire spinal canal. If an obstruction exists, part way along the spinal CSF channels, the same amount of energy cannot diffuse as easily and impacts, instead, upon the exterior surface of the spinal cord. Similarly, when herniated cerebellar tonsils 'punch', repeatedly, upon a column of CSF, which is effectively trapped within the spinal canal, the systolic energy waves cannot recoil freely, back into the head.

We may therefore envisage a normal state of anatomy, with rhythmic oscillation of the cerebellar tonsils, brainstem, and spinal cord within a continuous column of CSF, which rocks upwards and downwards in synchrony with the cardiac cycle. During Valsalva, the hindbrain structures will lift up, as CSF passes into the head, only to return when the straining ends. Obstruction to these movements of CSF, anywhere along the spinal canal, can cause significant disturbances of these normal flow patterns, with distortions of the normal pressure waves, generating significant symptoms and, in some cases, progressive anatomical changes.

Clinical investigations

Magnetic resonance imaging (MRI) provides the principal tool for investigating suspected disorders of spinal CSF movement. Ideally imaging should include the whole neuraxis because spinal CSF pathologies may be associated with anatomical abnormalities in the head, or may be manifested by signal changes intracranially. T2 sequences display the normal CSF channels clearly, as well as revealing abnormal accumulations of water. Moreover, a bright white signal indicates stasis of CSF whereas grey 'swirls' display turbulence. It may be difficult, at times, to distinguish presyrinx oedema of the cord from frank cavitation and T1 images my assist here. Oedema caused by an arteriovenous fistula can, potentially, be misdiagnosed as presyrinx oedema. Standard T2 may not reveal arachnoid webs but heavily weighted T2 images may do so. Contrasted scans are needed to exclude associated neoplastic lesions.

Cardiac gated phase contrast flow studies demonstrate 'to-and-fro' movement of CSF with systole and diastole. This can be useful in evaluating anatomically borderline cases of tonsillar descent. Quantitative measurements can be made in terms of volume of flow, which may be reduced, and velocity of flow, which may be increased, if there is a significant impediment to CSF movement.

Upright MRI may demonstrate subtle anatomical movements, occurring with a change from the horizontal to an upright posture. Such findings may suggest obstruction to CSF movement in an anatomically borderline case.

Ultrasonic imaging may be used intraoperatively, to help locate an abnormal collection of CSF within the spinal canal. It may also be used to determine whether an extradural decompression has effectively relieved obstruction to CSF movement at the craniovertebral junction.

Electrophysiological studies may be used as diagnostic aids. Somatosensory evoked potentials (SSEPs) may be abnormal, even when presenting symptoms do not match radiographic findings and when there are no supporting physical signs on clinical examination.

Motor evoked potentials and SSEPs have also been used as an aid for deciding, intraoperatively, whether there is a need to open the dura as part of a craniovertebral decompression.

Syringomyelia

Syringomyelia is the presence of CSF-filled cavities within the spinal cord. These are encountered in many different morphological forms (Fig. 65.1). Some authorities distinguish between hydromyelia and syringomyelia. The former are essentially dilatations of the embryonic central canal and are lined by ependyma. The later develop alongside the central canal and are lined with gliotic tissue. In either case the challenge is to explain just what causes these cavities to from and what determines how large they will become. Most cavities, of any size at least, are likely to be associated with an obstruction, somewhere along the spinal canal, to the normal movement of CSF (Box 65.1). Such obstructions are not always apparent but sequential imaging may reveal the direction in which a cavity is propagating. This will usually be away from the site of obstruction, meaning that the end of the syrinx that 'stays put' is at the site of obstruction to CSF flow.

The epidemiology of syringomyelia is imprecise. Significant geographical and ethnic differences exist and estimates have varied over time, possibly reflecting the changing make-up of populations studied. As working estimates, one may suggest an annual incidence ranging from 0.5 to 1.0 and a prevalence of between 5 and 10, per 10^5 population. Widespread application of MR imaging has led to the detection of more cases, at an earlier stage in their evolution, presenting with much less in the way of neurological disability. More cases of Chiari malformation are now detected, at least half of which do not have associated syringomyelia.

Clinical presentation

The mean age of presentation is the fourth decade of life but with a wide range, from childhood to retirement. Clinical features can be divided into those generated by the underlying pathology and those caused by the cavity itself (Box 65.2).

The classical picture of cape-distribution dissociated sensory loss, clawed and atrophied hands, covered with burns, together with lost

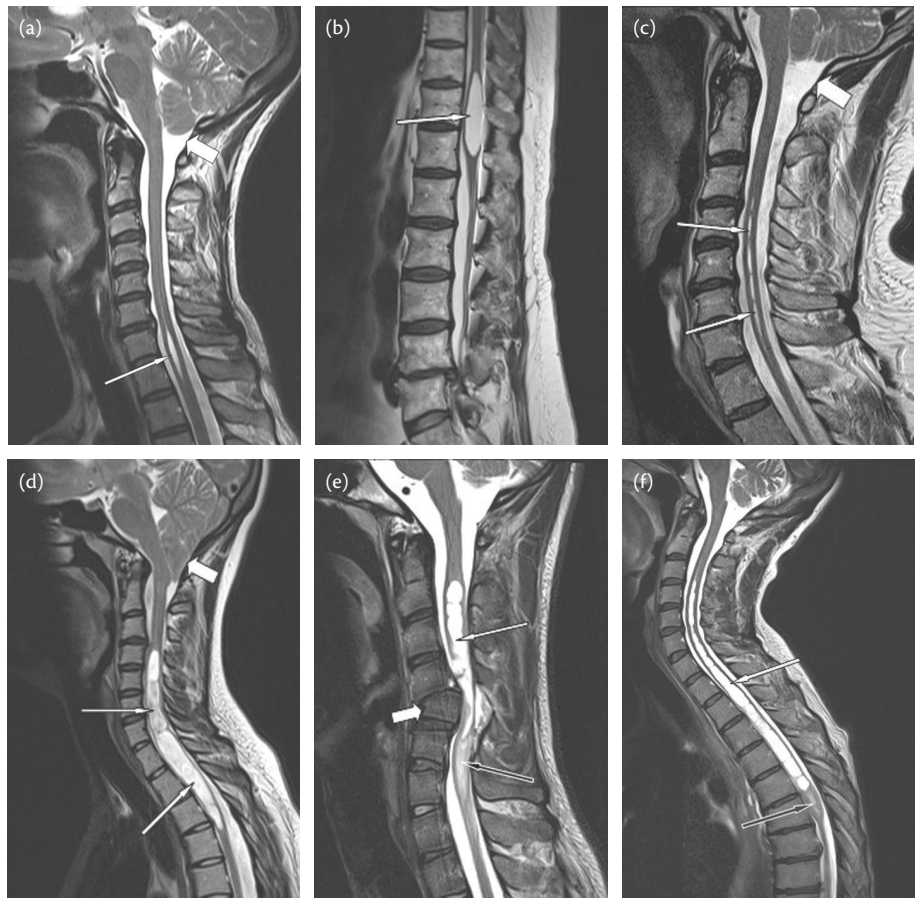

Fig. 65.1 Morphological variants of syringomyelia. T2-weighted MR images illustrating: (A) a spindle-shaped cavity, with pointed ends (long arrow). There is no obstruction to CSF movement along the spinal canal. The cerebellar tonsils are relatively low but not descended through the foramen magnum and the cisterna magna is open (short arrow); some would refer to this as Chiari type 0. (B) A short, plump CSF-filled cavity, with rounded ends (arrow), sometimes referred to as a glioependymal cyst. (C) an abnormally prominent central canal (long arrows) with a widely open cisterna magna (short arrow). (D) A large, tense syrinx (long arrows) resulting from a Chiari type 1 malformation (short arrow). (E) A post-traumatic syrinx cavity (long, white arrow) forming immediately above a C5 vertebral injury (short arrow). Below, the cord has developed presyrinx oedema (long, dark arrow). (F) An extensive syrinx cavity (white arrow), with visible haustrations, that is propagating well above an underlying intramedullary tumour (dark arrow).

Box 65.1 Classification and causes of syringomyelia

Hindbrain related

- Chiari type 1 malformation
  - Congenitally small posterior fossa
  - Craniosynostosis (e.g. Crouzon's)
  - Chronic pressure cone caused by a cerebellar mass
  - Spinal CSF leakage/lumboperitoneal shunt
  - Benign intracranial hypertension
- Chiari type 1.5 ± tethered cord
- Chiari type 2 malformations + open spina bifida
- Basal arachnoid fibrosis (posthaemorrhagic/inflammatory)
- Bone thickening or softening disorders ± basilar invagination (e.g. Paget's, rickets)

Primary spinal pathologies

- Spinal cord injuries *
- Infections—pyogenic or tuberculous *
- Subarachnoid haemorrhage—cranial or spinal *
- Arachnoid cysts or webs
- Intramedullary tumours

* Postinflammatory arachnoid fibrosis is the common element.

Idiopathic—site of obstruction to CSF flow not evident

- Chiari type 0
- Prominent central canal (hydromyelia)
- Isolated 'spindles'
- Glioependymal cysts

Box 65.2 Clinical features of hindbrain related syringomyelia

Local pressure

- Basal dura
  - Occipital headaches
- Neural elements
  - Bulbar/Lower cranial nerves
    - Diplopia/oscillopsia/nystagmus
    - Vertigo/ataxia
    - Tinnitus
    - Facial pain/numbness
    - Dysarthria/dysphonia/dysphagia
    - Sleep apnoea
    - Syncope
  - Long tracts
    - Somatic sensory disturbances
    - Subjective weakness/fatigue

Obstructed CSF flow

- Pressure dissociation headaches
  - Coughing/sneezing
  - Physical straining
  - Bending forwards
  - Blowing up balloons
- Syrinx formation
  - Central grey matter
    - Muscle wasting
    - Clawing of hands
    - Horner's syndrome
    - Scoliosis
  - Long tracts
    - Spinothalamic sensory loss
    - Central neuropathic pain
    - Lower limb spasticity
    - Autonomic disturbances (bladder, bowel, hyperhidrosis)

Occasional presentations include orthostatic hypotension, and various involuntary limb movements, which may mimic extrapyramidal syndromes.

upper limb and abdominal reflexes and with exaggerated lower limb tendon jerks, is still seen but only occasionally. More often now patients present with spinal or limb pains or somatic sensory disturbances, perhaps with clumsiness and feelings of disequilibrium. Fatigue is a common but less specific complaint. Such symptoms may be misdiagnosed as being due to fibromyalgia, causing resentment among patients when the correct diagnosis is eventually made.

True anatomical syringobulbia is rare and bulbar or lower cranial nerve features are more likely to be due to an underlying Chiari malformation. Associated skeletal abnormalities, such as Klippel-Feil, may occasionally be evidenced by a low hairline. In adolescents scoliosis is a common presentation. Very young children may present with respiratory difficulties, which may be life-threatening.

The filling mechanism

One might expect that obstruction to CSF movement in the spinal canal would lead to external hydraulic compression of the cord. This does occur but more often CSF accumulates inside the cord. Just why this comes about is still not fully explained.

Early theories suggested that, when the foramen magnum is obstructed, CSF is driven down through the obex, into the central canal of the cord, either by arterial pulsations or venous pressure waves. The advent of myelography using water-soluble contrast media revealed, however, that fluid appeared to pass from the spinal subarachnoid channels into the syrinx cavity. Experimental studies in animal models of syringomyelia have lent support to this explanation. For CSF to pass into a cavity that is itself under tension, some form of valve mechanism has to exist. When spinal CSF channels are obstructed, systolic pressure waves cannot dissipate freely so a transmural pressure develops across the cord parenchyma. This forces CSF along perivascular spaces, which presumably act as valves.

Other mechanisms may also operate. Below a point of partial obstruction to CSF flow, a Venturi effect may be created, once again resulting from arterial pressure waves. Increased velocity of CSF flow, immediately below the obstruction, creates a lower pressure outside the cord, as compared to within it. This alters the Starling forces acting across the capillary bed, leading to accumulation of interstitial fluid, initially as cord oedema, then coalescing into a fluid-filled cavity.

Thus, arterial energy seems the most likely driving force leading to syrinx formation and filling. Venous pressure waves, being of larger amplitude and longer lasting, may be responsible for subsequent propagation of syrinx cavities, by a hydraulic 'squeezing' effect.

Hindbrain related syringomyelia

Chiari type 1 malformations are the commonest cause of syringomyelia (Fig. 65.2A). They represent a heterogeneous group (Box 65.1) but most are thought to be the result of abnormal mesodermal development, where the volume of the posterior fossa is too small for the cerebellum contained within it. This probably has a genetic basis, as evidenced by the high incidence of Chiari-like malformation in

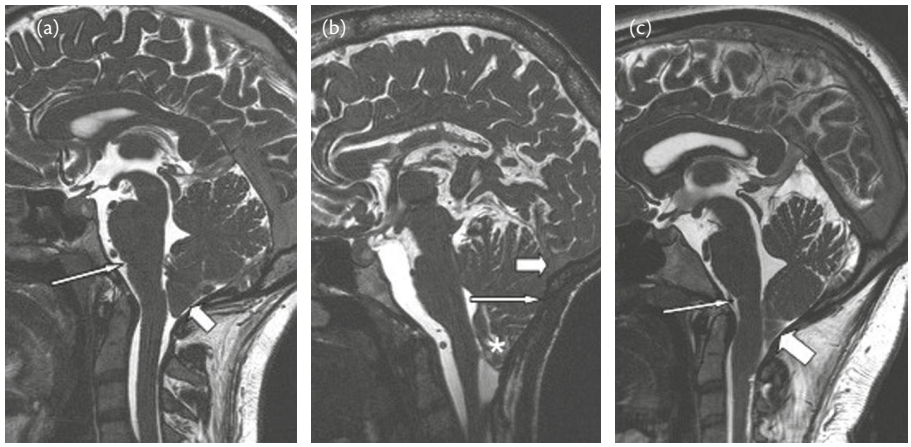

Fig. 65.2 Hindbrain hernias. MR images illustrating various types of Chiari malformation. (A) Type 1, with cerebellar tonsils that protrude through the foramen magnum, occupying the cisterna magna (short arrow). The pontomedullary junction is in a normal position (long arrow). (B) Type 2, where the medulla and a significant part of the cerebellum (asterisk) are prolapsed through a widened foramen magnum, into the upper cervical canal, as a consequence of lumbosacral spinal dysraphism. The posterior fossa is underdeveloped, the torcula (short arrow) being close to the posterior rim of the foramen magnum (long arrow). (C) Type 1.5, with features similar to type 1 but with a low pontomedullary junction (long, arrow) and a degree of tonsillar descent through the foramen magnum. The tonsillar herniation is otherwise morphologically similar to Chiari type 1 (short arrow).

certain breeds of dog. Familial clustering is also seen occasionally in humans. Posterior fossa size is the likely inheritable trait, tonsillar herniation being a secondary development. Symptoms often develop many years after skeletal growth is complete, suggesting that other factors, such as intracranial pressure, may play a role; indeed, about one in five patients with overt benign intracranial hypertension display tonsillar descent on their MRI scans.

Chiari type 2 malformations result from spinal dysraphism. Failed closure of the caudal neural tube, with consequent leakage of CSF into the amniotic sac, prevents normal development of posterior fossa structures (Fig. 65.2B).

MRI appearances intermediate between types 1 and 2 are sometimes seen, with descent of the medulla and obex, as well as the tonsils, but without spinal dysraphism or wholesale descent of the hindbrain (Fig. 65.2C)

Syringomyelia may develop with all these types of Chiari malformation but what determines whether or not this happens remains unknown. Syringomyelia may also be detected in the absence of overt hindbrain herniation and yet decompressive surgery may lead to collapse of the cavity. The term Chiari 0 is applied to such cases and the assumption is that CSF movement across the craniovertebral junction is impaired, either by a thin arachnoid web or by crowding of the cisterna magna. There is, in general, a poor correlation between the degree of anatomical descent seen on MRI and the severity of a patient's symptoms. Absolute radiological measurements of tonsillar descent are therefore of limited value in evaluating individual cases.

Clinical features of hindbrain hernias can usefully be considered in terms of those due to pressure on local structures and those caused by obstruction to CSF movement. Neuralgia and involuntary facial movements may mimic cranial rhizopathies caused by vascular compression. Sleep apnoea leads to some Chiari malformations first presenting to Ear Nose and Throat services. Drop attacks are a cause of particular concern. Once cardiac and epileptic causes have been excluded the question of medullary compression vs. non-organic causes arises. Blackouts which are clearly brought on by Valsalva-like activities certainly warrant consideration of surgery, but it may be difficult to recommend such major intervention when the cause of syncopal episodes is unclear.

The classic symptom of hindbrain hernias is the pressure dissociation headache, brought on by any Valsalva-like activity, including coughing, sneezing, laughing, shouting, straining, blowing up party balloons, or simply bending forwards.

Syringomyelia due to spinal pathology

Various pathologies can obstruct spinal CSF channels below the foramen magnum (Box 65.1). Principal among these is scar tissue formation, developing as a result of a previous episode of arachnoid inflammation, caused by infection or haemorrhage. Bleeding may have occurred intracranially or directly into the spinal canal, the latter most often the result of spinal cord injury (SCI).

Development of post-traumatic syringomyelia threatens to add to the burden already borne by SCI victims. While syringomyelia remains a relatively rare condition in the population as a whole, it is remarkably common among SCI victims, affecting 1 in 20 cases, if not more. Clinical presentation is often with increasing pain or alteration of bladder control. Other symptoms include hyperhidrosis, increased muscle spasms, loss of motor power, and ascending sensory levels. There is a wide range in the latent interval, between the original injury and the onset of symptoms, varying from a few months to many years. As with Chiari malformations, it is unclear what determines which SCI patients will go on to develop syringomyelia. Studies looking at possible predictors, including age of the victim, mechanism of injury, spinal levels involved, extent of the neurological deficit and whether initial management was surgical or conservative, have failed to provide consistent answers.

Idiopathic syringomyelia

Investigation by MRI, of almost any neurological symptoms that persist beyond a short period, has resulted in detection of many more syrinx cavities than was previously the case. Included among these are cavities for which there is no obvious underlying cause, in particular no detectable focal point of obstruction to CSF flow. Some

of these 'lesions' are no more than persisting central canals, essentially embryological remnants. The central canal is always patent in infants but reduces in size throughout life, especially during teenage years, but may still be visible on about 1% of spinal MR scans.

With other, more prominent cavities (Fig. 65.1C) three questions arise: (1) why are they present; (2) are they the cause of the patient's symptoms; (3) how should they be treated? At present there is no clear answer to the first question. Symptoms commonly consist of somatic sensory disturbances and discomforts, often characteristic of central neurogenic pain. There is no question of surgical intervention; any potential benefits are far outweighed by the likelihood of neurological deficits being produced. Standard pain clinic regimes, using neurotropic medications, TENS, acupuncture, and physiotherapy may help. If these prove ineffective a lumbar puncture and CSF drainage may be of benefit, although the physiological basis of this response is unclear.

Treatment of syringomyelia

Surgical treatment of Chiari is far from essential in most cases. Many authors advocate intervention if there is an associated syrinx cavity, but this is like shunting every case of hydrocephalus, irrespective of symptoms. Many syringomyelia cavities enter a state of hydrodynamic equilibrium and these patients require no more than observation. Deterioration is usually gradual and obvious to the patient. There is time for follow-up imaging and careful consideration of the role of surgery. Sudden deterioration is uncommon, usually following an episode of physical straining. It is, however, unnecessary to prohibit physical exercise, on the grounds that Valsalva will likely cause the syrinx to expand. Instead, the patient simply needs to be warned to avoid breath-holding during exercise.

Surgery seldom needs to be carried out urgently, at least in adults, although young children with Chiari may occasionally present in a parlous state, requiring prompt intervention. When performed, it aims primarily to halt motor deterioration. Relief of pain, control of sensory disturbances, reduction of sweating and spasms, and restoration of lost function are secondary aims. Options include opening up obstructed CSF channels, direct drainage of the syrinx cavity and lowering the overall pressure throughout the CSF pathways.

Craniovertebral decompression provides the best example of the first of these options and, provided the CSF channels are opened up adequately, the surgeon can expect syrinx cavities to collapse in at least three-quarters of cases. This may not always occur immediately and six months needs to elapse before a meaningful assessment can be made. Complications of craniovertebral decompression include chemical meningitis, CSF leakage, bacterial meningitis, hydrocephalus and, occasionally, acute cerebral swelling. An isolated fourth ventricle and brain slump are particularly difficult complications and the latter may, in fact, be the result of high pressure from above, rather than lack of support from below. Retractor damage to the greater occipital nerves can produce troublesome dysaesthesias, persisting for some time postoperatively.

Another example of creating an artificial conduit for CSF flow is laminectomy and lysis of intradural arachnoid adhesions, for post-traumatic syringomyelia. In comparison with the craniovertebral junction, the spinal canal is narrower and adhesions may reform postoperatively, with recurrent obstruction to CSF flow. Success rates for syringomyelia surgery at this level in the spine are not as good as they are following operations at the craniovertebral junction. In general, the likelihood of any surgery leading to permanent syrinx collapse is inversely proportional to the extent of any intradural arachnoid adhesions.

Direct drainage of a syrinx cavity may be appropriate when arachnoid adhesions are too extensive, for example in cases of pyogenic or post-tuberculous meningitis. Drawbacks include the need to make a myelotomy, causing some loss of dorsal column function. Drainage tubes, as with other CSF shunt systems, have a tendency to block with time and long-term efficacy is unlikely to benefit more than half of all cases. New cavities are prone to form, simply because the underlying filling mechanism has not been disabled. Receptacles for the drained syrinx fluid include the pleural cavity, the peritoneum, or the spinal theca itself. One particular form of direct drainage is transaction of the spinal cord, in patients who are completely paraplegic and in whom other measures have failed.

Beyond these manoeuvres, partial decompression of a syrinx cavity may be achieved by lowering the hydraulic pressure throughout the spinal theca, thereby reducing the amplitude of the arterial pulse waves within the spinal CSF column. Indeed, this may be a first choice of procedure if hydrocephalus is present at the time of clinical presentation. A ventriculoperitoneal shunt or even an endoscopic third ventriculostomy can reduce the intracranial pressure bearing down upon a Chiari malformation, relieve pressure dissociation headaches, and even lead to collapse of an associated syrinx. Thecoperitoneal shunts may be useful for other forms of syringomyelia, particularly if attempted creation of an artificial conduit has failed.

Even when a syringomyelia cavity has successfully been induced to collapse, following surgery, by no means will all symptoms settle in all patients. With Chiari malformations pressure dissociation headaches will usually resolve or lessen in most patients and ocular and motor symptoms tend to improve as well. Somatic pains and sensory disturbances, be these due to tonsillar pressure on long tracts or arising from a syrinx cavity, tend to persist, in up to half of all patients. Indeed, neuropathic pain remains a major challenge in the management of syringomyelia in general, often dominating a patient's life.

Extra-axial CSF collections

In addition to abnormal accumulations of CSF within the cord, we may encounter pathological collections in other planes within the spinal canal. These may be extradural or intradural and may or may not have neural elements within their walls. Their cystic nature implies that a valve mechanism must be operating, whereby they fill more readily than they empty. The resultant pressure may stimulate the adjacent meninges, producing local spinal pain. If nerve rootlets are involved radicular features may be present. Collections in the thoracic or cervical canal may cause a 'hydraulic myelopathy', producing motor, sensory, and autonomic disturbances of varying degrees.

The aetiology of these lesions remains unclear, with trauma, inflammation, and congenital defects all having been proposed. Familial clustering has been reported with some and associations have been made with various collagen disorders.

Spinal epidural cysts

Extradural collections are most often encountered in the lower thoracic spine, sited dorsally (Fig. 65.3). Their presence implies an underlying dural defect and this is most likely to be adjacent to a nerve root. If pain is intolerable or myelopathic features are prominent then surgery is justifiable. Smaller cysts may be excised but, for larger collections, multiple level laminectomies are impractical. A more limited exposure may, instead, permit sealing of the dural defect, if it can be located radiologically preoperatively. Otherwise, shunting into the peritoneum, pleural cavity, or the spinal theca may be options.

Arachnoid cysts and webs

Spinal CSF channels may be obstructed by thin diaphragms of arachnoid tissue, which can be difficult to spot radiologically. Clues as to their presence include displacement of the cord, on sagittal or axial images (Fig. 65.4). It is important then to check that the obstructing membrane is not the top of a more extensive, intradural cyst, most of which are located dorsal to the cord.

In the absence of a history of trauma, meningitis, intraspinal haemorrhage, or prior surgery, such lesions are regarded as being idiopathic. Presenting features include neuropathic pain and motor myelopathy. High lesions may cause headaches, presumably because of reduction in the compliance normally provided by the spinal theca.

Surgery is indicated if there is progressive motor deterioration. Excision is desirable, for isolated webs or short cysts. More extensive cysts may respond to fenestration manoeuvres. Neuropathic pains may, unfortunately, persist, despite an anatomically successful procedure.

Lumbar puncture, by temporarily reducing the filling pressure outside the cyst, may act as a useful test as to whether the lesion is the cause of the patient's symptoms. Alternatively, direct cyst aspiration may be performed.

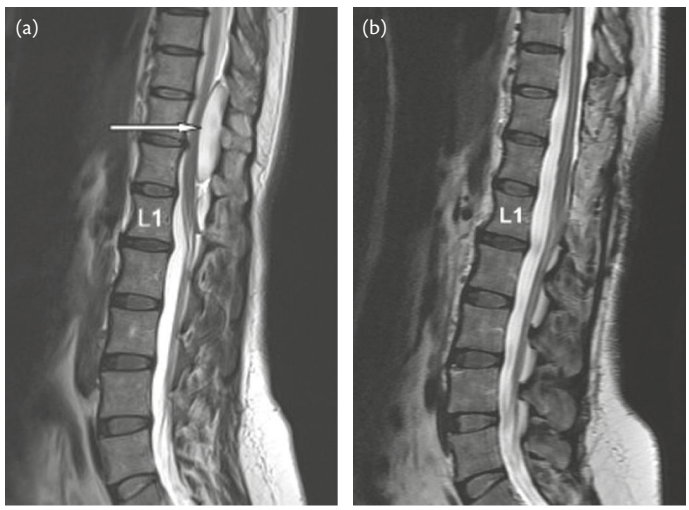

Fig. 65.3 Spinal epidural cyst. (A) T2 sagittal MRI displaying a spinal extradural, CSF-filled cyst (arrow). (B) Postoperative appearances two years later.

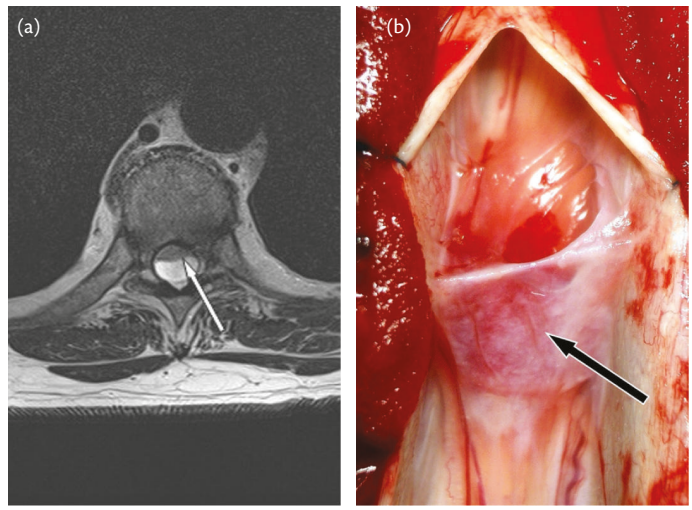

Fig. 65.4 Arachnoid web. (A) Axial T2 MRI image of the thoracic spine revealing anterior displacement and compression of the cord (arrow) caused by hydrostatic pressure built up above a spinal arachnoid web. (B) Operative appearances of an intradural arachnoid web (arrow) forming a diaphragm across the theca, dorsal and lateral to the cord.

Tarlov cysts

These perineural cysts are common incidental findings on MR scans, usually but not exclusively located in the sacral canal, and often multiple. Histologically, there are neural elements in the walls and they may generate spinal, perineal, or leg pains. They are best managed conservatively, using pain management methods. Surgical treatment may be indicated if there are clear problems with sphincter control or sexual function, caused by hydraulic pressure on the lower sacral rootlets. Dissection is difficult as the cyst walls are extremely thin and adherent to these vital structures. Various techniques are described, including fenestration, plication of the wall, and placement of shunts. Glue injection has also been used. Trial aspiration may be carried out, prior to open surgery being planned.

Spontaneous intracranial hypotension

Low pressure headaches, characteristically worse in the upright position and relieved by lying down, are a common sequel to lumbar puncture. When developing spontaneously, in the absence of any implanted CSF shunt apparatus, such headaches suggest spontaneous leakage of CSF, somewhere along the spinal canal. Causes include prior trauma, collagen disorders or dural diverticula (Fig. 65.5A) but many cases appear to be idiopathic.

Besides orthostatic headaches, symptoms may include altered hearing, diplopia, and spinal pain, although the last-mentioned is not sufficiently common for the site of leakage to be localized. Less common presentations include extrapyramidal movement disorders and altered conscious level. An interesting symptom is galactorrhoea, caused by a 'reverse Monro-Kellie' effect; reduction of the CSF volume intracranially leads to increased vascular perfusion of the intracranial contents, including the pituitary gland, with resultant increased prolactin production.

Increased blood flow is also responsible for the characteristic finding of widespread meningeal enhancement seen on contrasted

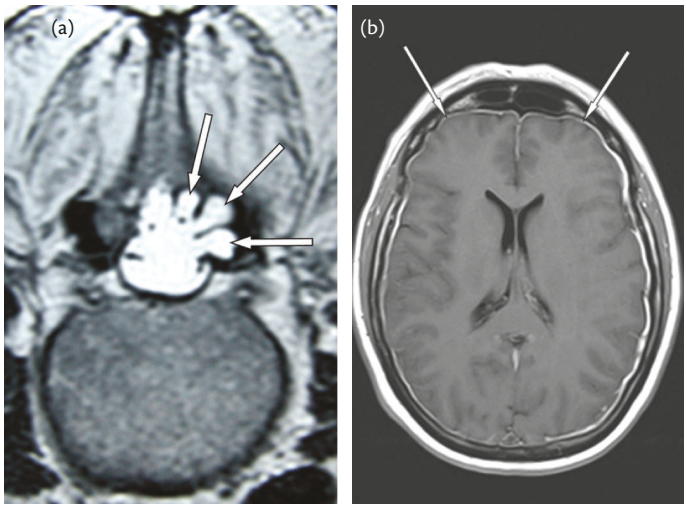

Fig. 65.5 Spontaneous intracranial hypotension. (A) Axial T2 MRI of the spine showing dural diverticula (arrows), a likely source of CSF leakage. (B) Axial T1 contrasted MRI of the head demonstrating diffuse meningeal enhancement (arrows) caused by leakage of CSF from the spinal canal.

cranial MRI (Fig. 65.5B). Brain slump and cerebellar tonsillar herniation may be seen. Occasionally subdural haematomas develop. More subtle features include distension of the transverse sinuses and collapse of the optic nerve sheaths.

Location of the site of leakage, in the spine, is often difficult. Isotope cisternography and computed tomography (CT) myelography have been used but involve a good deal of ionizing radiation. MR myelography using intrathecal gadolinium provides an alternative but it is also possible to generate T2 MR images that resemble conventional myelograms. Lumbar puncture may reveal a low opening pressure and may show a relatively low plateau pressure, if combined with an infusion study.

Treatment of spontaneous intracranial hypotension is initially conservative, with bed rest, maintenance of adequate fluid intake and simple analgesia, just as postlumbar puncture headaches are managed. The hope is that the leak will heal spontaneously. Persistent symptoms are treated with epidural blood patches, targeting the site of leakage if this can be identified but often performed 'blind' and repeated if necessary. Surgical repair would be exceptional and only when the site of leakage has been identified clearly, for example ligating dural diverticula.

Spinal cord hernias

While not a disorder of spinal CSF circulation as such, anterior spinal cord hernias produce MRI appearances similar to those generated by arachnoid webs, with anterior displacement of the cord and an increased volume of CSF dorsally. If the true nature of the lesion is missed, then inappropriate surgery may be undertaken. Phase contrast MRI or CT myelogram can be used to confirm the diagnosis of spinal cord hernia and differentiate it from a spinal arachnoid cyst.

Clinical assessment is therefore vital. Presentation, often in middle age, is that of an anterior cord syndrome, initially affecting one side of the cord. This may develop over a period, often in a stepwise manner, as the anterior columns progressively prolapse through the anterior thecal defect, most commonly encountered in the thoracic spine. The patient may display spinothalamic sensory loss in one lower limb, together with upper motor neurone deficits in the opposite leg. Dorsal column function is often spared but, if left untreated, the condition may progress to a more complete myelopathy.

Careful microsurgery can reduce the hernia, with a prosthetic barrier then being inserted between cord and dura, to prevent recurrence.

Controversies

A major area of contention, in the field of Chiari and syringomyelia surgery, concerns the best way of performing a craniovertebral decompression. Of the various methods used, the only manoeuvre they have in common is removal of bone. Beyond this, surgeons vary considerably in the extent of the dissection they perform (Box 65.3).

There is a good reason why many limit their approach because opening into the subarachnoid channels will inevitably lead to a chemical meningitis, to a greater or lesser degree. This will generate discomfort for the patient, increase the CSF pressure and, sometimes, provoke CSF leakage; this is then best treated with a lumbar drain, provided that hydrocephalus has first been excluded. On the other hand, partial or even no dural opening is less likely to lead to collapse of an associated syrinx cavity. Some surgeons advocate a limited approach, initially, with an option to return if it proves ineffective. This, however, will require the patient to go through another major and uncomfortable brain operation.

The additional measure of reducing the tonsils introduces a risk of causing cerebellar swelling, with potential obstruction of the fourth ventricle, leading to hydrocephalus. It does, however, remove the 'pistons' that have been impacting upon the trapped column of CSF within the spinal theca. While external decompression alone may open up the CSF channels, subsequent placement of a dural graft invites formation of adhesions, between it, the tonsils and the cervicomedullary junction. Spinal CSF dynamics can then become much worse than prior to surgery. Revisional surgery in these circumstances is very difficult, more hazardous, and less likely to succeed, compared to a virgin operation. Damage to the dorsal columns, with resultant loss of light touch and joint position sensation is a particular risk.

The author therefore prefers to open the dura and the arachnoid and to reduce the cerebellar tonsils, thereby creating an artificial cisterna magna into which the fourth ventricle opens freely and which itself communicates with the basal cisterns and the spinal CSF channels. There is no need for dural grafts, as it is seldom possible to make such repairs watertight. CSF will leak around and press

Scoliosis and spinal deformity

Nigel Gummerson

Introduction

A spinal deformity is a condition in which the spine is not the 'normal shape' because of illness, injury or because it has grown wrongly (i.e. the spine is misshapen or malformed).

In order to discuss spinal deformity, we must first consider what is normal. The spine is straight when viewed from the front or the back; there are no significant curves in the coronal plane (a slight lateral curve may be within normal limits). The sagittal profile is the shape of the spine when viewed from the side. The sagittal profile changes with growth and ageing.

At birth, the spine has a gentle C-shaped curve throughout its length. The normal cervical lordosis develops as the child gains head control and begins crawling; the lumbar lordosis begins to appear at the time of walking. There is continued development in the sagittal profile throughout growth until the normal adult pattern is achieved. The sagittal profile is never fixed, and will continue to change as the spine ages, becoming more kyphotic with advancing years.

The net effect of this normal spinal profile is to position the head and thoracic cage over the centre of the pelvis in the coronal plane. In the sagittal plane, the centre of gravity falls between the sacrum and the femoral heads. It is the relative positioning of head, shoulders, thorax, and pelvis that gives the normal body surface contour.

Traditionally, we have classified spinal deformities into scoliosis (affecting the coronal plane) and kyphosis (affecting the sagittal plane). In reality, the spine is a complex system, and changes in the coronal plane produce changes in the sagittal plane, which are accompanied by rotation (in the axial plane). Therefore, spinal deformity is a three-dimensional problem. In both the growing and ageing spine, deformities will evolve over time; the fourth dimension.

The last 30 years have brought a growing understanding of the relationship between the lumbar spine and the pelvis. Patients may tilt the pelvis to compensate for spinal deformity. There is a limit to the amount of compensation that is possible. Rotating the pelvis forwards or backwards from the normal position compromises hip function. Therefore, when considering the normal spine, we must also consider the pelvis.

Clinical assessment of spinal shape

It may be difficult to identify mild to moderate spinal deformity. Most of us spend the majority of our waking hours fully dressed and in motion. Movement and clothing obscure the subtle changes in body surface shape that spinal deformity may cause.

To assess the spinal shape clinically we must expose the patient, asking them to undress down to their underwear. The patient stands upright and still. We can observe any difference in the waist creases, trunk shift, and shoulder heights. Abnormal spinal rotation may manifest as asymmetry of the posterior chest wall or loin asymmetry. Having the patient lean forwards, bending at the waist, will usually make these asymmetries (due to rotation) more obvious. This is Adam's forward bend test. In this position, the spinal rotation (relative to the horizontal plane) may be measured with a scoliometer.

Check that the patient is able to stand upright with the hips and knees fully extended; patients with sagittal plane deformity may stand with their hips and knees flexed, allowing them to tilt the pelvis backwards and compensate for some or all of the spinal deformity.

There are several photographic techniques that may be used to generate a topographical spinal map of the back shape (e.g. ISIS 2—Integrated Shape Imaging System, Oxford, UK). This can quantify the posterior chest wall asymmetry and may be useful for monitoring scoliotic curve progression without using ionizing radiation, and for assessing the outcomes of surgery.

Radiographic assessment of spinal shape

The radiographic assessment of spinal shape is achieved with AP and lateral whole spine radiographs. These should be performed with the patient stood in a standardized position. Spinal deformities will change on standing, as the spine is loaded, so supine films (and supine MRI scans) are of limited value. Other factors, such as the position of the arms, or holding supports, will change the centre of gravity and thus change the appearance of the spine on the radiographs. The ideal radiographs will include C7, the whole rib cage, pelvis, and both femoral heads.

Radiographic assessment of the sagittal plane and pelvis

The normal spine is straight on the PA radiograph, and will have four curves in the sagittal plane. The sacral kyphosis is fixed; the sacrum is fused. The lumbar lordosis may be measured by finding the angle between the upper endplate of T12 and the endplate of S1 (normal range 40–60°). By convention, the thoracic kyphosis is measured from upper endplate of T5 to the lower endplate of T12

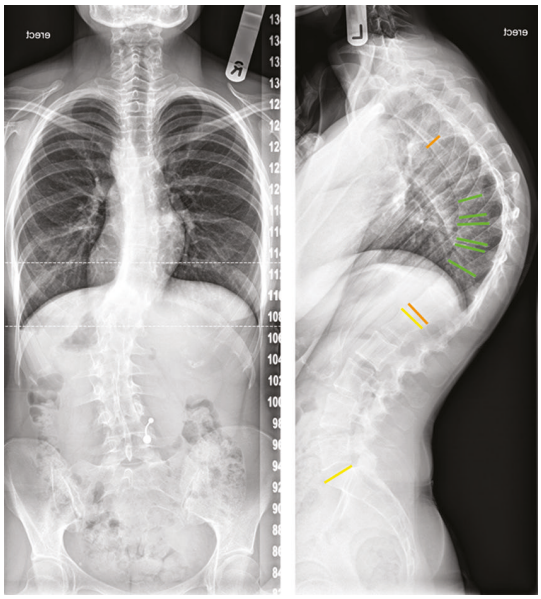

Fig. 66.1 Scheuermann's kyphosis. Increased thoracic kyphosis with wedging of at least 5° across three consecutive levels can be seen on the lateral X-ray (endplates marked in green). The AP film shows a small scoliosis, which is a common finding in Scheuermann's. In this case the lumbar lordosis (yellow) (L1–S1) measures 75° (normal range 40–60°) and the thoracic kyphosis (orange) (T5–T12) measures 96° (normal range 10–40°).

(the shoulders commonly obscure the higher thoracic levels). The normal range for T5–T12 kyphosis is 10–40°. The majority of the lumbar lordosis occurs at the lowest lumbar discs; the upper lumbar spine is relatively straight, as is the lower thoracic spine. Therefore, the segment from T10 to L2 is relatively straight (normal value 0–20° kyphosis). Pathological changes (e.g. Scheuermann's kyphosis) will disrupt the sagittal profile. See **Figure 66.1**.

It is good practice to include the pelvis on the radiographs as the anatomy and position of the pelvis has a fundamental effect on the spine; it is the foundation of the lumbar curve. The centre of gravity of the upper body should pass between the sacrum and the femoral heads. There is a concept that the spine is 'balanced' within a 'cone' of potential positions above the pelvis. Within this cone, it requires minimum muscular effort to stay standing. When the spine or centre of gravity moves outside of this cone then the spine becomes 'unbalanced' and the muscular effort required to stay standing is increased (Jean Dubousset, 'cone of economy').

We cannot easily measure the centre of gravity directly, and so substitute the relative positions of the centre of the C7 vertebral body and the posterior limit of the S1 endplate. A vertical line dropped from the C7 body should fall within 2.5 cm of the posterior limit of the S1 endplate on the lateral whole spine radiograph. This is the sagittal vertical axis.

Patients whose overall spinal balance lies outside this range are said to have decompensated sagittal deformity; this group has been shown to have lower quality of life scores.

There are three radiographic spinopelvic parameters that are commonly measured:

- Sacral slope (SS)—the slope of the S1 endplate relative to the horizontal plane (normal value 39 ± 8°).
- Pelvic tilt (PT)—the angle from the femoral heads to the midpoint of the S1 endplate relative to the vertical plane (normal value 13 ± 6°). A PT less than 25° is one of the desirable outcomes after spinal deformity surgery. See **Figure 66.2**.
- Pelvic incidence (PI)—the angle formed between a line drawn perpendicular to the S1 endplate and a line connecting the midpoint of the S1 endplate to the femoral heads. The PI changes with growth of the pelvis. Once skeletal growth is complete, the PI is fixed, and can only be changed by fractures or osteotomies to the pelvis or sacrum. The PI is equal to the sum of the sacral slope and pelvic tilt (normal value 55 ± 10.6°). Patients with a high PI tend to have a high lumbar lordosis.

A PT less than 25° and a PI within 9° of the lumbar lordosis are radiographic outcomes that statistically correlate with positive

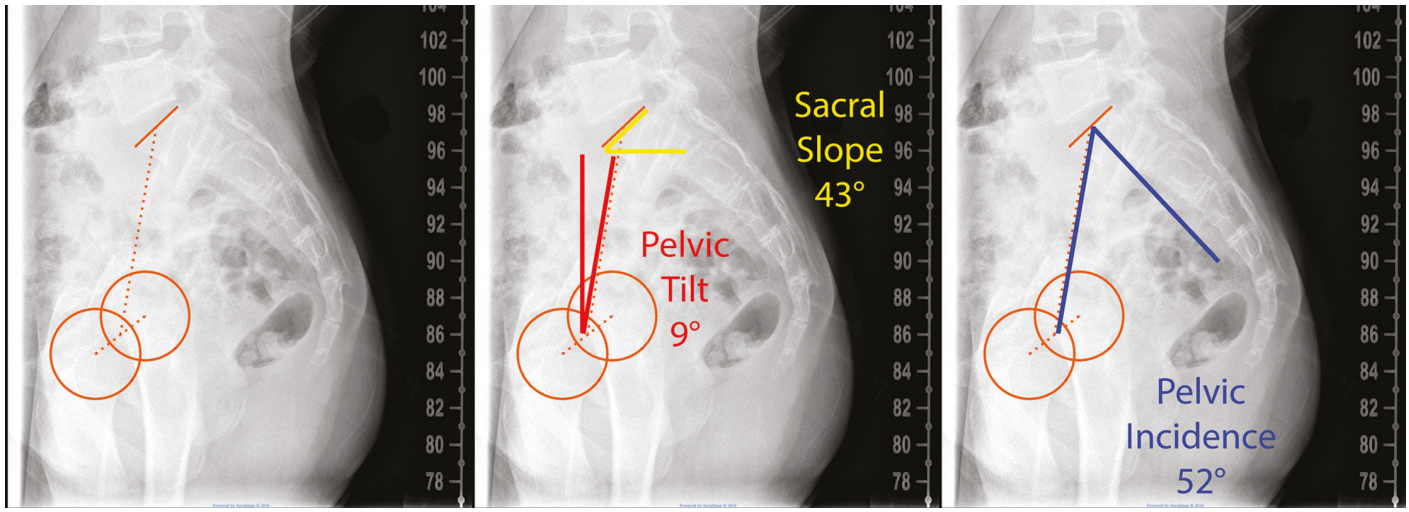

Fig. 66.2 Pelvic parameters. Outlining the femoral heads allows the centres to be identified. The S1 end plate is also marked, and a line is drawn from the midpoint of the S1 endplate to the midpoint of a line joining the centres of the femoral heads. Constructing horizontal and vertical lines allows measurement of the sacral slope (SS) and pelvic tilt (PT). The pelvic incidence (PI) is found by constructing a perpendicular line down from the midpoint of the S1 endplate. There is a fixed geometric relationship between these angles, such that: PI = SS + PT.

Table 66.1 Identification of the primary curve from the position of the apex

Curve type	Position of apex
Cervical scoliosis	C1 to the C6/C7 disc
Cervicothoracic scoliosis	C7 vertebra to T1 vertebra
Thoracic scoliosis	T1/T2 disc to T11/T12 disc
Thoracolumbar scoliosis	T12 to L1
Lumbar scoliosis	L1/L2 disc to L5

Scoliosis Research Society definitions.

outcomes after spinal deformity surgery. However, it is also important to appreciate that some patients are naturally more 'S-shaped', while others have a flatter profile: restoring a harmonious sagittal profile should be the surgical goal.

Common degenerative conditions, such as lumbar disc disease, will result in loss of anterior spinal height, while the height of the posterior elements remains unchanged. This leads to loss of lumbar lordosis and a sagittal plane deformity. Lumbar spinal fusion and decompression without restoration of the normal lumbar lordosis may improve a patient's radicular leg pain, but may leave them with a fixed sagittal deformity and a suboptimal surgical outcome.

'Whole-body' radiographs are becoming more widespread; advances in detector technology have allowed imaging of a wider field with lower dose. This has allowed researchers to examine the sagittal balance of the whole patient. The study of whole-body balance and its relationship to quality of life and outcomes after surgery is an evolving topic.

Radiographic assessment of scoliosis

The cardinal characteristic of scoliosis is a curve in the coronal plane of more than ten degrees.

Scoliotic curves may be structural or non-structural. A non-structural curve is a curve that is fully correctable. Non-structural curves may be due to posture, due to pain, due to paralysis or due to pelvic obliquity (e.g. if a curve is the result of a leg length inequality, then the curve will straighten when the patient is sitting). Structural curves have a fixed component and do not fully straighten (i.e. they do not correct to zero degrees). Non-structural curves may develop a structural component over time.

Scoliotic curves are usually described by the curve's location, direction, and magnitude. A curve can be described as having a convexity (the 'outside' of the curve) and a concavity (the 'inside' of the curve). The side of the convexity describes the side of a scoliotic curve. The position of the 'apex' of the curve is used to describe the position within the spine. The apex is the disc or vertebral body that is furthest from the midline (i.e. the most displaced from the central spinal vertical axis). See **Table 66.1**.

The magnitude of a curve is measured by finding the angle from the superior endplate of the most tilted vertebra at the cranial end of the curve to the inferior endplate of the most tilted vertebra at the caudal end of the curve. This angle is the Cobb angle.

The Cobb angle measurement is merely a two-dimensional (2D) approximation of a 3D curve. To fully describe a curve, we would need to record the number of spinal segments affected and the rotational deformity as well as the sagittal plane deformity. The Cobb angle provides a useful shorthand method for describing a curve, and is the measurement for which we know most about the natural history. See **Figure 66.3**.

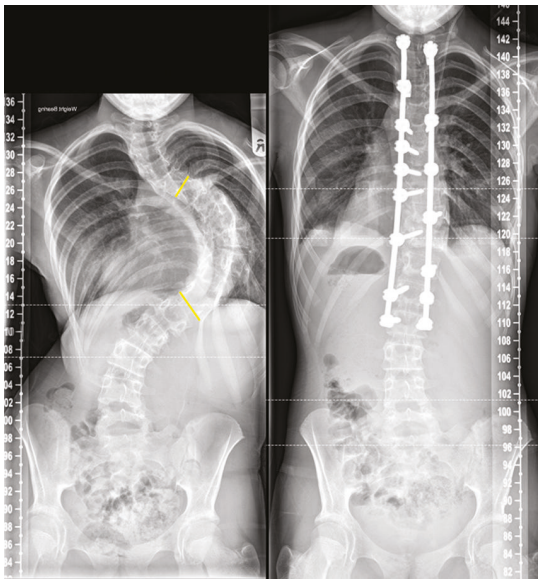

Fig. 66.3 Late onset idiopathic scoliosis (pre- and postoperative PA films). The Cobb angle is measured as illustrated. A line is drawn on the superior endplate of the most tilted vertebra at the top of the curve, and the lower endplate of the most tilted vertebra at the bottom of the curve. In this case, the Cobb angle of the thoracic curve is 108°.

Scoliosis

Scoliosis is a common, and relatively slowly evolving condition. With the exception of some neuromuscular conditions, young patients with scoliosis tend to be active and mobile. Scoliosis in children tends to present as a cosmetic problem, whereas scoliosis in adults tends to present with axial spinal pain and radicular symptoms.

Classification of scoliosis in children

Scoliosis in children may be classified by age of onset, by aetiology, or a combination of both.

Idiopathic scoliosis was traditionally divided into 'infantile' (0–3 years), 'juvenile' (4–9 years), and 'adolescent' (10–18 years). We now use the terms 'early onset scoliosis' (0–9 years) and 'late onset scoliosis' (10–18 years). The important factor here is lung development. Early onset scoliosis can lead to thoracic insufficiency syndrome.

Thoracic insufficiency syndrome is result of restricted lung growth, leading to the inability of the chest to support normal breathing. Scoliosis may restrict lung growth by limiting the height of the thoracic spine (18–22 cm of height from T1 to T12 is required for normal lung function), or because the apex of the curve rotates into the chest on the convex side, encroaching on the space available for the lung. Rib anomalies, in congenital scoliosis, may also contribute to this problem.

The details of chest and lung growth are complex, and arguments have been made for the cut-off between early and late onset at different ages. At the age of 10, the thoracic volume is 50% of its final

size. A 'late onset' scoliosis is unlikely to cause any change in lung function unless the curve becomes very large (>90 degrees).

The aetiology of a curve may be obvious, as in congenital (15%) or neuromuscular (10%) cases. In most cases there is no detectable underlying cause (idiopathic). This is the most common, with 70% of all cases of paediatric scoliosis being of the idiopathic type. A small proportion of patients with spinal deformity have an underlying syndrome.

Congenital scoliosis and kyphosis

The embryological development of the spine is described in Chapter 85. The classification of congenital scoliosis is descriptive. Congenital anomalies are divided in to defects of segmentation, defects of formation, mixed defects, and a small group of complex anomalies that defy description. This classification comes from the work of McMaster and Ohtsuka (1982), which was based largely on plain radiographs. Kawakami et al. have suggested an update to this system, analysing the 3D computed tomography (CT) appearances of the deformity. CT will reveal additional abnormalities in 50% of patients, over and above those seen on the plain films.

A 3D CT analysis allows for a better understanding of the relative (3D) position of the abnormalities, as well as providing more information regarding fusions between levels and the anatomy of the posterior elements around the abnormality.

Consideration of any associated rib anomalies is an important aspect of congenital scoliosis. Multiple rib fusions may be seen in Jarcho-Levin syndrome (spondylothoracic dysostosis). This condition causes marked reduction in thoracic growth and results in early death from thoracic insufficiency syndrome. A lesser form, spondylocostal dysostosis, causes less severe rib problems and has no appreciable effect on life expectancy. Isolated rib abnormalities may be seen in cases that do not have these syndromes, reflecting the common embryonic origin of the rib and vertebral body from the sclerotome of the somite. Non-syndromic rib anomalies are most commonly seen with unsegmented bars.

The natural history of deformity progression in congenital scoliosis is very variable. Around 50% of all cases of congenital scoliosis will progress by a significant degree, 25% do not progress, and the remainder progress only slightly or not at all. The chance of progression is dependent on the site and type of anomaly. Progression is the result of asymmetric growth.

The most benign form of congenital spinal anomaly is a block vertebra. This is the result of bilateral failure of segmentation. Block vertebrae do not cause progressive curves, but may cause shortening of the trunk when multiple block vertebrae are present.

An incarcerated or non-segmented hemivertebra has very little potential for progression. A wedged vertebra will cause only 1–2° progression per year. A single semisegmented or fully segmented vertebra will progress at 1–3.5° per year, worse at the thoracolumbar junction. Multiple hemivertebrae will progress more rapidly. Lumbosacral hemivertebrae will lead to compensatory lumbar and thoracic curves, which become stiff (and structural) over time. Early surgery is indicated to prevent this outcome.

An unsegmented bar will cause progression of between 2° and 9° per year. Again, this is worse at the thoracolumbar junction.

The most troublesome combination is the mixed defect of an unsegmented bar with a contralateral, fully segmented hemivertebra. The thoracolumbar junction is the worst location for this abnormality, where it may progress at more than 10° per year, necessitating early (prophylactic) surgical treatment when detected.

Congenital kyphosis is encountered less often than scoliosis. Kyphosis may progress at 2–7° per year. Most kyphotic anomalies are in the lower thoracic or thoracolumbar region. If left untreated, some patients with congenital kyphosis may become paraplegic.

There is a choice between continued observation and surgery in congenital deformity. Neither bracing nor physiotherapy can alter the natural history of these curves. Surgery is indicated for progressive curves. The potential for progression can be determined by a thorough work up with CT and MRI. Associated conditions should be actively sought and the possibility of an underlying syndrome considered prior to surgery. A formal assessment of pulmonary function before intervention, as a baseline, will help guide treatment and inform the prognosis.

The surgical options range from hemiepiphysiodesis (short segment anterior growth arrest over the convexity of the curve) to more complex osteotomies such as pedicle subtraction osteotomy (PSO), resection of a hemivertebra, or vertebral column resection. See **Figure 66.4**.

The choice of treatment will depend on the nature of the abnormality and the age at presentation. Techniques such as hemiepiphysiodesis rely on significant growth potential in the concavity, and are of little use in the older patient.

There is little to be gained by waiting 'to preserve growth' with a progressive deformity. Combined anterior and posterior fusion is often indicated in these cases. 'Normal' levels should be preserved where possible, but the whole curve may need to be instrumented to restore normal spinal balance.

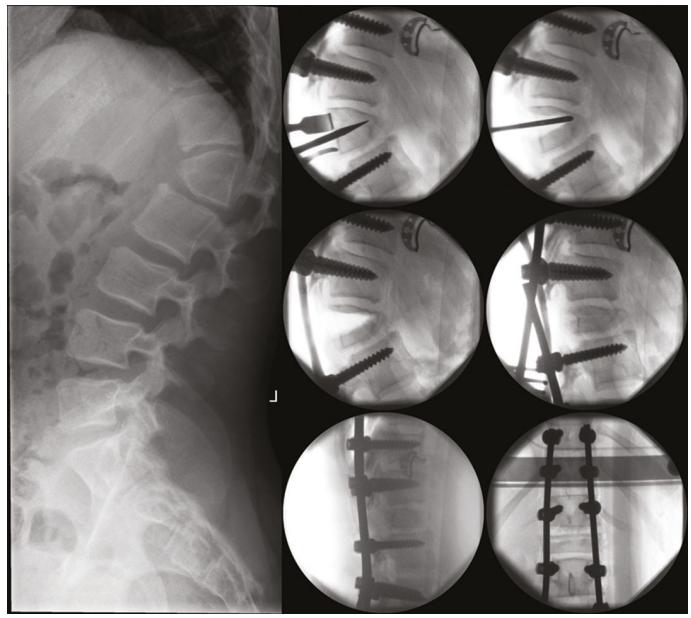

Fig. 66.4 Pedicle subtraction osteotomy (PSO) for Congenital Kyphosis. Spinal osteotomies may be required in deformity correction. In this case a wedge of bone (posterior element, pedicles, and body) has been resected, allowing the spine to be shortened posteriorly around the neural structures. This produces an angular correction with an axis of rotation at the front of the vertebral body. This osteotomy will typically produce 25–30° of correction.

Each congenital curve pattern must be assessed on its own merits but as a general rule, early surgical treatment should be considered for curves with more than one hemivertebra, a unilateral bar, or a mixed defect, as these are the curves which tend to progress.

Neuromuscular scoliosis

Disorders of the brain, spinal cord, nerves, or muscles may result in an inability to maintain normal spinal balance, leading to scoliosis. Examples include cerebral palsy, Duchenne muscular dystrophy, Friedreich's ataxia, and posttraumatic paralysis.

The frequency and severity of these curves is worse in children who cannot walk. Spinal balance is generally maintained in children who are still walking.

Neuromuscular curves are generally not painful, but they do cause problems with seating and hygiene. Poor sitting balance may mean that the child has to use an arm to help balance, depriving them of the use of that arm.

Early onset neuromuscular curves may lead to thoracic insufficiency syndrome. Patients with neuromuscular disorders are under the care of a multidisciplinary team. Non-operative treatment is appropriate for many patients with a neuromuscular curve. There is physiotherapy for all and seating modification for non-ambulators.

Operative treatment (typically posterior instrumented spinal fusion) is indicated when conservative treatment has failed. The goal is to prevent curve progression and to restore sitting balance.

Syndromic scoliosis

There are many syndromes which may cause scoliosis. Examples include neurofibromatosis, Marfan's syndrome, Ehlers–Danlos syndrome, osteogenesis imperfecta, and a very long list of others. A detailed discussion of these rare conditions is outside the scope of this article, but it is useful to examine patients very carefully for clinical signs which may suggest an underlying syndrome. If there is suspicion of an underlying syndrome, then an opinion from clinical genetics is indicated.

It is important to be aware of some of the common pitfalls in syndromic scoliosis, these are many, and vary by syndrome. The complication rate for surgery in this group is higher than in idiopathic scoliosis.

Idiopathic scoliosis

Idiopathic scoliosis is a structural curve in the absence of any other underlying problem. By definition, the deformity is self-generating, and the underlying cause is yet to be established, although there are many theories with regard to aetiology.

Early onset idiopathic scoliosis (EOIS)

EOIS is rare (1% in the United States, ~5% in Europe). It is typically a left-sided curve, which develops after birth, but is not present at birth. It is more common in boys (M:F = 3:2). EOIS is strongly associated with other conditions such as talipes equinovarus, developmental dysplasia of the hips, torticollis, and inguinal herniae. The classification of EOIS is descriptive, with useful discriminating features being the curve size, the rib-vertebral-angle difference (at the apex) and the appearance of the rib heads.

In EOIS, 90% of cases will resolve spontaneously. Interestingly and inexplicably, girls with a right-sided curve have a much poorer prognosis than those with left-sided curves. Progressive EOIS is associated with thoracic insufficiency syndrome and a consequent reduction in life expectancy.

It is likely that the historical descriptions of this group of patients included many who had an underlying cause for their scoliosis. Some 22% of patients with presumed EOIS with curves less than 20° have an underlying neural axis anomaly (i.e. they were not truly idiopathic). In one series, eight out of ten patients with a neural axis anomaly required neurosurgical intervention.

For prognostic purposes, it is useful to differentiate curves according to the RVAD (rib-vertebral-angle difference). See **Figure 66.5**. This measurement was defined by Mehta (1972) and is the difference between the right and left sides in the magnitude of the angle measured from the long axis of the rib and a line drawn perpendicular to end plate of the vertebra at the apex of the curve. Mehta showed that if this difference in the angles was less than 20°, then there was an 85–90% chance that the curve would resolve spontaneously. She went on to describe a second feature: the phase of the rib head on the convex side at the apex. A 'phase 1' rib head does not overlap the vertebral body and is associated with resolution in 84–98% of cases. A 'phase 2' rib head does overlap the vertebral body and is associated with progression in 84–97% of cases. Double curves are more likely to progress than single curves.

It has been suggested that EOIS is the result of intrauterine moulding; the counter to this suggestion is the fact that EOIS is rarely seen at birth. Others argue that it is the result of 'body moulding' from the positioning of the child. If the infant lies in the lateral decubitus position a curve will develop; this is supported by the observation of plagiocephaly in this group.

Most spinal surgeons agree that serial casting is a reasonable non-operative treatment option for progressive EOIS. Rigid braces are of

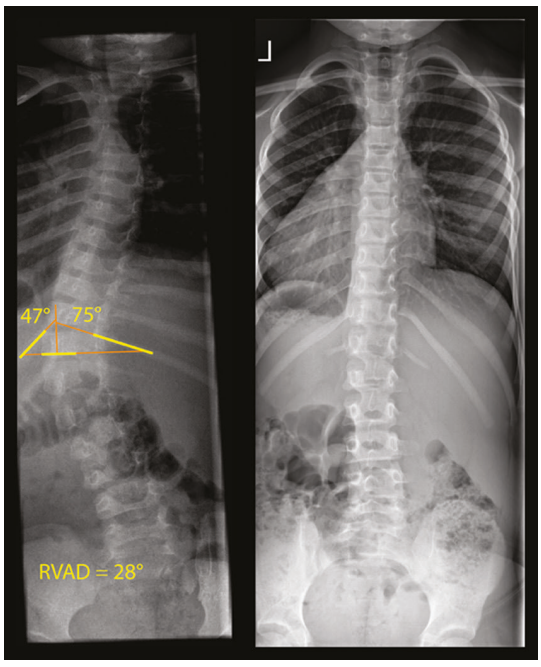

Fig. 66.5 Rib-vertebral-angle difference. In this case the RVAD at presentation (9 months old) was 28°—a marker for likely progression. The curve was progressive, and was treated with serial plaster casts (EDF casts). The curve has all but resolved by the age of 6 years.

little use, due to the rapid growth rate of the child, but serial plaster casts such as those popularized by Cotrel and used to good effect by Mehta (elongation derotation flexion, or EDF casts) can be moulded to control small, progressive curves.

Large curves (greater than approximately 50° Cobb angle) are best treated surgically. The dilemma is that early spinal fusion will prevent thoracic growth and this in turn will lead to thoracic insufficiency syndrome, respiratory failure, and reduced life expectancy. Therefore, the goal of surgical treatment is to control the curve, while maintaining growth. Many techniques have been tried.

The generally favoured technique is a dual rod growing system. Here, the curve is instrumented proximally and distally (usually two levels at each end), but the centre of the curve is left undisturbed. Rods are used on each side to connect the proximal and distal instrumentation. Traditional rods had to be lengthened every four to six months to allow growth, and this necessitated repeated surgical procedures. Complications such as wound infection or rod breakage were encountered in all of these cases eventually, due to repeated extension of instrumentation through the same scar. A rod with an intrinsic magnetic motor that allows telescoping has recently entered clinical use and offers the possibility of repeated lengthening using an external magnet in the outpatient clinic, obviating the need for repeated surgery.

Another possible solution is to selectively inhibit growth on the curve convexity. This technique is still somewhat experimental and not widely adopted.

Late onset idiopathic scoliosis (LOIS)

Late onset idiopathic scoliosis is a relatively common condition. Small curves are more common than large curves. The prevalence of curves greater than 10° is 2%; for curves greater than 30°, the prevalence is 0.2–0.3%. Overall, only 6 in 10 000 children will require treatment for LOIS.

The gender ratio approaches 1:1 for curves of 10° although for curves greater than 20°, the male:female ratio is 1:5. Small curves do not present clinically. The data on small curves originates from school screening programmes (Glassman et al., 2005). School screening programmes have largely been abandoned, as there is no reliable treatment that we can offer to children with small curves that would alter the natural history of the curve.

The development of a late onset curve is an insidious process. It is unsurprising that small curves go unnoticed by parents.

Classification of late onset idiopathic scoliosis

We have yet to find the ideal classification system for this multidimensional problem. Currently, the most widely used classification is that of Lenke et al. (2001). This has provided us with a useful tool, which allows reproducible descriptions of LOIS curves, can guide treatment, and promotes research. The Lenke classification is based on static erect and supine bending radiographs. There are three components: curve pattern, lumbar modifier, and sagittal thoracic modifier.

This classification is two-dimensional and addresses both the sagittal and the coronal plane. The rotational deformity is not classified. Work continues to find a truly 3D classification. These classification systems do not address the problems of which the patients complain—their cosmesis.

Aetiology of late onset idiopathic scoliosis

Idiopathic—arising spontaneously or from an obscure or unknown cause.

There are many theories regarding the aetiology of LOIS, but much remains unknown. Endocrine, neurological, muscular, and skeletal causes have all been postulated. It is more common in tall and slim (exomorphic) females. The deformity is lordosis with scoliosis, or lordo-scoliosis. The rotation of the curve as the spine deforms may give the appearance of kyphosis on the standard lateral radiograph, but a derotated view will give a more accurate assessment. One theory is that excess anterior spinal growth relative to posterior growth reduces the stability of the thoracic kyphosis, which then buckles, to produce a scoliosis.

Between 8% and 20% of patients with LOIS will have a first degree relative with the condition. The search for the genes responsible continues. It is likely that scoliosis is the result a complex interaction between multiple genes.

Natural history of late onset idiopathic scoliosis

The main driver of progression in late onset curves is growth. Indicators of remaining growth help predict curve progression. These indicators of remaining growth may be chronological, endocrine, or skeletal markers of maturity.

Age alone is a crude guide to remaining growth potential. Age of menarche adds further information. Girls grow rapidly for 18 months before and 18 months after menarche. A formal assessment of bone age using an X-ray of hand and wrist is also useful. The Risser grade is the degree of fusion of the iliac apophysis as seen on an anteroposterior (AP) radiograph. At grade 0 the apophysis has yet to appear. At grade 5 it is fully fused. Grades 1–4 represent progressive fusion of the apophysis to the iliac blade from lateral to medial. Age, pubertal stage, and bone age can be used to help predict the risk of progression (Table 66.2).

Even with significant remaining growth, small curves are unlikely to progress. Data for curves of 5–19° shows that 22% progress if the child is Risser grade 0–1, and only 1.6% progress if the child is Risser grade 2–4. (Note that a curve of 5° is below the current accepted threshold (10°) for a diagnosis of scoliosis.)

In the long term, LOIS patients have a normal life expectancy. The incidence of back pain is no higher than the general population, but when painful episodes do occur they may be a little more severe and last a little longer than the average. Unexplained back pain in this

Table 66.2 Predicting the risk of curve progression

Risk factor	Risk of progression (> 5°)
Age <10	88%
Age >15	29%
Premenarche	53%
Postmenarche	11%
Risser grade 0	68%
Risser grade 3–4	18%

Data from Lonstein JE, Carlson JM., The prediction of curve progression in untreated idiopathic scoliosis during growth, *The Journal of Bone and Joint Surgery Am*, Volume 66, Issue 7, pp. 1061–71, 1984.

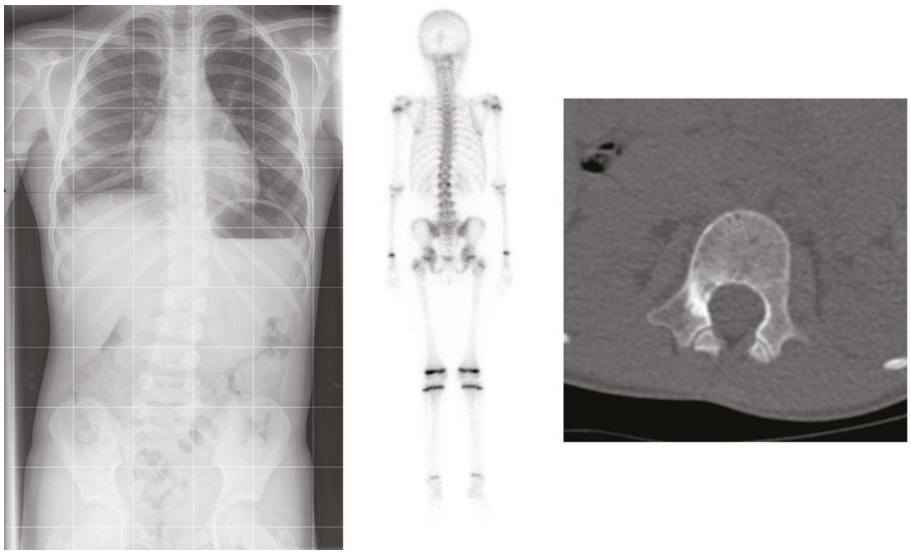

Fig. 66.6 Osteoid osteoma. This patient presented with a painful scoliosis which was investigated further with an isotope bone scan. Increased uptake can be seen in the pedicle of L2 on the bone scan. The axial CT scan shows a nidus with surrounding sclerosis.

group should prompt a search for other possible causes, especially pathologies that cause painful scoliosis such as osteoid osteoma or spondylolysis. See **Figure 66.6**.

There is an increased awareness of body image in this group, and there is certainly a psychological effect of the deformity. Girls with LOIS have a higher incidence of eating disorders and a lower BMI (body mass index).

LOIS does not cause significant cardiopulmonary compromise unless the curve is very large. A curve size of 90° is often quoted as a threshold for such compromise, although in truth some degree of measurable pulmonary dysfunction may be seen across all curve sizes. In contrast, severe pulmonary dysfunction is much more common in EOIS. The important distinction is where pulmonary dysfunction becomes *clinically* significant. Patients with a curve of more than 50° may have symptoms of exertional dyspnoea.

There is long term data to suggest that all curves progress a little, even after skeletal maturity. This progression is approximately 0.5° per year on average. Progression is more rapid in larger curves (>50°).

A number of LOIS patients will again present to spinal surgeons as adults with progression and degeneration in the curve, with symptoms of pain and possibly nerve root compression.

Treatment of late onset idiopathic scoliosis

Physiotherapy can be helpful for those children who develop back pain. There is no good evidence that physiotherapy can alter the underlying curve.

Bracing may play a role in the treatment of small curves with the aim of preventing curve progression, not correcting the curve. Bracing needs to be for 17 or more hours a day to be successful. Bracing has potentially significant physical and psychological morbidity. Ideally, bracing needs to be commenced before the growth spurt, and requires significant commitment from both patient and healthcare staff. Dynamic (elasticated) braces have been developed, and are still being evaluated.

Surgery can change the underlying spinal shape and the cosmetic appearance. A curve of less than 40° is unlikely to require surgical treatment on the grounds of dyscosmesis. The aims of scoliosis surgery are to prevent progression and leave a stable and well-balanced spine with the maximum safe cosmetic correction, preserving as many motion segments as possible. Cosmetic correction equates to level shoulders, centralization of the trunk with balanced waist creases and correction of spinal axial rotation to reduce the rib or loin prominence.

To identify fusion levels, the simple rule, followed in the majority of cases, is to identify the end vertebrae (i.e. the vertebrae with endplates that are most tilted from the horizontal plane and fuse all structural curves from the upper end vertebra to the lower end vertebra). The highest level should be chosen to ensure that the shoulders become or remain level and there should be a normal sagittal profile at the junction from fused to unfused. The lowest level should be selected based on the neutral and stable vertebra on the standing film, as well as examining the correction achieved across the disc spaces on the bending films.

Flexible curves make correction relatively straightforward. Stiff curves need some release to achieve the optimum correction. All facets joints are released as a means of achieving interfacetal fusions. Facets and the ligamentum flavum can be removed, as can the intervertebral discs, giving additional flexibility. Rigid curves require a more extensive osteotomy or complete resection of the vertebral column.

There is a decision to be made regarding the approach taken and which levels to fuse. The majority of scoliosis surgery is performed via a posterior approach. Anterior surgery may be indicated for larger, stiffer curves and is usually combined with posterior fixation. Choices regarding the precise levels of fusion will be determined by the choice of approach and the philosophy of correction.

Spinal deformity surgery is a major undertaking and carries significant risks. These risks can be managed and reduced with a systematic approach to the care of these patients. This involves any

number of protocols, including preoperative planning, patient blood management (tranexamic acid and cell salvage) and spinal cord monitoring using somatosensory evoked potential (SSEP) and motor-evoked potentials (MEPs) (see Chapter 56). 'Wake up' tests may be indicated if the electrophysiology shows persistent abnormalities.

Scheuermann's kyphosis

This condition has been given many names, but is commonly known as Scheuermann's disease or Scheuermann's kyphosis. Scheuermann first described the condition as the development of painful fixed kyphosis in teenagers. Radiographs show vertebral wedging with compression of the anterior vertebral borders.

Sorensen refined the diagnostic criteria, requiring more than 5° of anterior wedging in at least three adjacent vertebral bodies with abnormal kyphosis.

The incidence has been reported to be between 0.9% and 30%, although a figure of between 1% and 6% is more reasonable. Some studies have found that the condition is more common in boys, although others have found no gender difference.

The cause is unknown, although there are many theories. Among these theories, it has been suggested that the anterior vertebral body may have an abnormal blood supply, or that there may be abnormal ossification below the vertebral endplates.

Physiotherapy and extension exercise can be helpful for these patients. Bracing also has a role for patients with flexible curves (less than 65°), and may help patients back pain.

Surgery is indicated for unacceptable cosmesis (curves >70°) and disabling pain if conservative measures have failed. The aim of surgery is to correct the kyphosis to the upper limit of the normal range. Overcorrection may cause adjacent level junctional problems. Correction is achieved by shortening the posterior column, with multilevel osteotomies.

Spinal deformity in adults

Most adult spinal deformity patients present with a *de novo* degenerative scoliosis. We will all develop degenerative changes within the spine, but unfavourable degenerative changes such as stenosis, spondylolisthesis, lateral-listhesis, and loss of the lumbar lordosis may lead to symptoms. It is worth considering whether or not there is an underlying metabolic bone condition, such as osteoporosis, in this group of patients. Osteoporosis may be a factor in curve progression, and it will be a consideration if the patient should come to surgical treatment.

A smaller number of adult spinal deformity patients have developed degenerative change and curve progression within an adolescent idiopathic curve.

Unlike the paediatric patients, adult patients present with pain and radicular symptoms. The coronal plane deformity is relatively unimportant. It is the sagittal plane and pelvic parameters that have the biggest clinical impact. Focal subluxation, loss of lumbar lordosis, and global spinal imbalance have been correlated with disability.

With our ageing population there is an increasing number of potential candidates for adult deformity surgery. However, enthusiasm for deformity correction must be tempered by realistic goals, and an awareness of the significant potential for complications in this type surgery. Medical comorbidities may mean that some patients are not fit enough for the magnitude of surgery that is required.

A simple decompression (leaving the deformity uncorrected) may relieve radicular symptoms, but a 'small fusion' may leave the patient in a worse sate, if the problems of lost lordosis and global spinal balance are not addressed. In many cases the choice is to do nothing or a small decompressive procedure, or to consider a bigger operation and correction of the deformity, a procedure which will usually require an osteotomy or multiple intervertebral cages.

If the deformity is to be addressed, then the correction goals are restoration of the patient's sagittal vertebral alignment.

Be wary of the adult deformity patient whose deformity appears when they stand or walk, but disappears when they lie down. This may be camptocormia, which is an axial muscle myopathy associated with Parkinson's disease.

Kyphosis

Destructive pathologies such as trauma, tumour, and infection can all produce localized kyphosis. In some cases, there is sufficient flexibility across the uninvolved adjacent spinal segments for a normal global spinal balance to be maintained. In other cases, the localized destruction may result in a global sagittal spinal imbalance, which should be considered when treating the patient.

The treatment of trauma, tumours, and infections are discussed in more detail elsewhere within this text (see the chapters within Section 10, 'Neurotrauma and intensive care').

Managing spinal cord trauma

Saksith Smithason, Bryan S. Lee, and Edward C. Benzel

Introduction

Spinal cord injury (SCI), either traumatic or non-traumatic in aetiology, leads to temporary or permanent damage to the spinal cord function. Significant efforts have been directed towards the elucidation of the underlying pathophysiology of SCI. Both primary and secondary mechanisms of SCI exist, leading to immediate and often irreversible cell damage. Immediate treatment and adequate management in the setting of acute SCI are essential, preservation of even a small amount of functional neuronal tissue can permit ambulation.

SCI is associated with a prolonged hospital stay, rehabilitation stay, and often associated with enormous monetary costs. Neurological recovery after SCI is largely dependent on the extent of injury. The management of SCI and the determination of the role and timing of surgical decompression remain crucial and yet controversial. Further epidemiological research and studies are warranted in order to enhance healthcare planning and cost-effectiveness.

Epidemiology

Incidence, prevalence, gender, and geographic distribution.

The annual incidence of SCI is 15 to 40 cases per million people throughout the world, and 11.5 to 53.4 per million in the developed countries (Botterell et al., 1975). There are 12 000 new cases of paraplegia and quadriplegia as a result of SCI in the United States, and of these cases, 4000 die prior to reaching the hospital and 1000 during hospitalization (Sances et al., 1984). The incidence of SCI patients who survived and reached a hospital was 50 per million people per year. The prevalence of acute SCI is, however, varied. A study conducted in a single county reported the prevalence of SCI to be 583 per million, whereas a number reported from multinational studies ranged from 130 to 1125 per million (Griffin et al., 1985). Age distribution peaked in the second and third decades in most countries. Regarding gender ratios, males have been consistently found to be at higher risk for traumatic SCI. The actual ratio of men to women is approximately 3–4:1, and two-thirds of new SCI cases are found to occur in young individuals of less than 30 years of age (Griffin et al., 1985). The mean age and the proportion of older individuals, however, have been shown to increase with time (Sekhon and Fehlings, 2001). Regarding geographic distribution, a Canadian study reported that the incidence of SCI among rural residents was twice that of urban residents (Dryden et al., 2003). Motor vehicle collisions (MVC), falls, sports, and violence are the leading causes.

Economic impact

As SCI is often associated with a prolonged hospital and rehabilitation stay, there are often enormous monetary costs associated with treatment. The estimated management cost of SCI in the United States was $4 billion in 1990 (Stripling, 1990). From a national study in 1992, SCI patients was associated with an average hospitalization course of 171 days in the first two years postinjury, and initial hospital expenses averaged nearly $100 000. (Harvey et al., 1992). Today, the costs are far greater. In addition, there are significant expenditures for medical services, supplies, equipment, therapy, and rehabilitation (Harvey et al., 1992). Lifetime medical expenses can range from $50 000 in incomplete injuries to $2 million in cases of high cervical tetraplegia (Harvey et al., 1992).

Pathophysiology

Primary vs. secondary injury

The primary mechanism of acute SCI is generally considered to be irreversible; caused by rapid and violent spinal cord compression and distortion from displacement of normally protective structures due to traumatic fracture or dislocation (Fehlings and Tator 1995). Secondary mechanisms involve a cascade of injury mechanisms such as hypoxic-ischaemic injuries, electrolyte derangements, and lipid peroxidation—all initiated by primary injury mechanisms (Fehlings and Tator, 1995). A cascade of events occurs within minutes of the primary injury leading to subsequent cell death via hypoxia, ischaemia, ionic shifts, lipid peroxidation, free radical formation, protease activation, and prostaglandin-causing apoptosis (Fig. 67.1) (Carlson et al., 1998). A secondary injury with associated vascular compromise causing cellular necrosis, with the subsequent death of initially survived cells is hypothesized (Tator and Koyanagi, 1997). The secondary injury, however, has been suggested to account for only 10% of the total pathology after SCI from atomic absorption

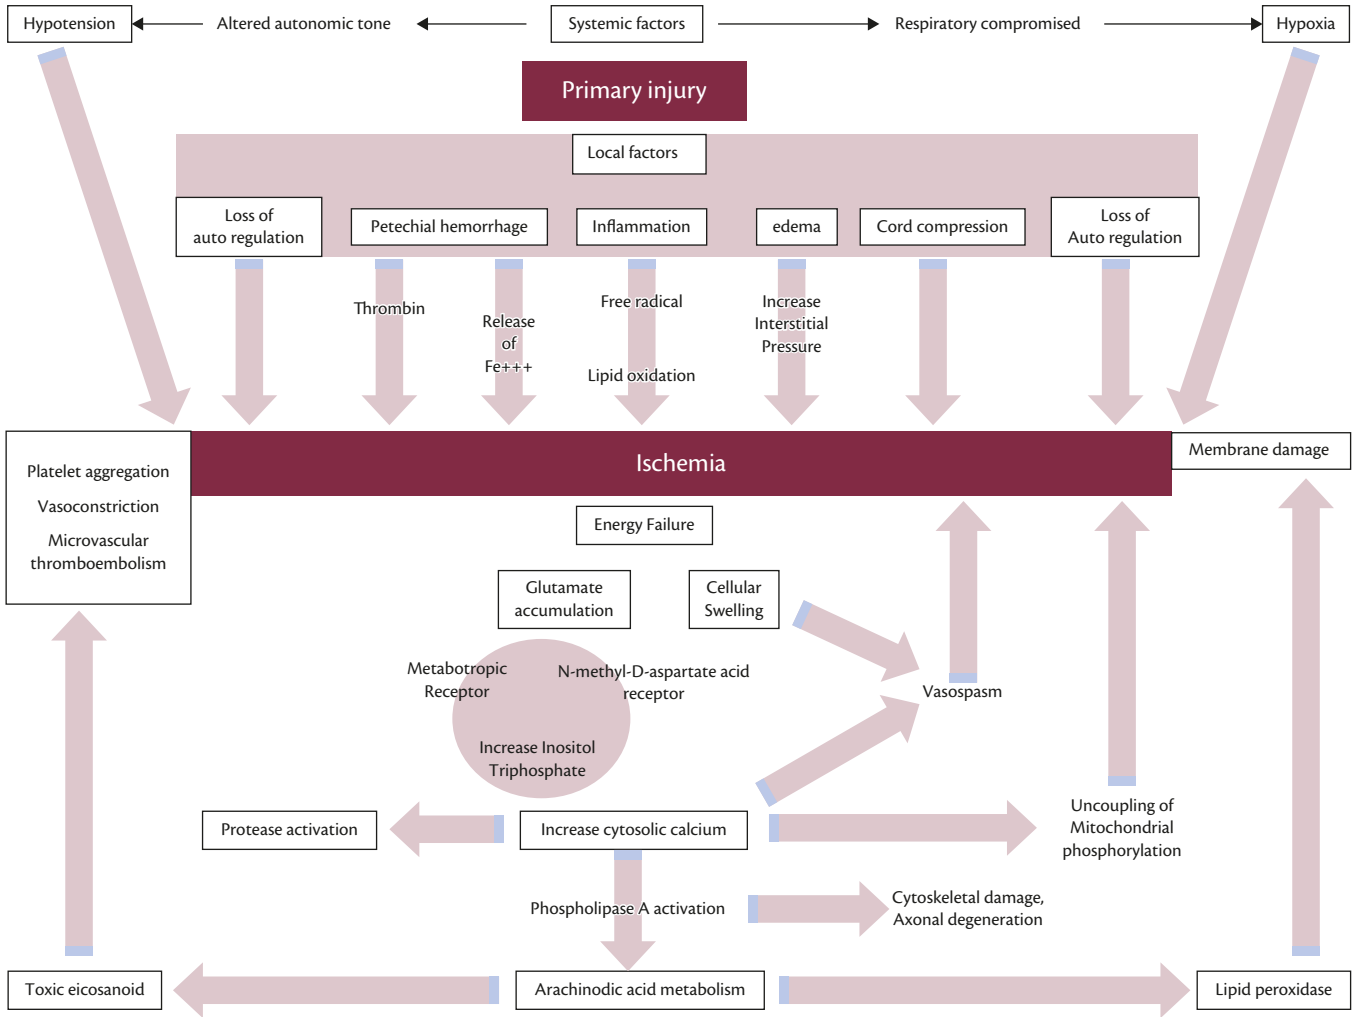

Fig. 67.1 Pathophysiology process underlying traumatic spinal cord injury.

spectroscopy (Young et al., 1982). Vascular mechanisms involved in SCI include changes in spinal cord blood flow, with the ischaemia persisting and worsening at least for 24 hours in animal models (Rivlin and Tator, 1978). Although mechanisms of such ischaemia remain unclear, vasospasm from mechanical damage, endothelial oedema, damage via focal haemorrhages with thrombosis, and the involvement of excitatory amino acids are some of the possible mechanisms (Sekhon and Fehlings, 2001).

Histological findings

Histological findings from the traumatized spinal cord specimens in the acute stage (3–5 days postinjury) demonstrated severe haemorrhages, predominantly in the grey matter This was likely related to damage to the anterior sulcal arteries. The surrounding white matter also demonstrated multiple lesions, including disrupted myelin and axonal oedema (Tator and Koyanagi, 1997). Although there were no findings of complete occlusion of major arteries, intramedullary veins were found to be occluded in the degenerated posterior white columns. It was concluded that the occlusion of such intramedullary veins from the initial mechanical stress or secondary injury likely produced the white matter lesions (Tator and Koyanagi, 1997).

Management of spinal injury

Prehospital phase, primary survey, and resuscitation

At the scene of trauma, the patient should be managed via advance trauma life support guidelines (ATLS) (Kortbeek et al., 2008). Initially, the patient should be carefully immobilized using devices such as the Kendrick extrication device, along with a rigid cervical collar, especially during extrication following a motor vehicle accident. Cervical spine immobilization must be maintained by stabilizing both the torso and the head during transfer to the nearest trauma centre, and vasopressors are recommended to maintain the systolic blood pressure above 100 mmHg (Gondim et al., 2004). Prehospital management is critical. Some 25% of prehospital fatalities are aggravated after the initial event (Bernhard et al., 2005).

Hospital phase and secondary survey

A rigid spinal board should be removed soon after the patient arrives in the emergency department to prevent pressure ulcers. Respiratory status must be monitored, since one-third of patients will require intubation in the first 24 hours. High cervical injuries

paralyse the diaphragm and intercostal muscles, whereas lower cervical injuries affect the intercostal muscles only. Paradoxical abdominal movement with respirations is often observed in patients with spinal cord injury above C5. Therefore, intubation is recommended in patient with vital capacity less than 1 litre (Ball, 2001). During the secondary survey, an entire evaluation of the spine is required since many injuries may not be obvious while the patient is kept in the supine position. It is recommended that a combination of low-molecular-weight heparin, rotating beds, adjusted dose heparin, or pneumatic compression stockings be used as prophylaxis for deep venous thrombosis. The first step is to define whether the injury is complete or incomplete. The bladder and bowel function must be assessed before one declares the presence of a complete injury. In order to accurately and consistently assess neurological function following SCI, the American Spinal Injury Association (ASIA) impairment scale is widely used due to its simplicity and similarity to the previously used Frankel scale (Fig. 67.2) (Kirshblum et al., 2011).

Methylprednisolone sodium succinate (MPSS) was extensively studied in five human SCI trials. Three multicentre, randomized, double-blinded National Acute Spinal Cord Injury Studies (NASCIS) had significant impact on the practice of spine trauma care in the United States (Bracken et al., 1990). MPSS was established as an effective neuroprotective agent for SCI on the basis of a NASCIS trial. Various dosage and administration recommendations were made over the course of the studies. However, some pitfalls have been identified in NASCIS II and III. It was alleged that conclusions were derived on the basis of non-standardized experimental design and statistical artefacts (Sayer et al., 2006). Despite all the conflicting data associated with MPSS in SCI, its known complications, and lack of proven efficacy, MPSS continues to be in widespread use for acute SCI in the United States, and many centres still resort to its use in order to avoid any possible legal repercussions (Hurlbert, 2000).

Imaging

The unconscious or uncooperative patient in the trauma setting should be assumed to have a spinal injury until proven otherwise. Helical CT was observed to identify 99.3% of all fractures of the cervical, thoracic, and lumbar spine, and those injuries missed by helical CT required minimal or no treatment (Brown et al., 2005). Magnetic resonance imaging (MRI) of the spine provides the best imaging of neurologic structures, ligaments, and discs. MRI is not routinely used in the evaluation of the polytrauma patient because of the time required. MRI is most useful in patients whose CT results do not explain the neurological status, most commonly seen in the neurologically impaired victim with an unremarkable CT. MRI may be used to exclude the presence of an associated extruded disc before or after a reduction manoeuvre in patients with cervical facet subluxations or dislocations.

Cervical traction

Halo application has been advocated in polytrauma patients given, its ability to facilitate further necessary diagnostic evaluations and emergent surgical treatment of associated injuries in the polytrauma patient. The benefit of closed cervical reduction and traction is controversial. Cervical traction can be used with a reported 80% success rate and 80% rate of improved neurological function, and worsening neurologic status from disc herniation after cervical traction may also occur. It is emphasized that such a strategy is not universally employed.

Cervical spine clearance

Issues with cervical spine clearance in polytrauma patients remains controversial. Coronal and sagittal reformatted CT scanning facilitates the visualization of bony injury. MRI is required if definitive evaluation of the soft tissues is indicated. MRI is used to confirm and quantify the anatomy of the lesion. The extent of spinal cord compression, swelling and parenchymal haemorrhage seen on MRI predicts adverse outcome after SCI (Miyanji et al., 2007). In order to definitively declare spinal stability after blunt trauma, both clinical and radiographic evidence must be thoroughly and systematically reviewed.

Mortality

Mortality after SCI has improved from 38% in 1970 to 15.8% during 1997–2000. (Bilello et al., 2003). Death at the scene is related to high-level SCIs, cardiovascular instability, or respiratory compromise. Mortality rates are highest immediately following and within the first hours after injury. It then drops precipitously after admission to the hospital (Evans et al., 2013). Odds of early death after traumatic SCI are increased by the following: older than 20 years of age, male gender, one or more comorbidities, concomitant systemic injury (Injury Severity Scale [ISS] >15), and concomitant traumatic brain injury (Varma et al., 2010).

Prognosis

Admission ASIA Impairment Scale (AIS) grade predicted neurological recovery at 1-year postinjury with a correlation between severity and expected level of recovery. Ten to fifteen per cent (10–15%) of individuals will convert from AIS grade A to an incomplete injury and only 2% will convert from AIS grade A to AIS D (Tator et al., 1999). For AIS grade C patients, the mean ASIA motor recovery score at 1-year postinjury is approximately 43 points for quadriplegic patients, with approximately 70% converting to AIS grade D or E (Kirshblum et al., 2011). Cervical SCIs demonstrate a 9.6-point increase in ASIA motor score compared to a 2.6-point average improvement seen in thoracic and lumbar complete lesions (Kirshblum et al., 2011). The chances of walking at 1 year after complete paraplegia is 5%, and 0% in complete quadriplegics (Wilson et al., 2012; Wilson et al., 2013).

Completed trials

GM1 ganglioside (Sygen)

The largest prospective randomized clinical SCI trial, enrolled more than 750 patients, involved the study of GM1 Ganglioside (Sygen). There is Class III clinical evidence that suggests the improvement of clinical outcome via optimization of spinal cord perfusion (Hurlbert, 2006). Such results, however, were not reproduced in long-term follow-up. As such, it is not in clinical use currently.

Muscle Function Grading

0 = total paralysis

1 = palpable or visible contraction

2 = active movement, full range of motion (ROM) with gravity eliminated

3 = active movement, full ROM against gravity

4 = active movement, full ROM against gravity and moderate resistance in a muscle specific position

5 = (normal) active movement, full ROM against gravity and full resistance in a functional muscle position expected from an otherwise unimpaired person

5* = (normal) active movement, full ROM against gravity and sufficient resistance to be considered normal if identified inhibiting factors (i.e. pain, disuse) were not present

NT = not testable (i.e. due to immobilization, severe pain such that the patient cannot be graded, amputation of limb, or contracture of > 50% of the normal ROM)

Sensory Grading

0 = Absent

1 = Altered, either decreased/impaired sensation or hypersensitivity

2 = Normal

NT = Not testable

When to Test Non-Key Muscles:

In a patient with an apparent AIS B classification, non-key muscle functions more than 3 levels below the motor level on each side should be tested to most accurately classify the injury (differentiate between AIS B and C).

Movement	Root level
Shoulder: Flexion, extension, abduction, adduction, internal and external rotation **Elbow:** Supination	**C5**
Elbow: Pronation **Wrist:** Flexion	**C6**
Finger: Flexion at proximal joint, extension. **Thumb:** Flexion, extension and abduction in plane of thumb	**C7**
Finger: Flexion at MCP joint **Thumb:** Opposition, adduction and abduction perpendicular to palm	**C8**
Finger: Abduction of the index finger	**T1**
Hip: Adduction	**L2**
Hip: External rotation	**L3**
Hip: Extension, abduction, internal rotation **Knee:** Flexion **Ankle:** Inversion and eversion **Toe:** MP and IP extension	**L4**
Hallux and Toe: DIP and PIP flexion and abduction	**L5**
Hallux: Adduction	**S1**

ASIA Impairment Scale (AIS)

A = Complete. No sensory or motor function is preserved in the sacral segments S4-5.

B = Sensory Incomplete. Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4-5 (light touch or pin prick at S4-5 or deep anal pressure) AND no motor function is preserved more than three levels below the motor level on either side of the body.

C = Motor Incomplete. Motor function is preserved at the most caudal sacral segments for voluntary anal contraction (VAC) OR the patient meets the criteria for sensory incomplete status (sensory function preserved at the most caudal sacral segments (S4-S5) by LT, PP or DAP), and has some sparing of motor function more than three levels below the ipsilateral motor level on either side of the body.
(This includes key or non-key muscle functions to determine motor incomplete status.) For AIS C – less than half of key muscle functions below the single NLI have a muscle grade ≥ 3.

D = Motor Incomplete. Motor incomplete status as defined above, with at least half (half or more) of key muscle functions below the single NLI having a muscle grade ≥ 3.

E = Normal. If sensation and motor function as tested with the ISNCSCI are graded as normal in all segments, and the patient had prior deficits, then the AIS grade is E. Someone without an initial SCI does not receive an AIS grade.

Using ND: To document the sensory, motor and NLI levels, the ASIA Impairment Scale grade, and/or the zone of partial preservation (ZPP) when they are unable to be determined based on the examination results.

INTERNATIONAL STANDARDS FOR NEUROLOGICAL CLASSIFICATION OF SPINAL CORD INJURY

ISCOS
INTERNATIONAL SPINAL CORD SOCIETY

Steps in Classification

The following order is recommended for determining the classification of individuals with SCI.

1. Determine sensory levels for right and left sides.
The sensory level is the most caudal, intact dermatome for both pin prick and light touch sensation.

2. Determine motor levels for right and left sides.
Defined by the lowest key muscle function that has a grade of at least 3 (on supine testing), providing the key muscle functions represented by segments above that level are judged to be intact (graded as a 5).
Note: in regions where there is no myotome to test, the motor level is presumed to be the same as the sensory level, if testable motor function above that level is also normal.

3. Determine the neurological level of injury (NLI)
This refers to the most caudal segment of the cord with intact sensation and antigravity (3 or more) muscle function strength, provided that there is normal (intact) sensory and motor function rostrally respectively.
The NLI is the most cephalad of the sensory and motor levels determined in steps 1 and 2.

4. Determine whether the injury is Complete or Incomplete.
(i.e. absence or presence of sacral sparing)
*If voluntary anal contraction = **No** AND all S4-5 sensory scores = **0** AND deep anal pressure = **No,** then injury is **Complete.** Otherwise, injury is **Incomplete.***

5. Determine ASIA Impairment Scale (AIS) Grade:

Is injury Complete? **If YES, AIS=A** and can record ZPP (lowest dermatome or myotome on each side with some preservation)

NO ↓

Is injury Motor Complete? **If YES, AIS=B**

NO ↓ (No=voluntary anal contraction OR motor function more than three levels below the motor level on a given side, if the patient has sensory incomplete classification)

Are at least half (half or more) of the key muscles below the neurological level of injury graded 3 or better?

NO ↓ **AIS=C** **YES** ↓ **AIS=D**

If sensation and motor function is normal in all segments, AIS=E
Note: AIS E is used in follow-up testing when an individual with a documented SCI has recovered normal function. If at initial testing no deficits are found, the individual is neurologically intact; the ASIA Impairment Scale does not apply.

Thyroid-releasing hormone (TRH), gacyclidine, nimodipine, and dynormin

A thyroid-releasing hormone (TRH) trial demonstrated improvements in the NASCIS and Sunnybrook scales in incomplete SCI patients. There, however, this study was criticized for a type I error (attrition with only 20 patients analysed) (Pitts et al., 1995). The gacyclidine trial, although of insufficient statistical power, demonstrated benefit in the treatment group, but this benefit did not persist at 1-year follow-up (Hirbec et al., 2006). The nimodipine trial compared nimodipine and MPSS to placebo (NASCIS II protocol). Neither agent showed benefit (Hall, 2011). Dynormin A, an endogenous opioid, administration showed no benefit in the NASCIS II trial, as well (Bracken et al., 1990).

Ongoing trials

Newer trials on traumatic SCI model are being investigated in two capacities: (1) neuroprotective agents to limit the secondary injury; and (2) neuroregenerative agents aiming at promoting and supporting repair and regeneration of axons (Fig. 67.3).

Neuroprotective capacity: Cerebrospinal fluid drainage, electrical field, hypothermia, and riluzole

Cerebrospinal fluid (CSF) drainage via a lumbar intrathecal line is under investigation in SCI patients, given the evidence of similar strategies reducing the incidence of paraplegia during thoracic aortic aneurysm surgery (Coselli et al., 2002). Generating an electrical field along the spinal axis to promote axonal growth has also shown improvement. (Shapiro et al., 2005). Adapting the protective effects of hypothermia during cardiac arrest to the animal SCI models has been shown to be associated with variable results (Kwon et al., 2008). Recent trials with patients systemically cooled to 33°C (91.4°F) demonstrated a beneficial effect of cooling (Levi et al., 2010). However, current evidence is insufficient to support the use of therapeutic hypothermia as a standard guideline. Riluzole, a sodium blocker and an antiseizure medication, in combination with MPSS, showed a protective effect even administered at 10 days after injury in animal SCI model. (Wang et al., 2004).

Neuroregenerative capacity

Attention has been focused on cell replacement therapy. Activated autologous macrophage transplants have shown promising results in a phase I trial, but the multicentre phase II trial was suspended due to financial problems (Knoller et al., 2005). Schwann cells play is known to play an important role in facilitating regeneration of the peripheral nerve. Olfactory ensheathing cell transplantation is safe and feasible, with up to 1 year follow-up. However, long-term follow-up results are variable (Lima et al., 2006). A trial of autologous human bone marrow stromal cells, combined with granulocyte macrophage colony stimulating factor, revealed benefit in acute SCI patients, but not in chronic SCI patients (Park et al., 2005). Human embryonic stem cell transplantation showed promising results in a rat SCI model. However, the FDA placed the human trial on hold due to the risk of tumourigenesis (Keirstead et al., 2005). Rho is an axon growth inhibitor protein that results in neuronal growth cone collapse, neurite retraction and cell body rounding,

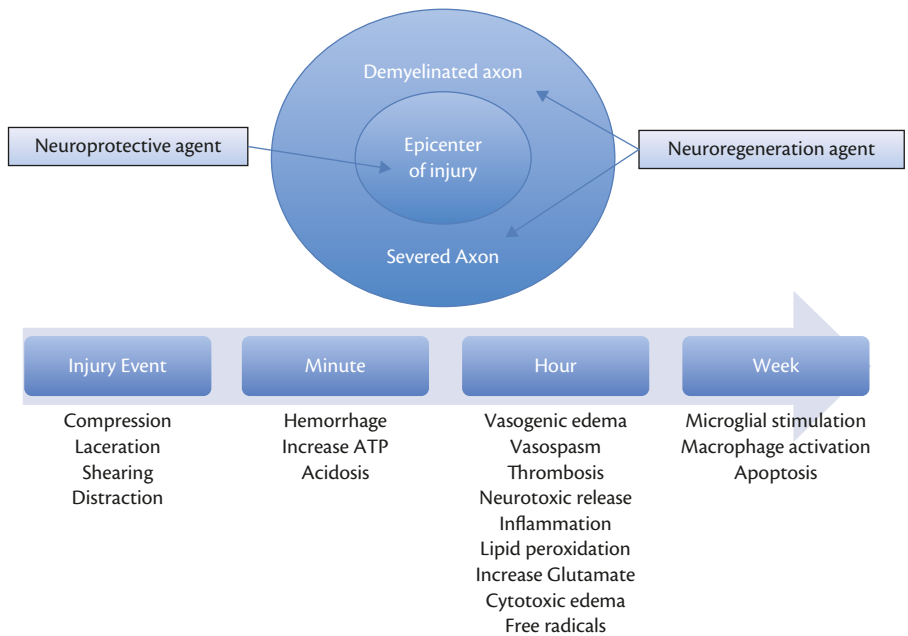

Fig. 67.3 Primary and secondary mechanisms of injury determining the final extent of spinal cord damage. The primary injury event starts a pathobiological cascade of secondary injury mechanisms that unfold in different phases within seconds of the primary trauma and continue for several weeks thereafter.

and rho associated kinase inhibitor and C3 transferase demonstrated effective cortical neuron regeneration in an *in vitro* study (Dergham et al., 2002). Local injection of activated autologous macrophages that are preincubated with sciatic nerve or skin has demonstrated a decreased synthesis of neurotoxic tumour necrosis factor (TNF-alpha), thereby promoting neuroprotective and neuroregenerative strategies (Bomstein et al., 2003).

Conclusions

SCI is a global problem with an enormous impact on financial, social, and personal cost. Treatment of the primary injury has proven amenable at present. Efforts have been made, with some success, to prevent and reduce the incidence of SCI. Secondary injury involves multiple pathophysiologic processes. Clinical guidelines have been established to minimize secondary injury. Newer pharmacological and biological agents are currently under investigation to mediate secondary mechanisms. With lessons learned from the completed trials in the past, a more effective management of SCI will obviously require multiple treatment modalities. Targeted to minimize initial damage, preserve residual function, and enhance recovery. It is hoped that a collaboration of multispecialist scientists and clinicians, will accomplish neural restoration after SCI in our lifetime.

Controversy

Early decompression surgery for spinal cord injury

Animal spinal cord injury models have demonstrated benefit from early decompression (Dimar et al., 1999). Benefit, however, is less clear in humans, especially in polytrauma patients. The first randomized prospective study regarding timing of surgery revealed no significant benefit when cervical spinal cord decompression after trauma is performed less than 72 hours after injury, as opposed to waiting longer than 5 days (Cadotte et al., 2010). The first randomized prospective trial, Surgical Treatment of Acute Spinal Cord Injury Study (STASCIS) demonstrated improved neurologic outcome, defined as at least an improvement by two grades on the AIS in patients who were decompressed prior to 24 hours after SCI (Fehlings et al., 2012).

Violent extension injury to a pre-existing degenerated compromised spine (with spinal stenosis) often results in the classic central cord injury. Poor outcome after early decompression for central cord syndrome has been published (Schneider et al., 1954). It, henceforth, has been recommended to avoid early surgery for central cord injury. Controversy has arisen when subsequent studies demonstrated benefit from early surgery. (Aito et al., 2007). Much remains unknown regarding the management of central cord syndrome. Therefore, practice patterns have often relied on clinical experience rather than scientific evidence.

Reports of mechanism of injury, the level of injury, and the timing of decompression on functional outcome from thoracic SCI are limited. A retrospective registry study compared recovery and outcome data in three groups: a control group (n = 93), an early surgery group receiving treatment within 72 hours (n = 156), and a late surgery group receiving treatment after 72 hours (n = 49). It showed the early surgery group fared significantly better than the late surgery group with regard to ventilator dependence, ICU stay, hospital length of stay, mortality, and pulmonary failure (Schinkel et al., 2006).

Cervical spine injuries

Calan Mathieson, Chris Barrett, and Likhith Alakandy

Introduction

The management of cervical spine fractures is a complex and fascinating topic. A multitude of descriptive terminologies and classification systems have been developed over the years in an attempt to better understand this heterogenous group of patients. Despite this however, there is often little consensus with regards to the best way to manage this population. This chapter will predominantly discuss the decision-making process involved in the management of cervical spine fractures.

The goal of the spine surgeon in managing patients with acute cervical spine injury is to prevent secondary neurological injury, deformity, and pain by re-establishing stability if necessary. Assessing how to achieve this goal can be very challenging. The surgeon will be faced with many questions. Which patients should undergo surgical intervention? Which operation will best stabilize the spine? Which patients should be treated with a collar or a halo vest? Does the injury require reduction with traction initially? There are also questions of timing. When should the surgeon plan the proposed procedure?

Cervical spine fracture incidence

The incidence of cervical spine fractures is estimated to be 9.2–12/100 000/year (Hu et al., 1996; Brolin and von Holst, 2002). There is a male predominance and the incidence is commonly reported as having two peaks, the first between age 15–45 years and the second 65–80 years. The mechanism of injury differs between these two groups, with the older population most commonly fracturing the C2 odontoid process in simple falls. The younger population is more likely to injure their cervical spine as a result of higher velocity injuries (Blizzard et al., 2016). Overall, approximately 10% of cervical spine fractures will be associated with neurological injury.

The association of cervical spine injuries with head injuries is well established. The reported incidence of cervical spine trauma in head injured patients ranges from 4% to 14% (Nazir et al., 2012). Those patients with moderate to severe head injuries are at the highest risk of concomitant cervical spine injury. The NICE guidelines advise a CT scan of the cervical spine in any head injury patient who fulfils the criteria for a head CT.

Assessment of the patient with a potential cervical spine injury

Assessment of potential cervical spine injuries requires careful history, examination, and investigation. Clearly a good history and examination will require a fully conscious patient. In fully conscious patients with no neck pain or tenderness, normal neurological function, and no distracting injuries (and no intoxication), the cervical spine can be cleared without the need for radiological assessment. The NEXUS group (National Emergency X Radiography Utilization Study) showed that significant bony cervical spine injury could be excluded when applying these rules (Eyre, 2006).

However, trauma patients who are not fully conscious or have distracting injures or are intoxicated will require radiological assessment. Three view radiography (lateral, open-mouth odontoid and anteroposterior (AP) X-rays of the cervical spine) and CT scans can all be utilized if necessary. Flexion/extension films are not recommended in the acute setting. MRI scans are helpful to assess damage to the posterior ligamentous complex and disc structures. They will provide significant information regarding the contents of the spinal canal. MRI is usually used, when necessary, and following a CT scan.

Trauma patients who fulfil the criteria for a head CT scan should also have a cervical spine CT scan. Patients with moderate or severe head injuries may be neurologically unassessable for several weeks. In these circumstances the author will remove the collar if the fine cut CT scan demonstrates no bony injury and no malalignment. The risk of missing a ligamentous injury with a normal modern CT scan is very low indeed and the risk of pressure sores around the cervical spine area secondary to a cervical collar is not insignificant (Eastern Association for the Surgery of Trauma, 2015). If the patient subsequently improves neurologically to the level required for clinical assessment, the cervical spine should be assessed again.

Every care should be taken to maintain alignment during the assessment period to minimize secondary injury. Special attention should be paid to the ankylosing spondylitis patient. These patients are particularly vulnerable to cervical spine fractures, often in low velocity impacts. A high degree of suspicion is required in these patients to make the diagnosis of a cervical fracture. Care should be taken when immobilizing such patients as it is not sensible to position these patients completely flat if the shape of their cervical spine precludes this position. They should be immobilized in their

preinjury flexed position and not forced into supine. A high degree of suspicion should also be given to patients who have a dangerous (i.e. high velocity) mechanism of injury and the elderly population (Clinical Effectiveness Committee, 2010).

Assessment of cervical spine trauma

Having made a diagnosis of a cervical spine fracture, the patient should continue to be treated appropriately to reduce the risk of secondary neurological injury. Careful immobilization should continue. Catheterization, placement of a nasogastric tube, prescribing low molecular weight heparin and a proton pump inhibitor may be necessary in those with spinal cord injury. Further information should then be sought that will enable the surgeon to make appropriate decisions about definitive management of the fracture.

When assessing a cervical spine injury, one must consider many important factors. These can be broadly subdivided into those obtained by history, examination, and investigation. One cannot make a sensible decision about how best to manage a cervical spine injury purely on radiological assessment.

When taking a history, the age of the patient, presence of underlying conditions such as ankylosing spondylitis or osteoporosis, and the velocity and mechanism of injury (is this a flexion or extension injury with axial loading?) must all be assessed. A history of tingling or weakness in the limbs at any time following the injury is important, the presence of other injuries should be recorded.

The patient should be examined to look for neurological signs, tenderness, increased distance between spinous processes, bruising around the spine, or deformity.

Investigations will frequently include X-rays, CT, and sometimes MRI scanning.

Classification systems

Classification systems are used by many clinicians and academics to aid communication, understanding, and decision-making about subsequent management. Over the years, there have been many different classification systems proposed to simplify and categorize cervical spine injuries. Criticism of these systems broadly falls into two categories, namely that the system is too complicated to be widely adopted or that it is an oversimplification of a varied and heterogenous group. A working understanding of some of these systems is advantageous as they highlight key elements of the information required to make sensible decisions about subsequent management.

Classification systems use different aspects of the aforementioned. The earlier systems tended to focus on the mechanism of injury while the newer classifications have favoured radiological and neurological status.

Allen's classification

In 1982, Allen et al. (1982) published a classification system based on the mechanism of injury. Subcategories included compressive flexion, vertical compression, distractive flexion, compressive extension, distractive extension, and lateral flexion. Each subcategory was further subdivided depending on the radiological severity of the injury. Commonly used phrases such as a burst fracture would be roughly equivalent to a moderately severe compression flexion injury. The importance of the posterior longitudinal ligament complex was commented on with more severe extension injuries demonstrating complete disruption of this important structure. The authors demonstrated the chance of neurological injury increased as the type and severity of the spinal column injury increased.

A full description of this system can be found elsewhere. The subcategories, although still useful today, are all based on plain X-rays. Modern imaging modalities with CT and MRI scans have led to newer classification systems being developed.

The subaxial injury classification (SLIC)

The anatomy of the C1 ring and C2 are very different to the anatomy of the remaining five vertebrae in the cervical spine (Vaccaro et al., 2007). The subaxial spine can be regarded as any level of the cervical spine below the inferior border of the C2 vertebral body. The subaxial injury classification score derives a score from morphological, ligamentous, and neurological information. See Table 68.1

Disruption of the ligamentous complex can be considered likely in the presence of facetal malalignment, abnormal widening of the anterior disc space, kyphosis over a motion segment or high signal on a STIR MRI sequence.

The Cervical Spine Injury Severity Score (CSISS)

This system can be used to grade the instability of fractures (Anderson et al., 2007). It supposes a four-column model of the cervical spine (the anterior, posterior, right lateral, and left lateral). The system uses a scoring system, where zero to five points are awarded based on the severity of the injury to bone and ligamentous structures in the four spinal columns. The scores are added together to give a final CSISS score.

Assessment using this system has proven to have a good interobserver coefficient, ranging from 0.75 to 0.98, with an average of 0.88. It is claimed that this grading system can predict the need for surgery. This however was only true for those patients with a score greater than seven (all of whom underwent surgical treatment) compared to 4 of 20 patients who scored less than seven.

The authors would advise using these scoring systems to become familiar with them. Prior to calculating the score however, one should think about all aspects of the patient's case and make a decision about their best management. The scoring systems are guides and should not be followed in all cases. For example, it may not be appropriate to manage an elderly patient surgically if the risks of anaesthesia preclude this. Other patients may simply refuse surgery. Some patients will require strict bed rest for a period of time due to

Table 68.1 The subaxial injury classification score

Morphology	Discoligamentous complex	Neurological injury
0 No abnormality 1 Compression 2 Compression with burst 3 Distraction 4 Translation rotation	0 Intact 1 Indeterminate 2 Disrupted	0 Intact 1 Root injury 2 Complete cord injury 3 Incomplete cord injury 4 Cord compression +1 in the setting of a neurological deficit

other injuries. This may mean that some fractures could be managed conservatively with bed rest when the aforementioned scores would suggest operative management.

Management of common eponymous cervical spine fractures

Jefferson's fracture

This eponymous fracture is a burst fracture affecting the C1 ring. It was originally used to describe a four-point fracture of the C1 bone, with two fractures noted to affect the anterior arch and two fractures of the posterior arch. Other patterns of bony injury are also often seen in the C1 ring. Examples are provided in Figure 68.1. Approximately 30% of C1 fractures will be associated with C2 fractures.

Isolated C1 fractures are only rarely associated with neurological injury as the bony elements tend to move outwards, away from the neural elements. The typical mechanism of injury is axial loading. It is important to assess for injury to the transverse ligament which can be indirectly assessed by measuring the atlantodental interval on a CT scan. This is usually less than three millimetres in adults and less than five millimetres in children. Sometimes a fleck of bone may be seen on an axial CT scan where the ligament has been avulsed for the medial side of the C1 lateral mass. When the transverse ligament is ruptured the lateral masses of C1 move outwards. On a transoral PEG view or coronal CT reconstruction the distance between the lateral edge of C1 and the lateral edge of C2 can be measured. Spence's rule of seven states that if the sum of the two sides is more than 7 mm then the transverse ligament is ruptured. Only very rarely is surgical intervention required for treatment of C1 fractures. If the transverse ligament is damaged, they are usually managed in a halo, if the transverse ligament is intact a collar is adequate.

Hangman's fracture

Hangman's fracture is a traumatic spondylolisthesis of the axis. See Figure 68.2. Although historically these fractures were noted following judicial hangings, the mechanism of injury most commonly associated with this pattern of fracture is road traffic accident.

Hangman's fractures have their own specific classification systems. The Effendi classification system later modified by Levine and Edwards has been used in 12 further papers assessing management of these injuries (Li et al., 2006). See Table 68.2.

A recent meta-analysis (Li et al., 2006) stated that 62.5% of publications advocated that primary therapy for Hangman's fractures should be conservative. The results of the metanalysis indicate that surgical intervention is not necessary in most type I, Effendi type II, and Levine-Edwards type II fractures. Patients with Levine-Edwards Type IIa and III fractures should be considered for surgical management. These are more likely to be associated with injury to the C2/3

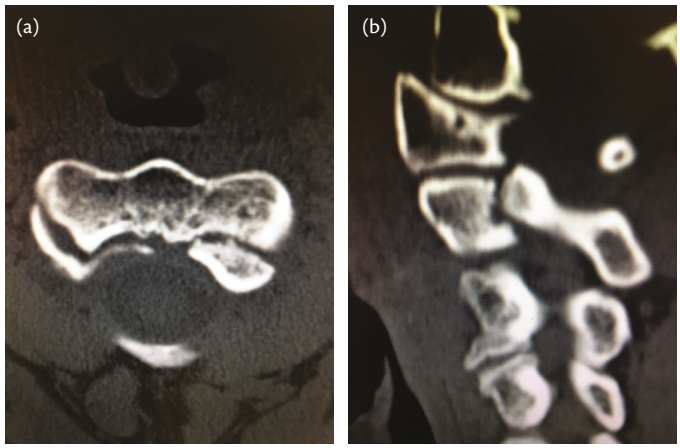

Fig. 68.2 Axial and sagittal image of Hangmans' fracture.

Table 68.2 Levine and Edwards Classification (OrthopaedicsOne, 2012)

Type I	Minimal translation (<3 mm) without C2–C3 angulation; stable
Type II	Significant C2–C3 angulation and translation (>3 mm); disc disruption, unstable
Type IIa	More angulation than type 2, without translation; unstable due to flexion-distraction injury
Type III	Severe C2–C3 angulation and translation; sometimes uni-/bilateral facet dislocation; unstable

disc, thus making the resulting overall injury less likely to heal well without surgical fusion. Conservative management is normally with a halo.

Anterior and posterior approaches are described to treat Hangman's fractures. The authors favour an anterior approach with a C2/3 anterior cervical discectomy and fusion. This can be approached via a submental incision to gain access to the appropriate level of the spine.

Odontoid peg fractures

Odontoid peg fractures (Fig. 68.3) are most common in elderly patients, following a fall but can also occur in younger patients following cervical hyperflexion or hyperextension injuries. This injury accounts for 10–15% of all cervical spine fractures. There are three types of fracture as described by Anderson and D'Alonzo (Table 68.3).

It is important to differentiate os odontium which is benign, chronic, and thought possibly to relate to longer term non-union of an old fracture or a failure of ossification of the dens during development.

Type I fractures are very rare but require no treatment except analgesia. Type III fractures are generally quite likely to fuse with conservative management in a halo (or a collar for elderly patients unable to tolerate a halo).

The treatment of type II fractures, however, remains controversial. They are associated with higher rates of non-union (20–30%) when compared to the type I and type III fractures. Some patients, especially older people, with type II odontoid peg fractures but without transverse ligament disruption will develop fibrous non-union and may remain asymptomatic. In others however, there can be pain, stiffness, myelopathy, and chronic instability. Non-operative treatment with cervical braces or a halo vest do not achieve rigid immobilization and are known to be associated with a higher risk of non-union than surgical techniques. Halos in particular are very poorly tolerated by elderly patients where a collar may be the only option.

The usual surgical techniques used for odontoid peg fractures are either anterior odontoid peg screw fixation or posterior C1/C2 fusion using either transfacetal screws or Harms technique. A rescue technique is craniocervical fixation without fusion where the metal work can be removed once the peg fracture has fused.

The anterior approach has the advantage of preserving motion and should therefore be considered as the surgical treatment of choice for type II fractures (Apfelbaum et al., 2000). However, not all patients are appropriate for direct anterior fixation of the fracture. Patients should carefully be evaluated with CT and MRI scans for the integrity of transverse ligament of the atlas and those with disruption of the transverse ligament should be treated with posterior C1/C2 fixation. The morphology of the fracture is also an important consideration. Comminuted fractures or fracture lines that do no enable the screw to be placed adequately should not be considered for this procedure. Similarly, fractures that cannot be easily reduced to a satisfactory position with gentle extension of the spine may also not be suitable. Large patients or patients with barrel chests may pose difficulty in obtaining an optimum trajectory for screw placement. Poor bone quality is a relative contraindication due to the risk of the screw 'cheese wiring' through the distal fracture fragment. The chance of achieving bony union is significantly lower in non-acute fractures and in such cases with instability, posterior C1/C2 fixation should be considered. Single-screw anterior odontoid fixation is associated with a relatively low complication rate and a high fusion rate and should be the technique of choice (Subach et al., 1999; Lee et al., 2004).

Facet fracture dislocations

Uni (Fig. 68.4) and bifacetal (Fig. 68.5) fracture dislocations are the most common significant injuries in the subaxial spine. They occur as a result of flexion and distraction commonly following sporting or vehicle accidents.

Unifacet fracture dislocations occur when the superior facet which is normally behind the inferior facet 'jumps' onto the anterior surface of the inferior facet on one side. This produces a rotational

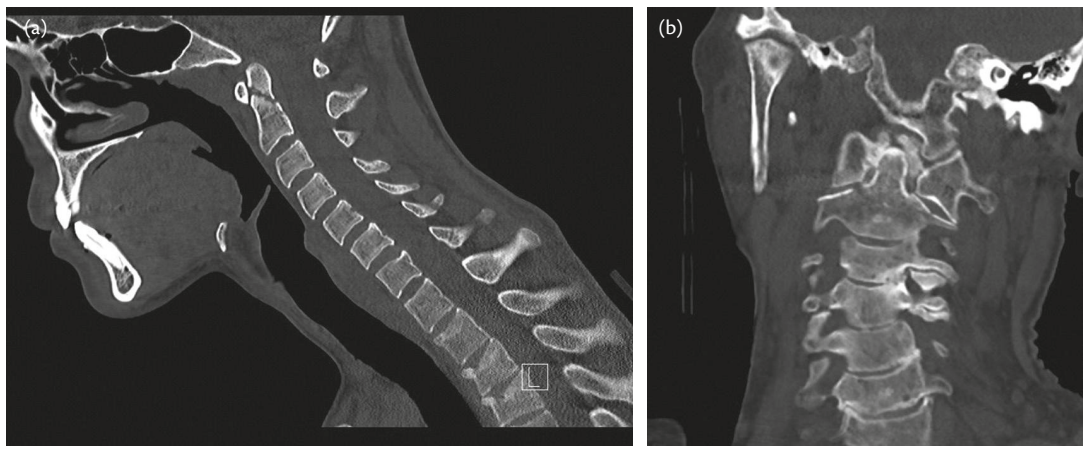

Fig. 68.3a (A) Type 2 peg fracture. (B) Type III peg fracture.

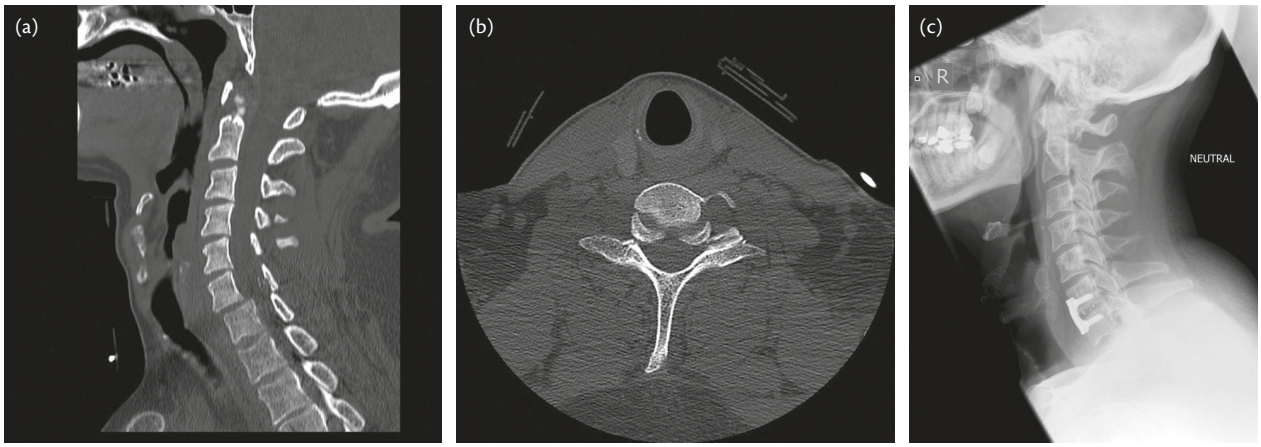

Fig. 68.4 Unifacetal dislocation at C6/7. (A) 25% dislocation on midsagittal CT scan. (B) Left-sided jumped facet shown on axial CT scan. (C) Postoperative X-ray showing reduction and anterior cervical discectomy and fusion.

malalignment which when viewed on a lateral X-ray appears as a 25% anterior subluxation of the superior vertebral body. The spinal cord is rarely affected but the nerve root exiting at that level may be compromised and radiculopathy may occur. A dislocation without a fracture can occur and a partial dislocation or perched facet is also sometimes seen. The C7/T1 level may be affected, thus a lateral X-ray may only be considered adequate if it shows the top of T1.

Bifacetal fracture dislocations are usually accompanied by spinal cord injury with complete spinal cord injury being common. These injuries are not rotational, they are true anterior subluxations, a lateral X-ray will show 50% or more subluxation.

The management of these fractures is covered in the controversy section of this chapter.

Other subaxial fractures

Patients may present with undisplaced cervical spine fractures of the lamina, pars interarticularis, or spinous processes, for example, the clay shoveler's fracture (spinous process avulsion fracture, most commonly C7), is well described (see Fig. 68.6). For the most part these fractures can be managed non-operatively, usually with just a collar, but careful observation is required as a small proportion will subsequently progress. This seems to be particularly true of fractures affecting the pars interarticularis where some authors do recommend early surgical intervention or halo immobilization.

Tear drop fractures from hyperextension injuries are fractures through the inferior, anterior portion of the vertebral body and are easily dismissed as insignificant (see Fig. 68.7). When a tear drop fracture is seen, and MRI confirms disc and/or ligament injuries, then surgery is the most definitive treatment. These being ligamentous injuries, they tend not to heal and most authors recommend surgical fusion.

Management options when treating cervical spine fractures

Cervical collar

A well-fitting rigid cervical brace is an effective way of restricting movements in the cervical spine, especially flexion and lateral flexion. In the surgical setting they are commonly used to immobilize a relatively stable spine injury during healing and often to provide additional support to the spine following surgical fixation.

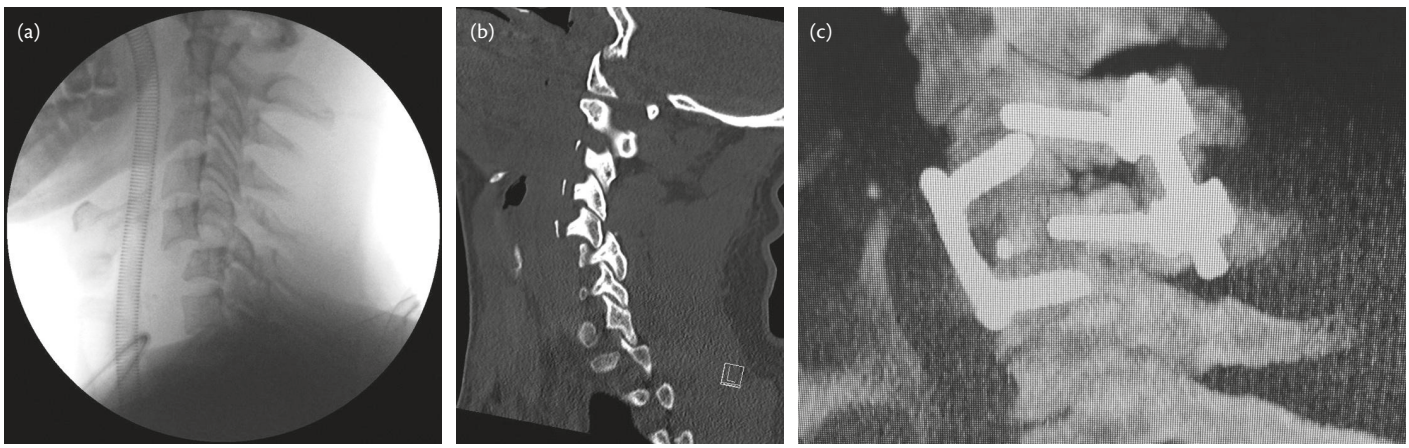

Fig. 68.5 (A) Bifacetal dislocation, shown on X-ray and (B) parasagittal reconstructed CT scan. (C) Sagittal reconstructed CT post anterior and posterior fixation at C4/5.

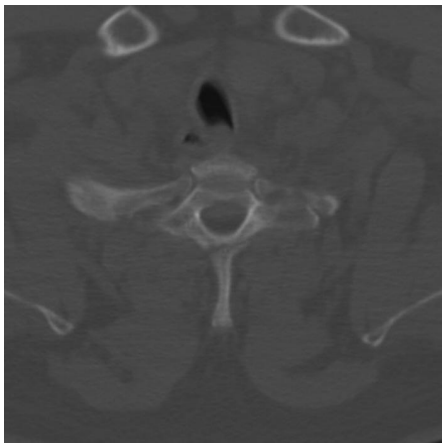

Fig. 68.6 Clay shovelers' fracture on axial CT image.

A collar is also used frequently by emergency personnel as an adjunct to spinal immobilization in patients who have sustained or are suspected to have sustained cervical spine injuries to prevent secondary spinal cord injuries. Less commonly they are also used for comfort and symptom relief following less serious soft tissue injuries. The effectiveness of immobilization diminishes in the lower cervical and cervicothoracic levels, where extensions to the cervical brace to incorporate the chest wall or halo immobilization may be necessary.

Fitting instructions

A range of rigid collars by various manufacturers are available. The typical design is a two-piece hard shell secured with straps and lined with removable soft padding. In addition to minimizing the risk of pressure related complications, a comfortable and well-fitting collar also improves patient compliance. When applying a collar in a patient with an unstable spine it is essential that the head and neck are kept in proper alignment throughout the procedure. The back piece of the collar is first carefully slid underneath the neck, and then the front piece is placed snugly against the patient's neck and secured with straps. In more stable cases the collar can be applied with the patient in an upright position. Once the collar is in place, it is important to ensure that the support extends from the mandible to the sternal notch and the pressure points are well padded. The tracheal opening and midline vents should be in the midline.

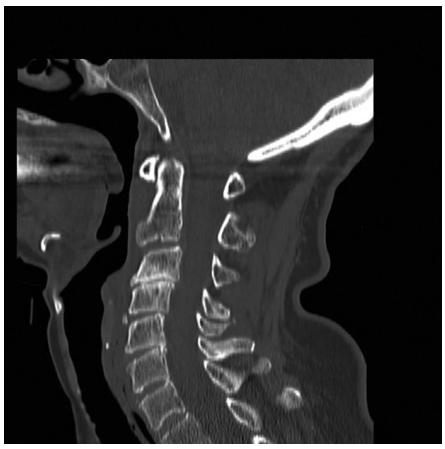

Fig. 68.7 Teardrop fracture of C2.

Complications

The main complication associated with a cervical collar is development of pressure ulcers. This risk of collar related skin problems includes minor erythema to serious ulcers and up to 10% of patients develop these complications with prolonged usage.

Cervical traction

Cervical spine fractures and traumatic subluxations/dislocations are generally treated by considering the principles of reduction, decompression, and stabilization. The aim is to achieve skeletal reduction and, if possible, decompression of the spinal cord. Stabilization self-evidently cannot be achieved by traction alone.

Cervical spine traction, which ultimately is a form of closed reduction, may be used in advance of, or occasionally as an alternative to, open reduction. In this context, if a good re-alignment can be achieved, and if patient factors preclude early surgery to stabilize the spine, the patient may be placed in temporary or definitive external immobilization (halo vest or Minerva cast).

The most effective methods of applying traction utilize tongs or a halo ring which are directly pinned to the skull. Systems which use slings or straps should be avoided: pressure sores on the chin are an extremely likely outcome and it is more difficult to apply the force in a precise direction. The ring or arc is then connected to vertically placed weights via a rope or cord which passes through a pulley, minimizing friction, and ensuring that the horizontal component of the force is directly pulling on the skull.

Tongs such as the Gardner-Wells tongs rely on two pins only. They are relatively easy to apply, especially if the clinician has limited assistance out of hours. An external, visible pin 'pops-out' usefully indicating when the skull pins have been tightened to the correct torque.

A halo ring (usually but not always an incomplete ring or C-shape) relies on a minimum of four-point skull fixation. It is slightly more difficult to apply than tongs and is often more uncomfortable for the patient as it can be difficult to achieve adequate local anaesthesia for the posterior or parietal pin sites in particular. It has, however, the distinct advantage that once adequate reduction is achieved there is an option to fit a temporary or permanent halo vest more easily.

Once the tongs or halo ring have been applied to the skull the rope is connected and passed through the pulley. By adjusting the angle of the pulley, force can be applied in the desired direction. It is important not to overly flex in an attempt to reduce the fracture as respiratory deterioration has been reported (Harrop et al., 2001). Gradually the weight can be increased, which requires good nursing care, often with careful analgesia and occasional judicious use of benzodiazepines. Regular lateral X-rays and careful patient observation for new or worsened neurological symptoms are necessary.

Various rules of thumb exist regarding the appropriate weight, which are generally dependent on the cervical spine level involved. Starting with a weight of 2 lbs per level that the fracture is distant from the occiput is reasonable (i.e. to reduce a C5 injury), a starting weight of 10 lbs is required. It is important to emphasize that often far greater weights are required to achieve reduction but these are

gradually added, with careful clinical and radiological observation, as described earlier. If neurological deterioration occurs the weight should be reduced or removed completely and an X-ray performed. Often full reduction using closed methods is not possible and general anaesthesia and open reduction are required.

In addition to neurological and respiratory deterioration as described, cervical traction is also subject to the pin site complications of the halo ring, although often traction is not of sufficient duration for such complications to occur, usually being in place for a matter of hours up to a day or two prior to definitive surgery. Prior to traction placement, an MRI should be performed. This is most important in situations of intact or partial neurological deficit, where, for example, a large disc fragment or haematoma can make closed reduction dangerous.

Halo immobilization

A halo is a more rigid and more invasive method of immobilization of the cervical spine. It consists of a ring secured to the outer table of the skull using pins, connected via adjustable metal rods to a fitted hard vest or jacket with a padded lining (Lind et al., 1988). This enables the patient to be mobile, while providing a considerably better degree of immobilization than a cervical brace. The adjustable rods provide precise control of the position that the cervical spine needs to be immobilized in. The halo crown and vest immobilization may also be used to provide stability during preoperative transfer, and also on occasions to supplement surgical fixation.

When applying the halo crown and vest, it is essential that the head and neck are kept in proper alignment throughout the procedure. The halo is typically fixed to the skull by four pins, two in the frontal region, one centimetre above the orbital rim and two in the posterior parietal region, posterior to the ears. The pins are inserted under local anaesthesia, with the eyes closed when applying the frontal pins. A torque wrench is used to prevent overtightening. The vest, which is formed by separate anterior and posterior components is then positioned and secured with straps. The metal rods are secured to the vest and connected to the halo crown. These versatile rods afford flexibility when positioning the spine. When all the rods are secured, the position of the cervical spine is confirmed with X-rays. The halo should be checked at regular intervals, during which the hardware is retightened and the pins inspected for loosening or infections. The position of the spine should also be checked radiographically. The duration of halo treatment is dependent on individual biology, but three months' duration is sufficient for most fractures.

Most patients tolerate a halo crown and vest well, although some may have difficulty mobilizing or sleeping with the halo fixator in the initial days. Pin loosening is often characterized by pain and can be visibly evident (Vertullo et al., 1997). This is avoided by inspecting the pin sites at regular intervals, more frequently in the initial period. Pin site infections are usually superficial and reported in 10–20% of patients. This may require repositioning of the pins and antibiotics. More serious infections like osteomyelitis of the skull and intracranial abscess secondary to skull penetration have been reported, but are exceedingly rare (Rizzolo et al., 1993; Van Middendorp et al., 2009). A pressure sore or localized skin breakdown can be caused by direct pressure from the vest or halo. Patients with respiratory difficulties may find it hard to tolerate the vest.

Surgical techniques

Subaxial posterior cervical fixation (C3–C7)

Posterior cervical fixation is indicated where instability is already present or is likely to result as a direct consequence, either immediate or delayed, of surgical decompression. Specific indications include trauma with bony or ligamentous instability, discitis/osteomyelitis with instability and kyphosis, degenerative spine disease with kyphosis or anterolisthesis, and where decompression is required (most commonly for myelopathy).

It is extremely important to add that any fixation, no matter how expertly constructed, will ultimately fail unless bony fusion or indeed fracture union is achieved. It is therefore incumbent upon the surgeon to fuse the spine after fixation and decompression have been undertaken. This involves the standard process of decortication of the graft recipient site followed by placement of autologous bone graft, either locally or remotely procured (e.g. bone removed following laminectomy or iliac crest graft).

A number of possible techniques exist, and these have gradually evolved over the years. Posterior cervical wiring and transfacet screws are best considered as salvage techniques where other methods are not possible or have failed.

Case series of cervical pedicle screws are reported in the literature. The pedicles in the lower cervical spine (C6 and C7) may have pedicles of sufficient calibre to present a useful surgical target, the mid-cervical spine less so. Nevertheless, the authors would contend that the presence of the vertebral artery in the foramen transversarium from C6 upwards, presents a specific, additional possible complication such that lateral mass screw placement remains the gold standard technique for posterior cervical fixation (Yoshihara et al., 2013).

Preoperative workup should include general considerations such as fitness for anaesthetic, in the context of lying prone for several hours. Specific considerations include the possibility of osteoporosis. While not an absolute contraindication to surgery, caution is required if the bone quality is extremely poor the screws may not gain an adequate hold. In such situations, there may be no alternative to lateral mass fusion without fixation with postoperative placement in a halo vest.

Standard preoperative workup is likely to include both CT and MRI and possibly dynamic imaging, either plain radiography or CT. The reconstructed CT scan is often the most useful test as it is possible to estimate screw size and trajectory and spot common pitfalls. These would include an extremely small lateral mass, often at C3, making screw placement difficult or an aberrant vertebral artery course, as indicated by the foramina transversaria. If the surgeon has specific concerns about the course of the vertebral artery, CT angiography of the neck vasculature is indicated.

Under general anaesthesia, the patient is placed prone on a suitable mattress and table in a reverse Trendelenburg position. The authors would strongly advocate the use of skull pins (e.g. Mayfield clamp) as opposed to a foam headrest or pillow. This allows more accurate positioning with intraoperative adjustment as required. It also avoids any pressure on the face or eyes and affords the anaesthetist good access at all times.

Once the patient has been positioned, lateral screening using the image intensifier should be undertaken, both to plan the skin

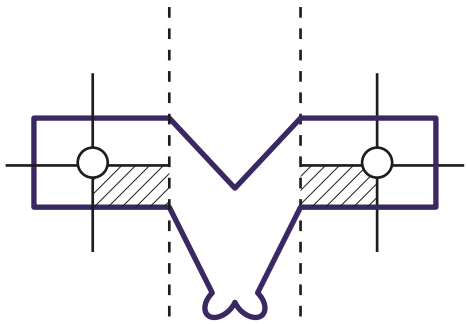

Fig. 68.8 Surgeon's view of the exposed lateral masses. The entry point is generally in the midpoint of the square or just inside the inferomedial quadrant (shaded).

incision and assess the cervical spine contour: a slight degree of flexion will improve access and exposure but fixation in an unduly flexed position should be avoided.

A midline incision is made and the avascular midline raphe is followed to the level of the spinous processes after which bilateral muscle stripping to expose fully the laminae and lateral masses is undertaken. Further lateral screening is required to confirm the levels to be instrumented.

Reduction of facet dislocations from the back can usually be carried out under direct vision of the dislocation, sometimes the inferior facet may need to be drilled off before reduction will occur. Care should be taken to avoid damage to the nerve root.

The surgeon should carefully define the lateral, superior, and inferior edges of each lateral mass: the medial edge of the lateral mass is at the point where the lamina, sweeping downwards, ends, and there is a distinct change of contour.

The lateral mass itself now presents a square to the surgeon. The entry point is effectively in the midpoint of this square or perhaps very marginally in the inferomedial quadrant (Fig. 68.8). A high-speed drill with burr is used to break the cortex.

The two primary considerations at this point are to aim the hand drill laterally enough to avoid the vertebral artery in the foramen transversarium and to aim superiorly enough to avoid the exiting nerve root in the neural foramen (Fig. 68.9). Several different screw angulations are described. Generally speaking an angle of around 20° in both the axial and sagittal planes should be sufficient. An instrument placed in the adjacent facet joint can give a useful indication of the screw trajectory in the sagittal plane, which in any regard should be confirmed and guided by radiographic screening or image guidance. Often the correct trajectory in both planes involves the drill resting on the spinous process immediately inferior to the level which is being instrumented.

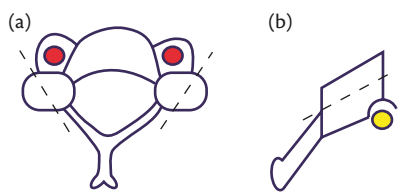

Fig. 68.9 Schematic diagram demonstrating the appropriate screw trajectory on the axial (A) and sagittal (B) planes. On the axial plane, the surgeon must aim laterally enough to avoid the vertebral arteries (red) and on the sagittal plane, superiorly enough to avoid the exiting nerve root (yellow).

After drilling has been completed and the drill tract has been carefully assessed for possible breaches using a ball-tipped probe, a 3.5 mm diameter screw of requisite length is placed (often around 14–16 mm if unicortical fixation is planned, slightly longer if bicortical). Once all the screws are positioned in a similar fashion, 3 mm diameter rods, cut and contoured to the desired length and shape are placed within the polyaxial screw heads on both sides. After appropriate final tightening, final X-ray screening is performed. Washout, fusion, and wound closure are then undertaken in the standard fashion.

Posterior C1/C2 fusion

This technique is covered in Chapter 58.

Craniocervical fixation

Craniocervical fixation is used if there is occipitocervical dislocation or a grossly unstable C1 fracture where this surgical option is preferred. Fixing from the occiput to C2 or the subaxial cervical spine is a morbid procedure, which patients find disabling, rendering the occipitoatlantal +/– the atlantoaxial joints completely immobile. It should only be utilized where other methods will not suffice (i.e. in circumstances of severe instability; see Bhatia et al., 2013).

Careful intraoperative positioning to ensure as 'anatomical' a position as possible is vital: an overly flexed position can make it extremely difficult to swallow; an overly extended position makes it difficult to walk due to an inability to see one's feet and an alteration of sagittal balance.

Once the patient is adequately positioned, prepared, and draped an incision is made from the external occipital protuberance inferiorly (the lower limit depending upon the planned lower limit of the fixation). The muscles are stripped to expose the occipital bone and the laminae and lateral masses. The techniques of C1, C2, and subaxial screw insertion is as described elsewhere.

Various occipital plates exist, most aim to utilize the naturally thickened keels of bone in the occipital region, the superior nuchal line (with certain transversely oriented plates) or more commonly, the midline from the external occipital protuberance to the foramen magnum (vertically oriented plates). In all cases, it is vital to carefully plan preoperatively (including CT scanning +/– contrast) with particular attention to any venous anomalies which would prevent safe screw placement.

The midline occipital keel thins gradually as it approaches the foramen magnum. Bicortical fixation is preferred. The inner and outer tables must be drilled and tapped to allow screw placement. If the dura is breached, bleeding or a cerebrospinal fluid (CSF) leak can often be plugged by placing the screw in the hole. It is frequently necessary to contour the plate and/or smooth the irregularities of the occipital bone to allow the plate to sit securely and snugly without rocking.

Once the plate and the chosen cervical instrumentation is in place, the rods must be placed to connect the two. The surgeon can contour a straight rod to fit or alternatively, prebent rods exist, which may need little further contouring and thus are stronger but it is almost always necessary to trim both ends to fit. Rod placement, which intuitively seems simple, can often be more awkward and time-consuming than the other parts of the procedure.

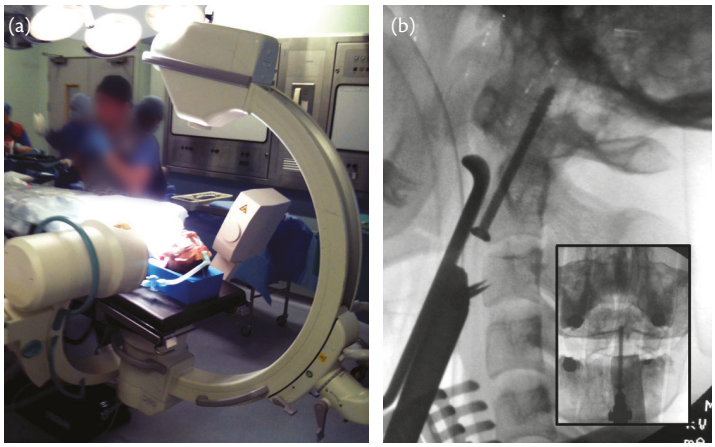

Fig. 68.10 (A) Two image intensifiers set up to obtain simultaneous images of the odontoid peg in both planes and the extended position of the cervical spine. (B) Intraoperative lateral and AP radiograph showing the position of the retractor, screw guide, and a single lag screw in position.

If one is carrying out occipito-cervical fixation for trauma, it is vitally important to decorticate all available bony surfaces and pack with bone graft material and/or synthetic bone substitutes. All metalwork will fail in the long run if fusion does not occur and the head presents a large mechanical lever arm relative to the cervical spine. It is often necessary to carry on with external immobilization postoperatively for a number of weeks until one is confident that fusion is occurring.

Cervicothoracic fusion

Using the techniques described earlier and thoracic pedicle screws (see Chapter 67), unstable junctional fractures that require extending the cervical construct to the upper thoracic spine can be treated. Cranio-cervicothoracic fixation, while possible, is an extremely morbid intervention for the patient and should be avoided if at all possible (Tanouchi et al., 2014).

Anterior odontoid screw fixation

Under general anaesthesia, the patient is positioned supine with the neck in slight extension. Biplanar radiographs should be used, with the second image intensifier positioned to obtain an open-mouth peg view. The mouth is kept open with a radiolucent mouth-gag and the endotracheal tube positioned to one side to ensure an adequate view of the odontoid peg (**Fig. 68.10**A).

The skin incision is marked by projecting the intended screw trajectory on the surface using a lateral X-ray, this typically is at the C5/6 disc level. Using a standard anterior cervical approach, the plane between the carotid sheath and the trachea and pharynx is developed down to the prevertebral space. Lateral self-retaining retractor blades are placed under the partially separated longus colli. An angled retractor blade is then used to extend the approach cephalad up to the C2/3 disc space under lateral X-ray guidance, while remaining within the prevertebral space. This blade is then attached to the lateral blades. A K-wire is inserted into the inferior lip of the C2 vertebral body slightly incorporating the anterior annulus of C2/3, and advanced partly into the body of C2 using biplanar imaging. An outer sleeve is passed over the K-wire with fixation pins anchored to the body of C3 to act as the guide for the inner drill guide and the drill. The superior edge of the annulus of the C2/3 disc and cortex of C2 is bored using a wider bore cannulated drill to create a space to countersink the screw head. The K-wire is removed once the outer sleeve is secured firmly in place. A power drill using a 3 mm drill bit is used to drill a pilot hole along the trajectory marked by the K-wire, using the outer sleeve as the guide. If necessary, the head of the patient or the partially drilled body of C2 can be manipulated, and the distal fragment reduced to achieve a suitable anatomical position. The drill is then advance into the distal fragment, taking it just past the outer cortex of the odontoid peg into the apical ligament. This hole is then tapped with a 4-mm tap through the outer sleeve. At the end of this step, the length of the screw can be measured using the markings on the tap. The screw is undersized by the distance between the fracture fragments, to account for the final compression of the fragments. A partly threaded 4.0 mm titanium lag screw is inserted into the pilot hole using biplanar imaging and tightened ensuring that the fracture fragments are well compressed, and the screw head is counter sunk (**Fig. 68.10B**).

There is evidence to suggest that early operative intervention results in a lower rate of non-union (Apfelbaum et al., 2000; Rao and Apfelbaum, 2005). Elderly patients and patients with osteoporosis have a significantly higher risk of screw failure. Loosening and back out of the screw can occur, where there is failure of bony union resulting in persistent stress at the fracture site. Elderly patients undergoing this procedure have been reported to have an increased incidence of swallowing difficulties, as the oesophagus is more fibrotic and thus less tolerant of retraction (Vasudevan et al., 2014). This may be compounded by the potential for injury to the superior laryngeal nerve, which supplies the cricothyroid muscle and provides sensory innervation to the mucosa of the larynx, it pierces the thyrohyoid membrane at approximately the C3/4 level.

Anterior cervical fusion

Anterior cervical discectomy and fusion or anterior cervical corpectomy are both commonly performed procedure in managing cervical spine injuries. These will provide two column stability with a very high fusion rate. Following removal of the affected disc(s), the surgeon will place either autologous bone graft or a cage filled with bone fragments, followed by an anterior cervical plate. Many surgeons feel it is unnecessary to incise the posterior longitudinal ligament in trauma cases where the aim is stabilization alone. A description of the techniques may be found in Chapter 58.

Internal reduction of a unifacet fracture dislocation may be carried out from the front, after the disc has been removed, by rotating one vertebra on the other using pins in the vertebral bodies, while applying traction. However, if surgery is delayed more than two to three weeks after the injury the facets may partially fuse and reduction from the front will become much more difficult.

Controversy: Unifacetal and bifacetal fractures

In cervical spine surgery, often the diagnosis is clear. The difficult decisions are related to management: conservative or surgical; anterior, posterior, both (360 degree); two, three, or more levels?

Such decisions ultimately come down to clinical judgement. Generally speaking, there are certain principles which can be used to at least guide management. Features which point towards more extensive surgery being required include evidence of gross displacement, multilevel involvement, bilaterality, evidence of ligamentous disruption on MRI and spinal cord injury.

Using these principles, one could consider the case of a unifacetal fracture. Most patients with such an injury do not have a significant spinal cord injury, although they may have a radiculopathy and root compromise, often unilateral. The contralateral facet joint may be intact, the injury confined to a single level, with no evidence of gross ligamentous disruption on MRI. In such circumstances, there may not be any requirement for surgery at all, if a reasonable reduction is achieved, the position could be maintained in halo and vest for sufficient time to allow fracture healing.

Should the position be lost or depending on patient preference, surgery may be required but this would not necessarily require anterior and posterior surgery. If the alignment is good, excellent reduction, fusion, and stability can be achieved from anterior cervical fusion or posterior cervical fusion alone. This avoids a lengthy procedure or indeed a second operation. Some surgeons, however, feel that the extra security of a 360-degree fusion is warranted.

Conversely a bifacetal fracture/dislocation is a very different injury. Often such patients have a complete neurological injury and gross ligamentous disruption on MRI. By its very nature, such an injury is bilateral and involves gross displacement.

Given the much more unstable nature of such an injury, more surgeons would consider anterior and posterior fixation to restore stability, facilitate fusion, and allow neurological rehabilitation. Other surgeons, however, would consider that this injury can also be managed with just an anterior or just a posterior fusion procedure. In the authors' opinion, the best initial procedure is often posterior reduction and fixation, followed by an anterior fusion except where the neurology is incomplete and there is a large anterior disc prolapse. In this case, posterior reduction as a first procedure could make the situation worse. Other surgeons would routinely do an anterior procedure first before doing the posterior part. If reduction cannot be managed from the front, then an anterior, posterior, anterior procedure may even be utilized. There is little consensus on which technique is best.

Thoracic and lumbar spine injuries

Bedansh Roy Chaudhary and Shiong Wen Low

Introduction

Trauma to the thoracic and lumbar spine may be classified using the Magerl's or Thoracolumbar Injury Classification and Severity Score (TLICS) classifications. Management may be conservative with analgesia and bracing or surgical with posterior, transthoracic, or circumferential spinal fusion.

In this chapter the classification of these injuries and their management will be discussed. The techniques to insert pedicle screws and the role of minimally invasive techniques will be explained.

Fracture classification

Older thoracolumbar trauma classification systems include those of Holdsworth, which emphasizes the mechanism of injury; Whitesides, which defines the two-column concept being analogous to a construction crane; Punjabi and White, who developed stability scoring systems; and Denis with a mechanistic classification based on instability pertaining to three columns of the spine.

In 1994, Magerl and colleagues devised a morphological classification system based on a review of over 1400 consecutive TL fractures presenting to their institution (Magerl et al., 1994). It was the most thorough classification based on fracture morphology at the time. The classification divided the injuries into three broad categories—compression, distraction, and axial torque—then labelled them as fracture types A, B, and C, respectively. The severity of injury progressed from A to C and within each group are several subdivisions.

The comprehensive nature of the Magerl classification resulted in 55 different subdivisions of TL fractures, a significant logistical hurdle even to those working in the specialty and its complexity has thus been considered impractical for day-to-day clinical use. In addition, isolated transverse or spinous process fractures were not considered in the AO Magerl classification.

To address these criticisms, the AO Spine Classification group embarked upon developing a consensus for an updated AO Spine TL injury classification system that would provide a reliable, relevant, simple, and robust clinical and academic tool for global application and would embody as many of the ideals of a TL classification system as possible. This resulted in the development of the TLICS published in 2005 (Vaccaro et al., 2005).

In 2013 Vaccaro et al. published an AO Spine Thoracolumbar spine injury classification system (**Fig. 69.1**), which incorporated clinical modifiers (Vaccaro et al., 2013). The AO Spine Thoracolumbar spine injury classification system is based on the evaluation of three basic parameters: fracture morphology, neurological injury, and clinical modifiers.

Morphology type A are compression injuries and are generally the mildest injury group affecting the vertebral body but without tension band involvement. Vertical fractures of the lamina may be present but do not constitute a tension band failure. There are five subtypes termed A0–A4. A0 are non-structural fractures that do not compromise the structural integrity of the spinal column such as fractures of the transverse or spinous processes. A1 are wedge-compression fractures of a single endplate without involvement of the posterior wall of the vertebral body. A2 fractures are split fractures of both endplates without involvement of the posterior wall of the vertebral body. A3 are incomplete burst fractures with involvement of the posterior wall but only a single endplate is fractured. Finally, A4 are complete burst fractures and have involvement of the posterior wall and both endplates.

Morphology type B are distraction injuries and have failure of the tension band which might be the posterior tension band, the anterior longitudinal ligament, or the bony component. There are three subtypes termed B1–B3. B1 is a pure transosseous tension band disruption or chance fracture, which is a monosegmental osseous failure. B2 fractures are posterior tension band disruptions with bone and/or ligament failure of the posterior tension band usually combined with a morphology type A fracture. B3 is a hyperextension injury through the disc or vertebral body leading to a hyperextended position of the spinal column. Anterior structures, especially the anterior longitudinal ligament, are ruptured.

Morphology type C describes displacement or dislocation. There are no subtypes because as a consequence of the dissociation between the cranial and caudal segments various configurations are possible in different images. Morphology type A fractures may also be present.

Neurological status at the moment of admission should be scored according to the following scheme: N0 neurologically intact; N1 transient neurologic deficit, which is no longer present; N2 radicular

symptoms only; N3 incomplete spinal cord injury or any degree of cauda equina injury; N4 complete spinal cord injury; and NX neurologic status is unknown due to sedation or head injury.

There are two defined clinical modifiers, which can be used. The M1 modifier is used to designate fractures with an indeterminate injury to the tension band based on spinal imaging with or without MRI. This modifier is important for designating those injuries with stable injuries from a bony standpoint for which ligamentous insufficiency may help determine whether operative stabilization is a consideration. The M2 modifier is used to designate a patient-specific comorbidity, which might be a factor either for or against surgery for patients with relative surgical indications. Examples of an M2 modifier include ankylosing spondylitis or burns affecting the skin overlying the injured spine.

In 2015, Kepler (Kepler et al., 2015) published the AO Spine Injury Score which allocates scores to features of the injury so that a calculated total can be used to guide whether patients should be managed conservatively or surgically (Table 69.1).

The surgical management of thoracic and lumbar fractures

Patients with spinal injuries should be managed according to the advanced trauma life support guidelines as covered in Chapter 65. Spinal cord injury is also covered elsewhere. In this chapter only the specific surgical indications and techniques relevant to thoracolumbar spinal fractures will be addressed.

X-rays have a limited role in the assessment of spinal injury in acute major trauma although they are used in assessing patients with osteoporotic crush fractures. All patients will need a computed tomography (CT) scan of the whole spine with reconstructions so that the images can be examined in all three plains. The CT scan should be studied to look at the fracture morphology, soft tissue swelling, and adjacent or other injuries in the spine or body organs. The CT also gives information relevant to surgical planning such as the size of the pedicles and can be used in an image

Table 69.1 AO Spine Injury Score

Fracture type		Neurological		Clinical modifiers	
A0	0	N0	0	M1	1
A1	1	N1	1	M0	0
A2	2	N2	2		
A3	3	N3	4		
A4	5	N4	4		
B1	5	NX	3		
B2	6				
B3	7				
C	8				
Score 0–3 Score 4–5 Score 6–13		Manage conservatively Can be managed surgically or conservatively Manage surgically

Koerner et al, Reliability analysis of the AOSpine thoracolumbar spine injury classification system by a worldwide group of naïve spinal surgeons, *European Spine Journal*, Volume 25, Issue 4, pp. 1082–6, Copyright © 2015 Springer Nature.

guidance system. However, the CT scan does not exclude a ligamentous injury.

All patients with persisting neurological symptoms and most other patients with a significant spinal injury on CT will also be investigated with MRI scanning. MRI should include T1, T2, and short tau inversion recovery (STIR) sequences. T1 and T2 will demonstrate spinal cord or root compression, the STIR sequence is especially useful for detecting fractures, disc, and ligament injuries.

Where indicated, the aim of surgery is to achieve neurological decompression, biomechanical stability, and restoration of alignment but there is a wide variation in clinical practice with regards to which spinal injuries should be operated on.

Neurological symptoms

Surgical spinal decompression and fusion is considered the first line treatment for most patients with persisting neurological compression. Spinal cord injury can be thought of as a primary mechanical insult that then triggers a secondary chain reaction that includes haemorrhage, vasospasm, ischaemia, oedema, excitotoxicity, inflammation, and further apoptosis of neurons.

The twin aims of surgery, therefore, are firstly to decompress, removing mass lesions and preventing secondary neural apoptosis by restoring normal perfusion to the spinal cord and secondly to fuse thus preventing further damage to the neural elements which might be incurred during movement and to allow early aggressive mobilization.

Patients who only have nerve root compression should be assessed for surgery based on the nature of the biomechanical stability of their injury and not purely on their neurological injury.

Fracture stability

In the absence of a neurological injury, fractures that are unstable and risk displacement and late neurological compromise should undergo surgical stabilization. The challenge for the surgeon is to determine which fractures are stable and can therefore be reliably treated conservatively as compared to which ones require fixation.

Over the years, no single fracture has created more controversy than the treatment of neurologically intact thoracolumbar burst fractures (Anderson et al., 1991; Miyanji et al., 2006; Aleem and Nassr, 2016; Vaccaro et al., 2016). Even a recent Cochrane review determined that contradictory evidence exists and that no conclusions can be drawn with respect to a patient's pain or functional outcome (Koller et al., 2008). The presence of a retropulsed fragment is of limited clinical relevance. There is an increased risk of complication, revision surgery, and increased cost in the surgical group.

A survey of 483 surgeons from around the world has recently been performed by Vaccaro et al. (2016) where surgeons were presented with a series of clinical cases and asked about their preferred management. While significant regional practice differences existed, the following generalization can be made with respect to A type fractures. Surgery was not favoured for A1 or A2 fractures, surgery was not favoured for A3 (incomplete burst) or A4 (complete burst) fractures so long as the posterior ligamentous complex was intact and the patient was neurologically intact. Patients with A3 or A4 type fractures and radiculopathy were generally considered to be surgical candidates, A3 or A4 fractures with an indeterminate injury to the tension band (M1 modifier) were also generally considered surgical candidates.

Patients with burst fractures who are neurologically intact should have an MRI to assess the posterior ligamentous complex (PLC). If the PLC is intact, non-operative treatment is recommended. In patients with an indeterminate PLC, surgery might be considered. In cases where there is frank disruption of the PLC, the fracture should be reclassified as B2 and surgical treatment is recommended. Burst fractures accompanied by radiculopathy can be considered for decompression and fixation.

Type B fractures (Fig. 69.2) are generally treated surgically but there has been some literature to suggest that bony chance fractures (B1) which are well aligned and have appropriate bony contact can be treated in an extension brace and go on to uneventful healing (Kim and Lenke, 2005; Lakshmanan et al., 2009; Wood et al., 2015). This can be considered in patients with less than 10 degrees of focal kyphosis, no neurological compromise, and with the ability to comply with a close follow-up schedule.

Type C injuries, which are translational or rotational injuries, are considered biomechanically unstable by definition. They are normally managed with surgical reduction and fixation (Fig. 69.3).

The level of a fracture can predict stability. High or mid thoracic fractures are supported by the rib cage and sternum and are relatively stable while fractures at the cervicothoracic or thoracolumbar junctional zones are relatively unstable. A high velocity injury is much more likely to be unstable than a low velocity injury with the same radiological characteristics. Ankylosing spondylitis is frequently complicated by osteoporosis so that chance fractures are much more common. The long lever arm created by multiple fused segments makes these fractures massively less stable than chance fractures in normal individuals. Surgical intervention across multiple levels should normally be undertaken. Osteoporosis and patient comorbidities may also be relative contraindications to surgery.

Over the last decade, it has become increasingly clear that sagittal spine balance plays a key role in predicting both surgical as well as patient outcomes. While this maxim has been intensely studied in

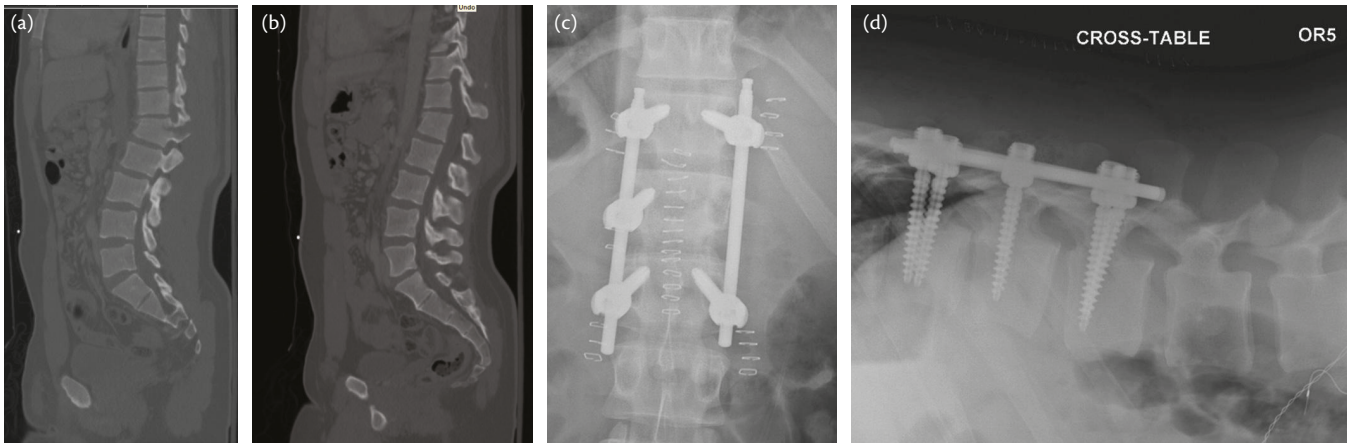

Fig. 69.2 A 23-year-old male was a restrained driver in a high-speed single vehicle motor accident. He presented with this isolated injury. He was neurologically intact. There is significant kyphosis with disruption of the interspinous and supraspinous ligaments as evident from the interspinous widening, as well as the facet disruption on the contralateral side. He had a percutaneous fixation consisting of one level above and one level below the injured level, as well as a limited open interspinous fusion. A pedicle screw was placed within the uninjured pedicle on the right.

deformity surgery, its role in trauma is less well defined, and is considered more controversial.

Koller et al. studied the role that post-traumatic deformity plays in long-term patient reported outcomes after a thoracolumbar burst fracture. They followed 21 patients treated conservatively for an average of 9.5 years. They determined that patients who suffered from greater focal kyphosis and loss of lumbar lordosis after their injuries had worse outcomes as measured by SF-36 and Visual Analogue Scale-spine scores (Koller et al., 2008). They concluded that patients with more severely crushed burst fractures, correction and maintenance of the kyphosis should be considered.

The challenge for the treating surgeon is that posterior instrumentation alone has not proven to be effective in preventing kyphosis. Lakshaman et al. (2009) have demonstrated that in burst fractures, while kyphotic deformity can be corrected initially with posterior instrumentation and positioning, there is often a 'settling' of the fracture in long term follow-up back to its baseline deformity. They concluded that posterior treatment of burst fractures to correct moderate kyphosis as a primary surgical goal without other compelling indications, such as instability or neurological deficit, is of unclear benefit (Vaccaro et al., 2016).

Wood et al. similarly performed a prospective randomized controlled trial that included 47 patients with a stable thoracolumbar burst fracture. At their final follow-up period (ranging from 16 to 22 years), there was no difference in kyphosis angle (Miyanji et al., 2006) between the operative and non-operative groups in those treated with posterior fixation only.

Pekmezci et al. in their paper instead focused on performing a minimally open corpectomy and percutaneous posterior short segment fixation in the treatment of single level traumatic lumbar burst fractures. They reported on 12 patients with an average of 38 months follow-up. They were able to effectively hold their correction, and had good patient reported outcomes (Fig. 69.4).

It is therefore the authors' opinion that severe kyphosis as a result of a thoracolumbar burst facture may be considered as an indication for surgery in the appropriate patient, especially in those

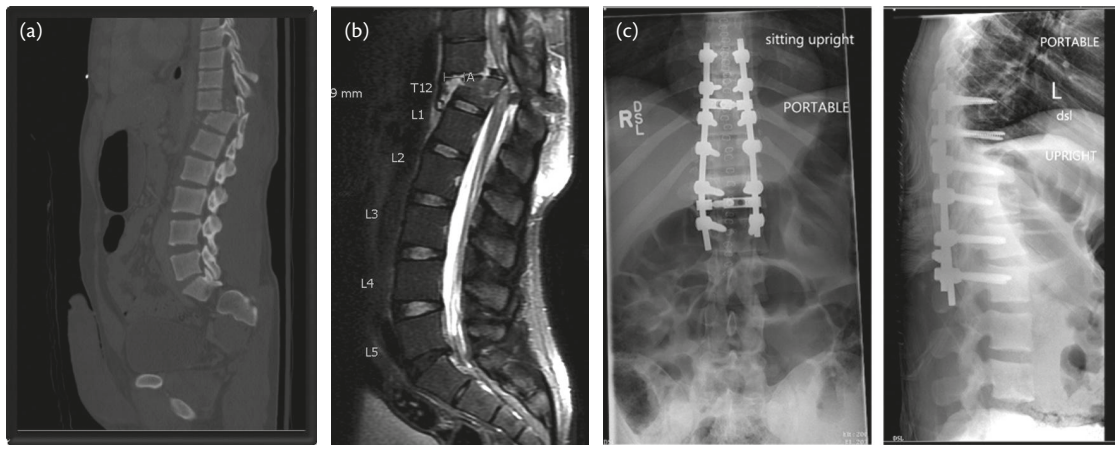

Fig. 69.3 A construction worker had a heavy object pin him onto the stairs. A T11–T12 fracture dislocation is evident on the CT scan. The patient was intubated at the scene of the accident and not clinically examinable, therefore an MRI was obtained to assess the neural elements. This type C injury was treated with an open reduction and posterior instrumented fusion as well as a decompression of the spinal cord. Postoperatively, the patient regained some sacral sparing and partial voluntary control of his bowel and bladder.

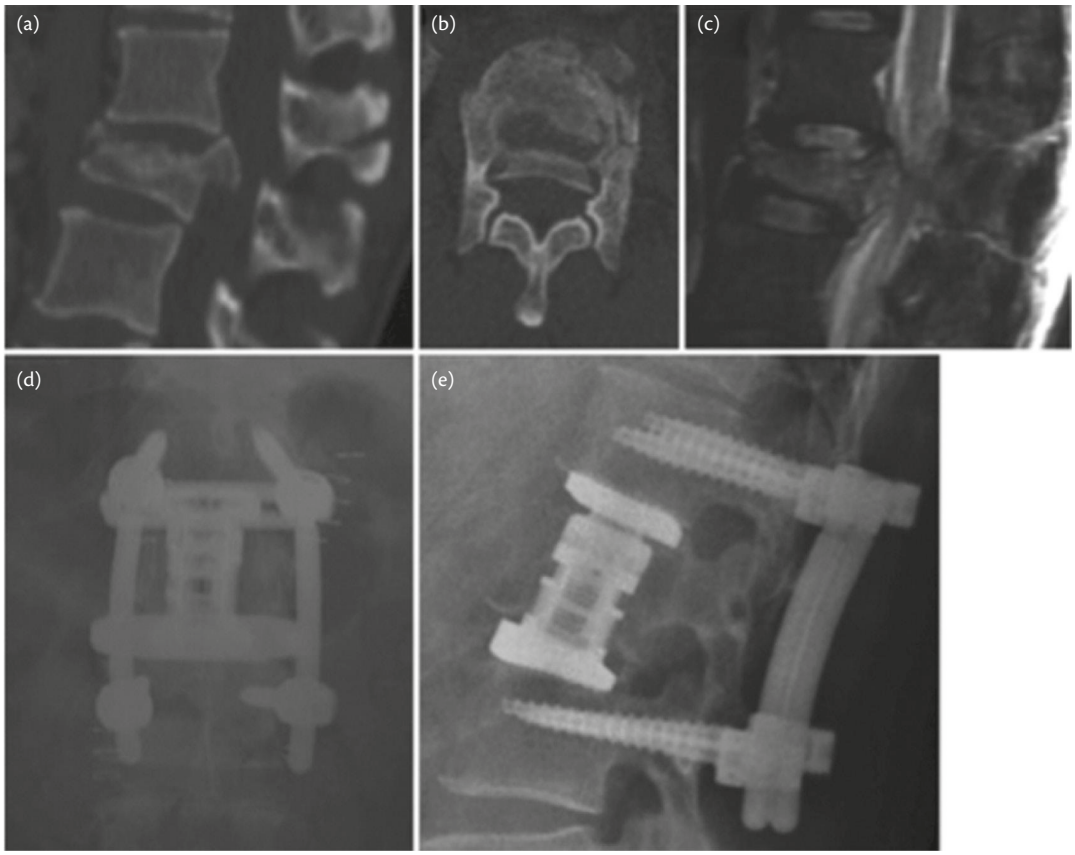

Fig. 69.4 Radiographic images of a 48-year-old man who sustained an L1 burst fracture (A–C) without neurological deficits after falling 15 feet. His fracture was stabilized with short segment posterior pedicle screws placed percutaneously and anterior decompression and stabilization. The construct shows no sign of loss of correction at the 12-month postoperative visit (D–E).

who acquire a significant mismatch between their lumbar lordosis and their pelvic incident. In order to maintain the correction, anterior column support is often required in addition to posterior instrumentation.

Bracing

Thoracolumbosacral orthoses (TLSO) are external rigid spinal braces that span the thoracic, lumbar, and sacral spine to limit motion, correct deformity, or improve the function of certain segments of the body. A TLSO brace limits motion and stabilizes injured structures resulting in reducing pain, enhanced stability, healing, and prevention of progression of deformity. These orthoses are used for spinal stabilization when surgery is not needed, after surgery, or in patients where surgery cannot be attempted safely.

The Jewett Hyperextension Orthosis reduces flexion in the lower thoracic and lumbar spine. It works through posteriorly directed pressure from the anterior sternal and suprapubic pads, with anteriorly directed pressure from the posterior thoracolumbar pad. It is indicated for fractures of the lower thoracic and thoracolumbar regions. The contraindications for the Jewett orthosis are unstable or burst-type fractures.

A custom fabricated TLSO, sometimes referred to as a clam-shell orthosis, provides rigid exterior bracing to the thoracic and lumbar spine with an effective range from T3 to L4. It is moulded from polypropylene or plastic to fit the patient. It covers anteriorly from the sternal notch to the pubic symphysis and posteriorly from the scapula to the coccyx. There is soft padding between the moulds for the patient's comfort, with Velcro straps to provide a snug fit.

The TLSO brace offers the maximum amount of external stabilization in all planes of motion. The TLSO is commonly used to provide non-operative spinal stabilization for fractures from T3-L4. These fractures include burst, compression, and chance fractures. Postoperative use of the TLSO is to limit mobility and increase bony fusion rates.

Prefabricated TLSO braces of various sizes are available. This has the advantage of immediate usage. However, they may have fitment issues and therefore may result in less stabilization of the spine and less patient comfort. The contraindications to TLSO bracing are morbid obesity, the need for increased lateral stability, presence of a chest tube, colostomy, or large wounds within the area being braced. The most common complication of external bracing are skin and soft tissue pressure sores at the contact points of the brace to the wearer's body.

A lumbar corset wraps around the abdomen, usually fastened with Velcro straps and contains posterior steel plates. The corset provides anterior and lateral trunk containment. This assists by elevating intra-abdominal pressure. The steel plates at the posterior restrict flexion and extension of the lumbar spine. This provides the weakest stabilization compared to the other orthoses. Its use is mostly limited to low back pain from prolapsed lumbar intervertebral discs, lumbar

muscle spasms, or stable single-column compression-type lumbar fractures.

Posterior thoracolumbar fusion techniques

There are generally three different methods of inserting pedicle screws. The first is done free hand, with X-ray guidance and reference to anatomical landmarks, to obtain start points and a trajectory. The second is done percutaneously, with the use of intraoperative fluoroscopy for guidance on start points and trajectory of the cannulated screws, and the last is done with the use of computer-assisted navigation.

In all cases the surgeon needs to study the CT scan preoperatively to note the patient's pedicle size, trajectories, and to look for anatomical variants. A detailed plan should be brought to the operating theatre.

The most important part of performing freehand pedicle screws is the ability to select the appropriate start point. Anatomical landmarks differ for varying levels of the thoracic spine. In general, we use the anatomical method described by Kim and Lenke (2005). In order to facilitate memorization of the start points, we group thoracic vertebra in groups of three. See **Figure 69.5**.

Thoracic Vertebra Group	
T1–T3, midpoint of the transverse process and in line with the lateral pars of the level above.	T4–T6, the lateral third of the facet, and on the superior ridge of the transverse process, which is usually one-quarter of the way from the superior edge of the transverse process.	
Fig. 69.5 Thoracic vertebra groups.

Thoracic Vertebra Group	
T7–T9, the most proximal and medial of all thoracic start points, are located at the lateral third of the facet and in line with the superior border of the transverse process.	T10–T12 start points return to a more inferior and lateral aspect, similar to the T1–3 start points. They are in line with the midpoint of the transverse process, and on the lateral aspect of the pars.	
Fig. 69.5 Continued

Thoracic Vertebra Group	
Lumbar pedicle start points are located at the intersection of the midpoint of the transverse process, and with the lateral aspect of the pars.	
Fig. 69.5 Continued

Freehand screw placement

A radiolucent operating table is used. Great care should be exercised in ensuring that the facet capsule, supraspinous and intraspinous ligaments at the superior and inferior aspects of the last instrumented levels are not stripped of muscle in order to prevent junctional kyphosis. After appropriately exposing the spine to identify anatomical landmarks, the starting point is identified by referencing the articular facet, the transverse process, and the pars. anteroposterior (AP) X-rays can be used to identify the pedicles and must be aligned carefully as described next. Once the starting points are identified, an awl or high-speed burr is used to create a shallow pit for the start point through the outer cortex. This prevents slipping while using the pedicle probe. The medial aspect of the transverse process may need to be removed to allow the screw head to sit correctly in the thoracic spine. In the lumbar spine, the facet may need to be reduced in size. The curved pedicle probe is then used to cannulate the pedicle. A combination of AP and lateral X-rays can be used to monitor the progress of the probe, the probe should not cross the medial wall of the pedicle, as seen on the AP X-ray until it is in the vertebral body as seen on the lateral X-ray. The curved pedicle finder is typically used, with the curve pointing away from the spinal canal for the first 20 mm. Once that depth has been reached, it is then rotated 180 degrees and reinserted. A gentle 'wiggling' motion is performed while constant forward pressure is applied. A sound is then used to palpate four walls and the floor of the pedicle. The sound is often marked at the anticipated depth of the pedicle, to prevent it being inserted too deeply if a floor is not felt. The pedicle path is then tapped, often intentionally using a tap which is undersized by 1 mm as compared to the final screw. Once the tap is removed, the pedicle is then once again sounded to ensure that a new trajectory was not inadvertently tapped. Again, four walls and a floor should be felt. The appropriate screw is then inserted, taking great care to be colinear with the previously tapped trajectory and using X-ray guidance.

Cannulated fluoroscopic technique

The second method of inserting pedicle screws described here involves using intraoperative radiographs and a cannulated pedicle screw system. The key to this technique lies in obtaining proper radiographic views for each vertebra that is to be fused.

A proper radiographic view for insertion of a pedicle screw ensures that the beam of the C-arm is parallel to the endplates of the vertebra, and that the spinous process bisects the centre of the body between the two pedicles. The start points for the pedicle screws are located at the 3 o'clock for the right pedicle and the 9 o'clock position for the left pedicle. See **Figure 69.6A**.

Trochars are then inserted, advancing them slowly with a mallet and stopping prior to crossing the medial wall of the pedicle. In order to avoid a medial breach, it is important to confirm on a lateral X-ray that the trochar has entered the vertebral body BEFORE it crosses the medial wall of the pedicle on the AP view. See **Figure 69.6B**.

A lateral X-ray is then obtained to demonstrate that the trochar has entered the vertebral body before it crossed the medial wall. It can then safely be advanced further. Note that advancing the trochar further will now give the AP radiograph the appearance of having breached the medial wall. See **Figure 59.6C**.

The inner core of the trochar is then removed, and a guidewire is advanced. The floor of the vertebra is palpated. Note that since the anterior wall of the vertebra is convex, the wire may strike the anterior wall before appearing to reach the apex on the lateral radiographic view of the spine. The trochar is then removed ensuring that the guidewire stays in position. The cannulated tap is then advanced over the wire. Lateral radiographs are obtained to ensure that the wire does not bind to the tap and inadvertently advance past the anterior wall of the vertebra. Lastly, the cannulated screw is advanced over the wire, again using lateral radiographs to ensure that the wire does not bind as may happen if the tap or the screw are not properly aligned with the wire as they are advanced.

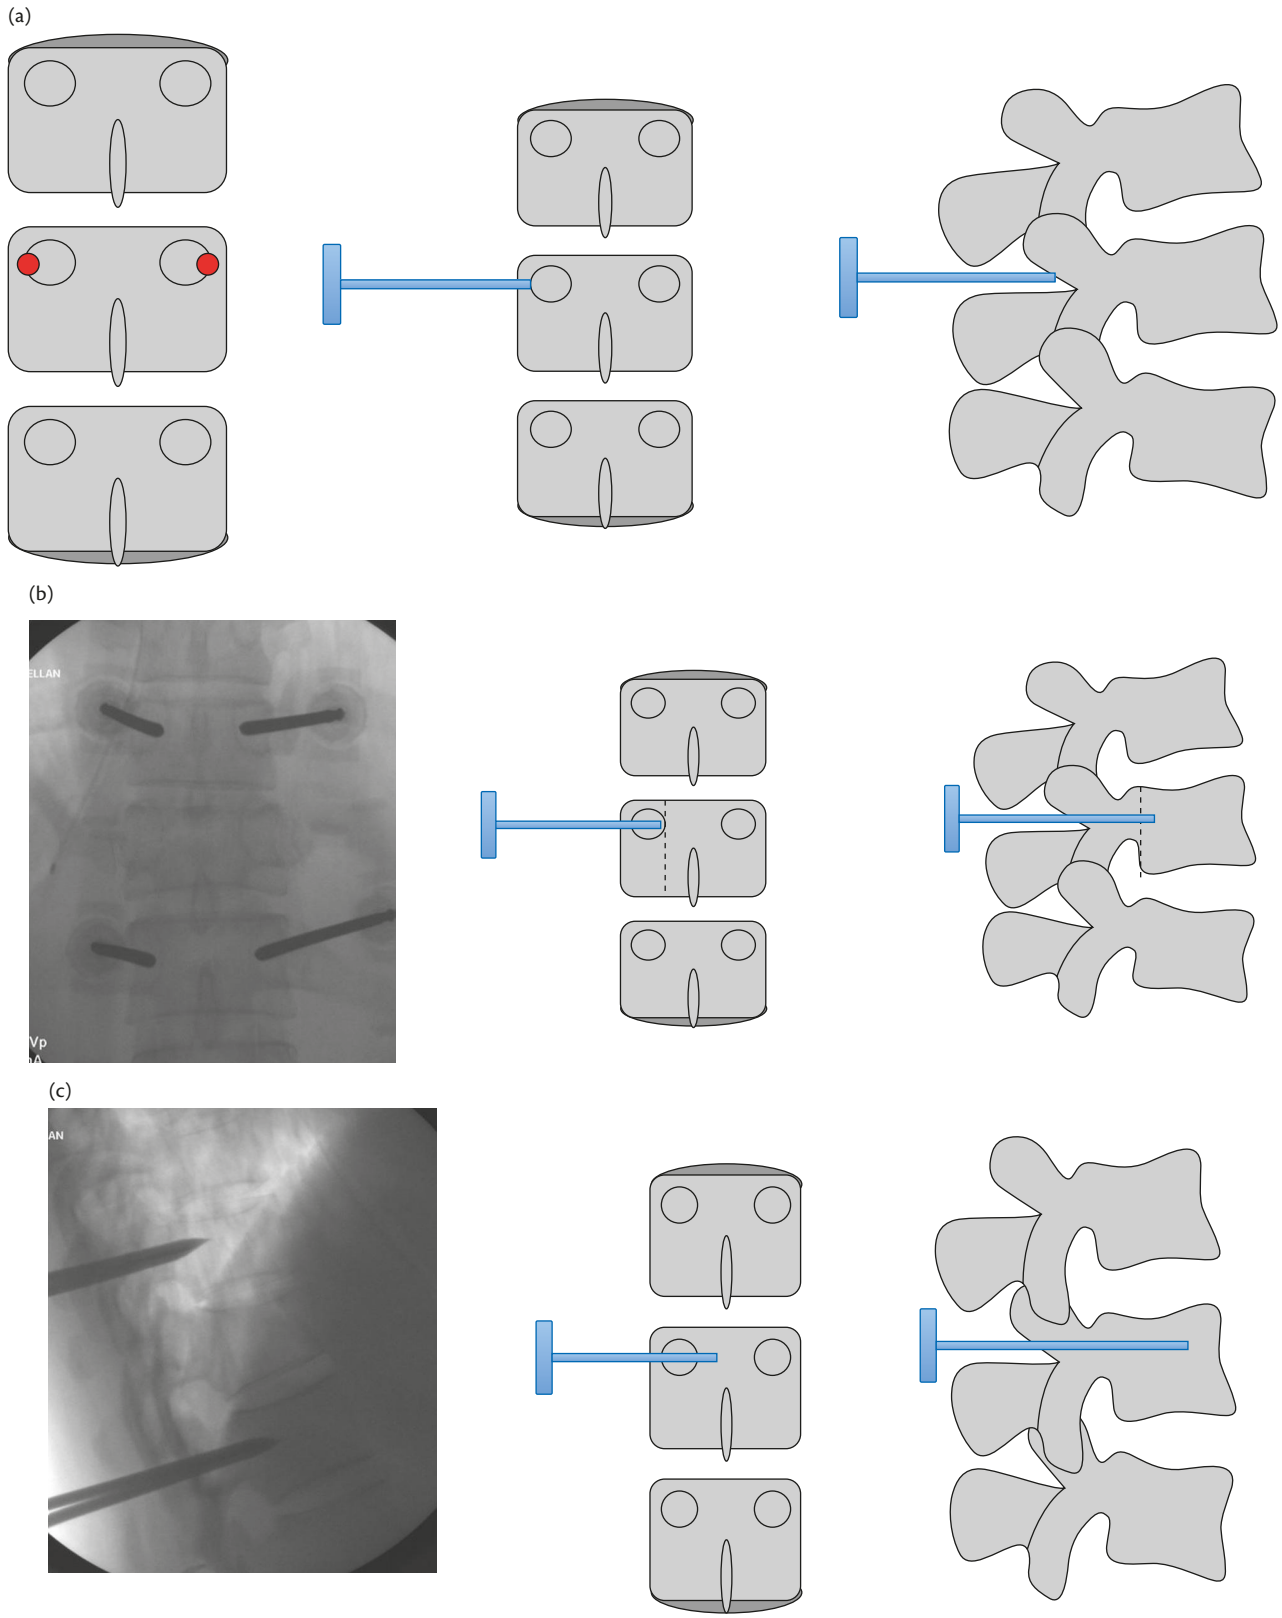

Fig. 69.6 Technique for inserting pedicle screws. The end plates must be square with the spinous process in the middle (A). Anteroposterior (AP) (B) and lateral (C) views allow the surgeon to position the screw in the pedicle. On AP views the screw should not traverse the medial wall until the screw tip is seen to have entered the vertebral body.

Image guided pedicle screw insertion

Pedicle screws can be inserted using image guidance rather than X-ray. Screws may be cannulated (to facilitate percutaneous techniques) or non-cannulated to be used with open techniques.

The neuronavigation system reference has to be securely attached to a spinous process of the vertebra and registered using anatomical landmarks from the back of the laminar or by an X-ray system for minimally invasive cases.

Image guidance reduces X-ray exposure, allows three-dimensional visualization which is especially useful in patients with abnormal anatomy. It is at least as accurate as the other techniques described.

Complications of pedicle screw insertion include breach of the pedicle wall in up to 20% although less than half will be symptomatic and require revision. The breach may be medial where there is a threat to the spinal cord or cauda equina, lateral where the great vessels are located or inferiorly where the nerve root may be compromised. Postoperative radicular pain is most commonly caused by a screw breaching the pedicle wall. The incidence of pedicle wall breach can be reduced by feeling the walls and floor with a pedicle feeler prior to inserting the screw, by neurophysiological monitoring, by careful interpretation and positioning of the X-ray machine, using neuronavigation, or with an impedance device that can detect breach of the pedicle.

Pedicle fractures occur when a screw of too great a diameter is inserted into the pedicle. The complication can be avoided by using the correct screw size and by inserting the screw slowly, so that the pedicle has time to accommodate it.

Screw pull out or screw fracture will occur if there is a failure of fusion. As with all internal fixation techniques, the metal construct will fail if the bones fail to fuse. The patient must be encouraged to stop smoking, NSAIDs should be avoided, while decortication during surgery and the use of bone graft are all helpful in promoting fusion.

Postoperative follow-up

Whether managed surgically or conservatively patients require physiotherapy and rehabilitation. Postoperative CT scanning is performed by some surgeons to assess screw and fracture positions, but it is not mandatory. X-rays should be taken at intervals over 3–6 months or until fusion occurs to monitor for progressive kyphosis or instability.

Spinal cord injury rehabilitation

Fahim Anwar, Wail Ahmed, Tamara Tajsic, Damiano G. Barone, and Harry Mee

Spinal cord injury rehabilitation in the acute phase

The importance of spinal cord injury rehabilitation

Rehabilitation is rather an educational process aimed at disabled people enabling them to achieve and sustain their optimal physical, intellectual, psychological, and social functional levels (World Health Organization, 2011). The importance of spinal cord injury rehabilitation stems from the fact that the establishment of specialist SCI rehabilitation units have improved the life expectancy of tetraplegics from approximately one month to almost normal life expectancy.

Understanding the diagnosis and pathophysiological changes in the acute phase

A prerequisite for rehabilitation is to have an understanding of the diagnosis by taking a history, conducting thorough general and neurological examinations, and reviewing relevant investigations (e.g. radiological images). More importantly, correlating the history, examination and radiological findings can help identify certain patterns of spinal syndromes such as central cord, anterior cord, or cauda equina syndromes. Furthermore, identifying associated injuries in the context of poly-trauma and recognizing their impact on additional functional impairments and rehabilitation needs is imperative to guide the process and direction of rehabilitation. For instance, it is reported that acute spinal cord injury occurs in 5–15 % of patients with severe head injury (Michael et al., 1989). Therefore, comprehensive assessment of the severity of head injury and specialist brain injury rehabilitation takes priority over specialist spinal cord injury rehabilitation in these cases.

Recognizing common pathophysiological changes associated with acute spinal cord injuries such as neurogenic shock, spinal shock, and postural autonomic dysfunction is important for the rehabilitation team to make the necessary and relevant interventions. In the acute phase of spinal shock following SCI, the neurogenic type of bladder and bowel dysfunction is primarily areflexic (and atonic) as opposed to the reflexic (and spastic) dysfunction, which is the predominant feature in the chronic phase. Consequently, the nursing management and care are also different. Another example occurs in postural autonomic dysfunction, where in addition to the medical treatment, physiotherapy treatment will concentrate on gradually adapting the patient's autonomic response to their new physiology using a tilt table.

Determination of the neurological level of injury and classification of the SCI

The standard practice across major trauma and spinal injury rehabilitation services is to use the International Standards for Neurological Classification of Spinal Cord Injury (ISNCSCI, 2015) to document the examination findings. This is a widely used international chart designed and reviewed on a regular basis by the American Spinal Injuries Association (ASIA) and the International Spinal Cord Society (ISCoS) since they joined forces in 1992 (Kirshblum et al., 2011; Kirshblum and Waring, 2014).

The main aim of the neurological examination in the context of SCI is to determine whether there is a sensory or motor level of injury and hence determine the neurological level of injury (NLI). The sensory level is the most caudal, intact dermatome for both pinprick and light touch sensation. The motor level is defined by the lowest key muscle function that has a grade of at least 3 (on supine testing), providing the key muscle functions represented by the segments above that level are judged to be intact (graded as a 5). The neurological level of injury is the most cephalad of the sensory and motor levels (Kirshblum et al., 2011; Kirshblum and Waring, 2014; ISNCSCI, 2015). If a patient has weakness in all four limbs but no sensory level (i.e. intact pinprick and light touch sensation in all dermatomes), then the injury is likely to be supraspinal as opposed to SCI.

The other aim is to determine the classification of the SCI using the ASIA Impairment Scale (AIS). By definition, an injury is classified as complete SCI (AIS A) if no sensory or motor function is preserved in the sacral segments S4 and S5. If there is any S4 or S5 sensory or motor function then the injury is classified as incomplete SCI (AIS B, C, or D). AIS B is sensory incomplete where sensory but not motor function is preserved below the neurological level and includes the S4 and S5 sacral segments (light touch or pinprick or deep anal pressure) and no motor function is preserved more than three levels below the motor level on either side of the body. AIS C is motor incomplete where motor function is preserved at the most caudal sacral segments for voluntary anal contraction or the patient meets

the criteria for sensory incomplete and has some sparing of motor function more than three levels below the ipsilateral motor level on either side of the body including non-key muscles. For AIS C, less than half of the key muscle functions below the single NLI have a muscle grade of 3 or more. AIS D is motor incomplete (as defined in AIS C) with at least half (or more) of the key muscle function below the single NLI having a muscle grade 3 or more. The importance of defining the NLI and AIS is to establish the SCI diagnosis as well as predict long-term possible functional outcomes.

Recumbent rehabilitation versus active mobilization

It remains controversial whether early decompression following a SCI conveys benefit in neurological outcome when compared to late decompression or no surgery at all. No randomized clinical trials are available on this subject, but several case-controlled studies found that surgery does not convey improved neurological outcome. What early surgery allows for is earlier mobilization thus reducing the rate of pulmonary complications such as pneumonia or atelectasis and effectively decreasing the length of stay and overall hospital costs (Donovan, 1994; Fehlings and Perrin, 2006).

Autonomic and cardiovascular system interventions

Patients with severe acute SCI are at risk of developing life-threatening cardiovascular instability and respiratory insufficiency. Primary spinal cord injury triggers several secondary injury mechanisms involving vascular compromise leading to reduced blood flow, loss of autoregulation, loss of microcirculation, vasospasm, thrombosis, and haemorrhage. Acute SCI also causes systemic vascular alteration such as bradycardia (associated more frequently with cervical injuries), cardiac arrhythmias, reduced mean arterial pressure, reduced peripheral vascular resistance, and compromised cardiac output. Systemic hypotension with concomitant loss of autoregulation reduces spinal cord perfusion and worsening ischaemia. Life-threatening cardiovascular instability may be recurrent in the first 7–10 days after injury. Several clinical series of human patients with acute SCI managed in an aggressive fashion with attention to blood pressure, oxygenation and hemodynamic performance report no deleterious effects and suggested improved neurological outcome (Hawryluk et al., 2015). The American Association of Neurological Surgeons guidelines and Congress of Neurological Surgeons recommendations (AANS and CNS, 2002) are highlighted in Table 70.1.

Chest and ventilation interventions

Respiratory insufficiency and pulmonary dysfunction are common after traumatic spinal cord injury, particularly when the injury occurs at cervical spinal cord levels (Reines and Harris, 1987; Como et al., 2005; Berlly and Shem, 2007). These are most likely to happen in the first 7–10 days after the injury (Berney et al., 2010a; Berney et al., 2010b). AANS and CNS (AANS and CNS, 2002) guidelines recommend that all patients with high cervical cord (C4 or higher) injury should be intubated immediately, and those with lower cord injuries should be evaluated on a case-by-case basis. However, in the acute setting, respiratory mechanics will be disrupted with any spinal cord lesion above T11.

Table 70.1 Summary of AANS and CNS Guidelines for management of SCI

1	Management of patients with acute SCI in an intensive care unit or a similarly monitored setting where cardiac, haemodynamic, and respiratory monitoring can be used to detect cardiovascular dysfunction and respiratory insufficiency.
2	Avoid systemic hypotension (defined as systolic blood pressure <90 mmHg) and correction as soon as possible.
3	Maintenance of mean arterial blood pressure at 85–90 mmHg for the first seven days following acute SCI to improve spinal cord perfusion.

Reproduced with permission, Guidelines for Management of Acute Cervical Spinal Injuries, *Neurosurgery*, Volume 50, Issue suppl 3, p. S1, Copyright © 2002 Oxford University Press on behalf of the Congress of Neurological Surgeons.

Critically ill mechanically ventilated patients experience impaired airway clearance due to an ineffective cough and impaired secretion mobilization (Hassid et al., 2008). Early tracheostomy in patients with lesions above C5 may reduce the number of ventilator days and the incidence of ventilator-associated pneumonia (Como et al., 2005). A diaphragmatic pacer may be useful in very selected patients. Cough augmentation techniques, including mechanical insufflation-exsufflation (MI-E), manually assisted cough, and lung volume recruitment, improve cough efficiency (AANS and CNS, 2002).

Gastrointestinal system interventions

Paralytic ileus usually accompanies severe acute SCI, and when prolonged, the resulting abdominal distension leads to splinting of the diaphragm which can affect ventilation, particularly in tetraplegics. IV fluids should be prescribed for at least 48 hours postinjury and a nasogastric tube should be inserted. All acute spinal cord injured patients will benefit from receiving chemical prophylaxis for stress ulceration. The duration of treatment is ill-defined but should be continued until risk factors are no longer present (Anwar et al., 2013).

Bowel management interventions

Neurogenic bowel dysfunction results from loss of extrinsic innervations arising from the spinal cord including pelvic splanchnic (S2–S4; parasympathetic), superior and inferior mesenteric (T9–T12; sympathetic), hypogastric (L1–L3; sympathetic), and pudendal (S2–4; somatic) innervations.

Generally, neurogenic bowels can be classified into upper motor neuron or reflex bowel resulting from a suprasacral cord injury and lower motor neuron or areflexic bowel, resulting from a complete injury at the sacral segments and/or the cauda equina.

The purpose of bowel care is to have a regular, predictable, and complete evacuation of the bowel contents (No authors listed, 1998). History taking, general and neurological examinations including assessment of the sacral segment's (S4–S5) sensory, motor, and reflex function is essential prior to prescribing a bowel care regime.

Bladder management interventions

In the initial stage of spinal shock, the resultant neurogenic bladder is flaccid and areflexic leading to urine retention with overflow incontinence. The aim of bladder management at this stage is to decompress the bladder to prevent vesicoureteric reflux and urinary tract infection. This is done by inserting an indwelling urethral catheter.

Using a closed drainage system, proper fixation of the catheter and regular catheter changes are important to avoid catheter-associated infections (Consortium for Spinal Cord Medicine, 2006).

Pressure sores prevention

Pressure ulcers are a serious secondary complication of SCI. The primary cause is felt to be externally applied pressure for a prolonged period over bony prominences, such as the sacrum and ischial tuberosities. This leads to ischaemia of overlying soft tissues, which ultimately can lead to necrosis. Muscle is believed to be even more sensitive to ischaemia caused by pressure then skin and soft tissues. Pressure sores can be life-threatening as a source of overwhelming sepsis. Pressure ulcers are staged according to the degree of tissue damage observed. The *National Pressure Ulcer Advisory Panel (NPUAP)* staging system is widely used for this purpose (Haesler, 2004).

Pressure ulcer prevention is paramount in SCI patients, and it should start in the acute setting as soon as practically possible after injury, continues into the chronic recovery phase and is lifelong for a great proportion of SCI patients. Pressure relief measures involve weight shifts or repositioning, mechanical reclining, and tilting. Optimal pressure relief should be performed every 15–30 minutes for 30–120 seconds depending on the technique used. In the chronic phase a forward leaning position, leaning side to side, having the wheelchair tipped back by 65° or more or doing a pressure relief lift for an appropriate length of time (i.e. 2 minutes) were found to be the most effective pressure relief techniques.

Nutrition interventions

Protein catabolism is common after acute, severe SCI. Changes in the body mass, resulting from muscle atrophy, leads to huge nitrogen losses, prolonged negative nitrogen balance, and rapid weight loss, especially in the first two weeks. However, the marked hypermetabolic response is blunted in SCI patients, by the flaccidity of denervated musculature after SCI. Indirect calorimetry is the recommended technique to assess energy expenditure in both the acute and chronic settings (AANS and CNS, 2002). Nutritional support of the SCI patient to meet caloric and nitrogen needs, not to achieve nitrogen balance, is safe and may reduce the deleterious effects of the catabolic, nitrogen-wasting process which occurs after acute spinal cord injury (AANS and CNS, 2002). It appears that early enteral nutrition (initiated within 72 hours) is safe, but has not been shown to affect the neurological outcome, the length of stay, or the incidence of complications in patients with acute SCI (Rowan et al., 2004). There has been no report assessing the mix or composition of nutritional supplementation for SCI patients. The literature on nutritional support for head injury patients supports a protocol beginning with high nitrogen enteral or parenteral solutions containing at least 15% of the calories as protein, no greater than 15% glucose or dextrose, a minimum of 4% of total energy needs to be as essential fatty acids and vitamins, essential elements, and trace minerals should be added (AANS and CNS, 2002).

Multidisciplinary rehabilitation team interventions

Early involvement by the multidisciplinary rehabilitation team (led by a consultant trained in rehabilitation and spinal cord medicine) is essential to improve function, prevent complications, and avoid further deterioration. The initial assessment by the team would lead to the formulation of an individualized rehabilitation plan in the acute phase. The main focus of physiotherapy is to maintain the full range of movement in all joints, help with bed mobility, improve physical capacity, and prevent secondary complications such as contractures in the muscles by providing splints. A seating and posture plan is implemented as soon as the patient can tolerate the seated position. The tilt table may help to improve autonomic control, fatigue, and exercise tolerance in the acute phase. Pulmonary interventions in the acute phase include chest physiotherapy, postural drainage, breathing exercises, and use of cough assist.

An Occupational therapist helps with upper extremity stretching and splinting, posture in the wheelchair, and oedema management. Early speech and language therapy involvement will help to establish augmentative communication, use of assistive technology to promote independence and assessment of swallowing.

Psychological interventions

Accepting the disability caused by the spinal cord injury is a lifelong process. In the acute stage of spinal cord injury acute stress reaction is very common, which if left untreated may lead to post-traumatic stress disorder. It is, therefore, essential that psychological interventions start early in the acute stage to reduce the impact of these psychological conditions and improve the quality of life. The psychological interventions that may be helpful include providing emotional support, facilitating the process of adjustment, early identification and management of anxiety and depression and interventions encouraging self-care, independence, and psychological well-being.

Prognosis and family support

The diagnosis of SCI is very devastating for patients and their families. They usually ask for the prognosis soon after the injury. Neurological recovery sometimes occurs at the level adjacent to the normal level and below the level of the injury. Neurological recovery is more common in patients with initial ASI Impairment Scale (AIS) C or D status. Patients who present with initial ASI C (age <50 years) and ASI D are expected to be walking (with or without assistive devices) on discharge from rehabilitation (Burns et al., 1997). Consultant led rehabilitation teams play a vital role in explaining prognosis and supporting the families through the acute phase of SCI.

Spinal cord injury rehabilitation in the chronic phase

Medical management of complications

Autonomic dysreflexia

Autonomic dysreflexia is a potentially dangerous clinical syndrome in SCI resulting in acute uncontrolled hypertension, leading to seizures, retinal haemorrhage, pulmonary oedema, renal failure, myocardial infarction, cerebral haemorrhage, and death. It develops due to an overactive autonomic nervous system which results in the abrupt onset of excessively high blood pressure in SCI patients with a neurological level of injury at T6 and above (Krassioukov et al., 2009). Between 48% and 90% of SCI patients with cord injury T6

and above will suffer from autonomic dysreflexia and is more likely in complete than incomplete SCI.

Any noxious or non-noxious stimuli from the intact peripheral nerves below the level of the injury produces strong sympathetic activity from the sympathetic nerves. This leads to vasoconstriction and hypertension. The brain responds to this by initiating descending inhibitory signals to shut down the sympathetic system. These signals fail to pass through the injury level at T6 and above. At the same time, the brain tends to activate parasympathetic system through the intact vagus nerve and produces bradycardia. The reflex sympathetic activity resolves as soon as the stimulus is removed. See **Table 70.2**.

Early recognition is paramount to prevent dangerous complications. A management algorithm (Acute Management of Autonomic Dysreflexia, 2001; Krassioukov et al. 2009) is shown in **Figure 70.1**.

Venous thromboembolism (VTE)

Thromboembolic disease is a common occurrence in patients who have sustained a cervical spinal cord injury and is associated with significant morbidity (AANS and CNS, 2002). Low molecular weight heparin in combination with pneumatic compression stockings or electrical stimulation is recommended as a prophylactic treatment strategy. There are multiple reports of the beneficial effects of prophylaxis therapy for 6–12 weeks following spinal cord injury (AANS and CNS, 2002). A 3-month duration of prophylactic treatment for deep vein thrombosis and pulmonary embolism is recommended in severe cervical SCI. Vena cava filters are not recommended as a routine prophylactic measure but are recommended for selected patients who fail anticoagulation or who are not candidates for anticoagulation and mechanical devices (AANS and CNS, 2002).

Spasticity management

Spasticity is defined as a motor disorder characterized by a velocity-dependent increase in tonic stretch reflex (muscle tone) with exaggerated tendon reflexes resulting in hyperexcitability of the stretch reflex, as a component of the upper motor neuron syndrome (Feldman et al., 1980). Spasticity affects 70% of patients with spinal cord injury (Johnson et al., 1998; Noreau et al., 2000).

The pathophysiology of spasticity in spinal cord injury is multifactorial. A relative overexcitation of the alpha motor neuron due to the absence of descending inhibitory signals is considered as the main pathophysiological explanation. In spinal cord injured individual, this overexcitation mainly is due to the inability of the inhibitory impulses to reach the alpha motor neuron. However, more recently it is documented that there is increased afferent input to the spinal motor neurons due to an increase in the sensitivity of muscle spindles as well as changes in the intrinsic properties of the spinal motor neuron leading to hyperexcitability of the motor neuron causing self-sustained firing in response to stretch (Nielsen et al., 2007). Similarly, there are changes in the intrinsic properties of the muscles leading to the physiological changes in the muscle fibre and tendon compliance contributing to spasticity (Friden and Lieber, 2003).

Spasticity is not always harmful and in some situations spinal cord injured patients may use it to their advantage to transfer, mobilize, or perform activities of daily living. In the lower limbs, it also helps to aid circulation and help prevent oedema and decreases the risk of deep vein thrombosis (Ashworth, 1964). The harmful effects of spasticity include functional deterioration, difficulties in activities of daily living and hygiene, postural abnormalities, contractures, pressure ulcers, and pain.

Complete multidisciplinary clinical assessment of spasticity is essential to plan any treatment. There are several clinical scales to quantify spasticity. The most widely used scale in clinical practice is the Ashworth and the Modified Ashworth Scale.

Several factors exacerbate spasticity such as infections, pressure ulcers, menstrual pain, in-growing toenails, and renal tract calculi. It is therefore imperative that these exacerbating factors are looked for and treated before treating the spasticity itself. Spasticity can be focal, multifocal, regional, or generalized. Physical modalities are the first-line treatment for spasticity. Sustained passive stretching of the muscles throughout the normal range of movement of the joint helps to reduce spasticity. The 'range of movement' exercises should be performed regularly to help prevent the development of spasticity. Well maintained posture in the wheelchair and positioning in the bed can aid in prolonged stretching of spastic muscles. Various orthoses and devices can be used, both in bed and in a wheelchair, to help maintain proper positioning.

Oral medications are used in multifocal, regional, and generalized spasticity. The most commonly used oral medication is baclofen. It is a gamma-aminobutyric acid (GABA) analogue and reduces spasticity by inhibiting monosynaptic and polysynaptic spinal reflexes. The maximum dose is 100 mg per day in three to four divided doses.

Table 70.2 Causes, signs, and symptoms of autonomic dysreflexia

Examples of triggers for autonomic dysreflexia	Symptoms of autonomic dysreflexia	Signs of autonomic dysreflexia
• Bladder distention or irritation; urinary infections, calculus, epididymitis, or scrotal compression • Bowel distention due to faecal impaction • Bowel instrumentation—colonoscopy • Haemorrhoids • Anal fissure • Gallstones • Pressure sores • Fractures • Deep vein thrombosis/pulmonary embolism • Burns • In-growing toenail • Pregnancy esp. labour • Menstruation • Sexual intercourse	• Bilateral pounding headaches • Blurred vision • Nasal congestion • Restlessness • Anxiety • Flushing of the skin above injury level	• Hypertension • Bradycardia • Dilated pupils • Goose bumps below the level of injury • Excessive sweating above the level of injury • Dry skin below the level of injury • Arrythmias, atrial fibrillation

Step 1
• Check Blood Pressure (BP)
• If elevated sit the patient up
• Loose any constrictive devices and clothing
Step 2
• Look for any triggers, starting with the urinary system
• Catheterise the patient if no indwelling catheter is in situ
• If catheter is in situ, check for a kink, fold, constriction or obstruction
• If catheter is blocked, initiate gentle irrigation with normal saline at body temperature
• If catheter is not draining, remove and replace the catheter
Step 3
• If bladder is draining and the symptoms persists, consider faecal impaction
• Check the rectum for stool with a lidocaine jelly (if the BP is less than 150 mm Hg systolic)
• If rectum is impacted, consider gentle manual evacuation
• Check pulse and BP every 2 to 5 minutes until BP normalises.
Step 4
• If BP is at or above 150 mm Hg, consider pharmacological management
• Use rapid onset and short acting anti-hypertensive agents
• Common agents used are Nifedipine (10 mg sublingual) or Glycerile Trinitrate spray (1–2 doses under the tongue)
• Diazepam is used to control intractable spasms or seizures
• Monitor the patient for symptomatic hypotension
Step 5
• Consider less frequent causes if the episode of dysreflexia continues
• Once patient is stabilised, initiate close monitoring for 2 hours (watch for recurrence)
• Review the cause and devise an appropriate care plan
• Other pharmacological agents used in autonomic dysreflexia include captopril, hydralizine and betablockers (used in specialist settings with monitoring)

Fig. 70.1 Management algorithm for autonomic dysreflexia.

Common side effects are nausea and sedation. Abrupt termination of baclofen may lead to withdrawal symptoms like epileptic seizures and psychosis.

Tizanidine is used if baclofen is not tolerated or ineffective. It is a centrally acting α2 adrenergic agonist. It reduces spasticity by decreasing the release of excitatory neurotransmitters at the spinal interneuron level. It is well tolerated; the maximum dose is 36 mg per day in four to five divided doses. It has the potential of causing reversible liver damage and therefore strict monitoring of liver function is required during its usage.

Dantrolene is a skeletal muscle relaxant and reduces spasticity by inhibiting the release of calcium from the sarcoplasmic reticulum. The maximum dose is 400 mg per day in three divided doses. Like tizanidine, it also affects the liver and monitoring of liver function is required. As it is a peripherally acting medication, it does cause sedation.

Benzodiazepines (diazepam and clonazepam) have also been used to treat spasticity and painful spasms as they bind to GABA receptors. Prolonged use of benzodiazepines is associated with sedation and cognitive impairment and is therefore not recommended.

Gabapentin has also been used in spasticity and can be useful in combination with other oral medications. It also helps to relieve painful muscle spasms. Common side effects are sedation and weight gain. Similarly, clonidine can be useful in reducing spasticity, but its use in clinical practice is limited due to its side effects.

For focal spasticity, targeted botulinum toxin injections can be very effective. It weakens the muscle by inhibiting the release of acetylcholine from the presynaptic nerve terminal. The effects of botulinum toxin last for three to six months and repeat injections are needed. The effects can be enhanced by localizing the muscle under electromyography (EMG) or ultrasound guidance. Phenol nerve and motor point blocks are a useful alternative to botulinum toxin injections. Phenol is a neurolytic agent and can be used in 3–7% aqueous solutions. Needle electric stimulation is required to localize the nerve and the motor points. The effects of phenol last for more than six months and can be repeated as required. Side effects of phenol include bruising, swelling, bleeding, and neuropathic pain. Phenol and botulinum toxin injections can also be combined to treat multifocal or regional spasticity.

Generalized spasticity in spinal cord injured patients can be treated successfully by intrathecal administration of baclofen through a pump. The patient should respond to a test dose of intrathecal baclofen before the pump is implanted. The dose of baclofen can be adjusted with a hand-held programmer with the ability to give boluses at specific intervals. The pump needs refilling regularly. Pump failure or catheter problems may lead to baclofen withdrawal symptoms. For intractable lower limb spasticity, intrathecal phenol is an option. However, it should only be used in patients with no bladder, bowel, or sexual functions, and where an effective bladder and bowel management plan is already in place. Cannabis products are not recommended for spasticity treatment because of their narrow therapeutic range and risk of dependence (Karst et al., 2010).

Definitive bowel management

The aim of bowel management in the chronic phase is to ensure compliance with the regular bowel care regime and manage complications. Following emergence from spinal shock, SCI patients will either end up with complete or incomplete reflexic bowel function, complete or incomplete areflexic bowel function, mixed bowel function (conus lesions), or normal bowel function if they recover neurologically. The severity of neurogenic bowel dysfunction depends on the level and completeness of the SCI. The higher the SCI level and AIS grade, the more severe the dysfunction.

To maintain predictable stool consistency laxatives (bulkers, osmotics, softeners) should regularly be taken while stimulants (such as Senna) should be taken only before planned evacuation of the stool as they increase bowel activity leading to movement of stool into the sigmoid colon and rectum.

Other more invasive options of neurogenic bowel management include transanal irrigation, antegrade continence enemas, colostomy (and percutaneous endoscopic colostomy), sacral anterior nerve root stimulator (SARS) and sacral nerve stimulator.

The management of the neurogenic bowel (No authors listed, 1998; Multidisciplinary Association of Spinal Cord Injured Professionals, 2012) is outlined in **Figure 70.2**.

Definitive bladder management

Following the stage of spinal shock (weeks to months), the extent of neurogenic bladder dysfunction depends on the level (supraspinal versus conus versus cauda equina lesion) and scale (complete versus incomplete) of SCI. Therefore, clinical history (including using frequency/volume charts) general examination and neurological examination (including sacral segments motor, sensory and reflex function) all play an important role in the management of the neurogenic bladder. Supraspinal lesions would usually result in a reflex neurogenic bladder (neurogenic detrusor overactivity, NDO) leading to bladder spasms which manifest as urinary leakage around a urethral or suprapubic catheter or between intermittent self-catheterizations. Occasionally, suprasacral lesions (above the sacral spinal cord) resulting from spinal cord infarction (e.g. from T6 down to the conus) can result in an areflexic bladder similar to the conus or cauda equina lesions which manifest as urinary retention with overflow incontinence.

Suprasacral lesions resulting from spinal cord injury interrupt the neural pathways between the 'pontine micturition centre' and the 'sacral micturition centre' (Blaivas et al., 2008). This usually results in detrusor external sphincter dyssynergia (DESD) which is characterized by involuntary contractions of the striated musculature of the urethral sphincter during an involuntary detrusor contraction (Blaivas et al., 2008).

The management of the neurogenic bladder usually starts early with intermittent clamping of the indwelling urinary catheter to train the bladder. This could be achieved using a flip-flow valve between the catheter and urinary bag to allow closure of the catheter. This is usually coupled with administration of oral anticholinergic medication to relax the bladder in patients with a complete (AIS A) or sensory incomplete (AIS B) spinal cord injury. Over a period of 1–2 weeks, bladder training is usually done by increasing the hours of catheter closure during the day up to three to four hours or until the patient gets the urge to empty their bladder. Patients who develop bladder sensation (or urge to empty) during bladder training may have a chance of success in emptying their bladder voluntarily following a trial without catheterization. Consistent and repeated readings of postvoid residual urine volume, using an ultrasound, of less than 100 ml is usually considered normal. Patients who fail to empty their bladder or empty their bladder incompletely (high postvoid residual urine volume) should have catheter drainage to maintain a safe low-pressure system. For patients with good hand dexterity (paraplegics and some low tetraplegics), the ideal way to manage the bladder is to learn how to do clean intermittent self-catheterization (CISC) every 4 to 5 hours depending on oral intake. For those with impaired hand dexterity, a long-term indwelling suprapubic catheter is preferred to a urethral catheter to avoid genital complications (ulcerations, urethral tears, hypospadias) and recurrent infections.

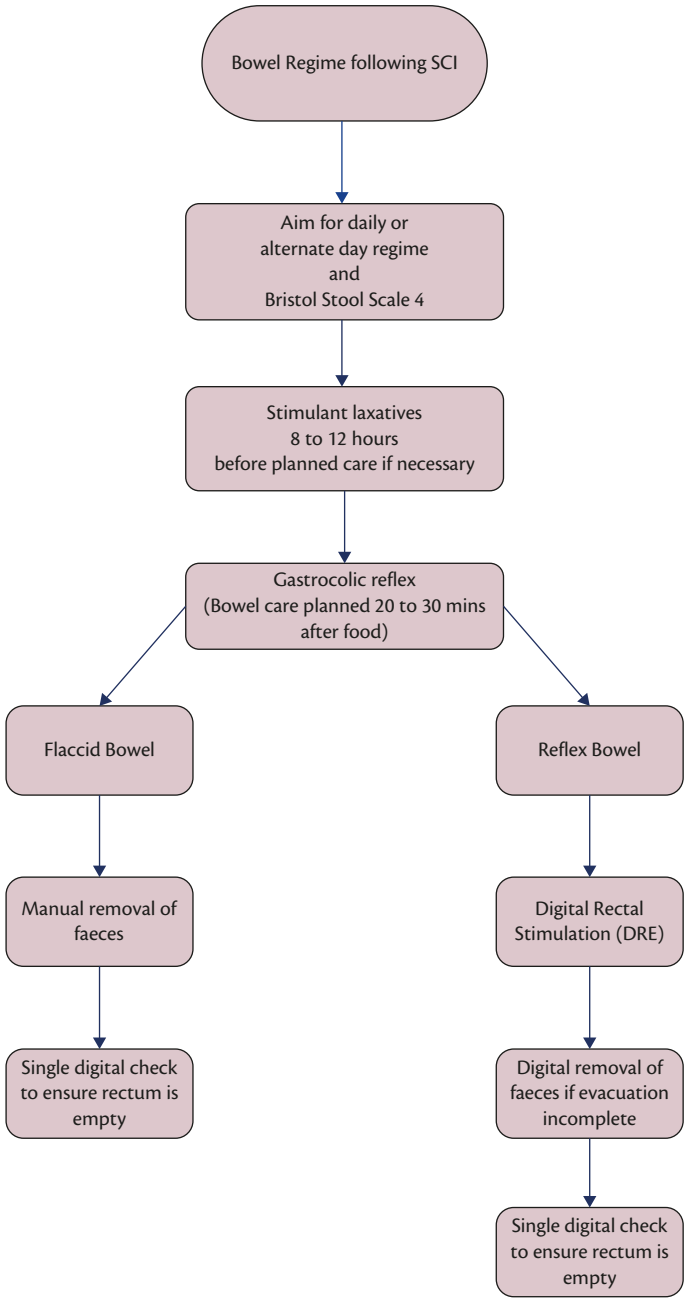
Video-urodynamic studies are particularly useful in determining the intravesical pressures, diagnosing vesicoureteric reflux, and detecting the severity of DESD. They are not a means to determine the best option of bladder management for a particular patient.

In severe DESD, intravesical botulinum toxin injection can be very effective in managing NDO symptoms of spastic urinary incontinence. Other methods include surgical bladder augmentation, neuro-modulation, neuro-stimulation and sacral anterior root stimulation (SARS).

Sexual function management

Sexual dysfunctions following spinal cord injury are common and may affect males and females in very different way. Females with spinal cord injury may experience a change in perineal sensation, delayed orgasm, and require more stimulation to achieve orgasm. Similarly, the lack of vaginal lubrication can lead to vaginal irritation during intercourse. Use of water-based lubrication agents helps to prevent this. For females, body image may be a significant factor in sexual dysfunction and accepting the impairments can lead to a happy and satisfying sexual relationship. In the acute phase, there is a loss of menstrual cycle, this spontaneously resumes between three to six months after the injury. Once the menstrual cycle becomes regular, then childbearing is usually not affected. Pregnancy following spinal cord injury is managed by a multidisciplinary team of professionals.

In males, T11 and above complete injury will lead to loss of psychogenic erection but patients can still achieve reflexogenic erection. Ejaculation may be possible in less than 10% of patients in this group (Subbarao and Garrison, 2016). Conversely, T12 and below complete injuries can cause loss of reflexogenic erection with a possibility of preserved psychogenic erection but ejaculation is usually



Bowel Regime following SCI
Aim for daily or alternate day regime and Bristol Stool Scale 4
Stimulant laxatives 8 to 12 hours before planned care if necessary
Gastrocolic reflex (Bowel care planned 20 to 30 mins after food)
Flaccid Bowel
Reflex Bowel
Manual removal of faeces
Digital Rectal Stimulation (DRE)
Single digital check to ensure rectum is empty
Digital removal of faeces if evacuation incomplete
Single digital check to ensure rectum is empty

Fig. 70.2 Management of neurogenic bowel.

Data from https://www.mascip.co.uk/wp-content/uploads/2015/02/CV653N-Neurogenic-Guidelines-Sept-2012.pdf; also Neurogenic Bowel Management in Adults with Spinal Cord Injury, *Journal of Spinal Cord Medicine*, volume 21, issue 3, pp. 248–93. © 1998 Taylor and Francis.

not possible (Subbarao and Garrison, 2016). Male fertility issues after spinal cord injury are common and mainly related to lack of ejaculation. This is managed by either electroejaculation, intrauterine insemination, or by *in vitro* fertilization.

Heterotopic ossification

Heterotrophic ossification (HO) is the formation of bone in ectopic sites such as soft tissues. It occurs in 20–30% of patients with spinal cord injury (Snoecx et al., 1995). The aetiology and pathogenesis of heterotrophic ossification is not known. In spinal cord injuries, muscle trauma (tears, ruptures, bleeding) is thought to trigger heterotrophic ossification (van Kuijk et al., 2002). The most common site of HO is at the hip (Sullivan et al., 2013) (Fig. 70.3) but it can occur around the elbows, shoulders, hands, and knees.

In the acute phase, raised alkaline phosphatase may raise the suspicion of HO. An isotope bone scan and MRI scan in the acute phase are sensitive in diagnosing HO. In the early stages X-ray would not show HO due to insufficient deposition of calcium.

Non-steroidal anti-inflammatory drugs (NSAIDs) have been used successfully to treat HO. However, their use is limited due to their side effects as well as their ability to inhibit bone healing after fractures (Johnson and Lanig, 1996). Treatment of established HO

Fig. 70.3 Heterotrophic ossification around the hip joint.

aims to stop the process of HO, maintain range of movements of the affected joint and prevent pain. There are very few pharmacological agents which have been tried to treat HO. Studies have been mainly on the use of indomethacin and etidronate, these agents are most helpful when given earlier, as preventative measures. Etidronate has been shown to prevent secondary HO formation, but the length of treatment is unclear, and there is a risk of osteomalacia.

Surgery is considered when HO is interfering with the quality of life or causing secondary complications. Surgical resection is considered once HO has matured as in the acute stages there is a risk of excessive bleeding. Etidronate, NSAIDs, or radiation therapy is indicated after surgery to reduce the risk of recurrence.

Neuropathic pain management

Pain following spinal cord injury may interfere with active rehabilitation and also have a negative impact on the quality of life and activities of daily living. The cause of pain after spinal cord injury is unknown. There are two distinct types of pain after spinal cord injury; neuropathic (secondary to damage to the spinal cord) and musculoskeletal (as a consequence of the spinal cord injury). Clinically neuropathic pain can be divided into three categories (Cardenas et al., 2002); spinal cord injury pain (below the level of the lesion), transition zone pain (bilateral at the level of the lesion), radicular pain, and visceral pain. Taking a detailed history and performing a physical examination followed by a focused investigation helps to make a diagnosis and also differentiate conditions like syringomyelia.

It is important to know that chronic pain following a spinal cord injury is difficult to treat. The aim of treatment is to manage the pain and improve the quality of life. The psychological factors impacting on the perception of pain should be explored and managed appropriately to improve the outcome of treatment. Pain is managed with a wide variety of therapeutic modalities such as physical therapy, cognitive behaviour therapy, self-management strategies, biofeedback, acupuncture, transcutaneous electric nerve stimulation, mindfulness, and pharmacological intervention. A comprehensive pain management plan includes a combination of all of these modalities.

Non-steroidal anti-inflammatory medications (NSAIDs) and acetaminophen are often used as first-line treatment for pain in spinal cord injury patients with variable efficacy. Prolonged use of NSAIDs is associated with a risk of gastric ulceration and acute renal damage.

Neuropathic pain is treated with antidepressants and anticonvulsants. Tricyclic antidepressants (amitriptyline, nortriptyline, and imipramine) are effective in treating neuropathic pain but anticholinergic side effects can limit their use. However, a randomized controlled trial failed to show significant pain relief from these agents in mixed neuropathic and nociceptive pains in the SCI population (Cardenas et al., 2002).

Anticonvulsants (gabapentin, pregabalin, lamotrigine) are calcium channel modulators and have been studied in spinal cord injury patients. Gabapentin (300–3600 mg per day) can cause drowsiness and weight gain limiting its use but it is effective in reducing neuropathic pain in paraplegics with complete injuries (Levendoglu et al., 2004). Pregabalin (50–600 mg per day) is better tolerated than gabapentin and has a better side-effect profile. It is also effective in reducing pain and improving sleep in both complete and incomplete spinal-cord injured patients (Siddall et al., 2006). Lamotrigine in a randomized controlled trial failed to show a statistically significant effect in the whole sample but in patients with incomplete injury, it significantly reduced pain at or below the level of the injury (Finnerup et al., 2002). Serotonin noradrenaline reuptake inhibitors such as duloxetine and venlafaxine have not been studied in spinal cord injury pain but are usually very effective in neuropathic pain.

Opioids have been used to treat pain following SCI with varying efficacy but only tramadol has a positive effect on pain. Prolonged use of opioids may lead to serious side effects particularly drowsiness, constipation, respiratory depression, endocrine abnormalities, tolerance, addiction, and opioid-induced hyperalgesia. Intrathecal drug administration should be considered only in intractable pain conditions where the oral administration has not been tolerated or effective. A combination of morphine and clonidine has been used in one clinical trial with good effect (Siddall et al., 2000). The long-term efficacy and safety of spinal cord stimulation, deep brain stimulation, and dorsal root entry zone lesions have not been evaluated clinically.

Role of tendon transfer surgery

In incomplete cervical cord injuries, tendon transfer surgery may help the patients to achieve independence by restoring some useful function in the hand. However, this type of surgery is complicated, requires experience and is not offered until the neurological examination has stabilized, and the patient has undergone an extensive rehabilitation programme.

A thorough clinical assessment is required to plan tendon transfer surgery. The aim of the tendon transfer surgery is either to restore elbow flexion or extension, wrist flexion or extension, or to improve grip.

Postoperative extensive upper limb rehabilitation helps to improve the outcome of the surgery. It is imperative to note that during the rehabilitation phase patients may lose the ability to use the limb or hand for 12 weeks as the tendon transfer heals.

Musculoskeletal interventions following spinal cord injury

Musculoskeletal interventions following SCI commence once the patient is medically stable and able to tolerate therapy. The musculoskeletal interventions may vary depending on the type and location of the SCI. The three main principals of interventions are to increase strength, prevent, and treat contractures, and improve the performance of a motor task. SCI patients respond to strength training programmes. For the upper limb, the aim of strength training programmes is to help the SCI patients lift themselves up from the floor to a wheelchair, achieve effective and safe transfers, and engage in functional tasks. Strength training in the lower limbs may help to achieve walking with aids or the ability to do standing transfers.

Passive movements are vital to prevent contractures and stretching can be used to treat contractures. The optimal quantity and duration of passive movements and stretches remains unknown and should be tailored according to the SCI level as well as to the patient's needs. Repetitive practice is used to improve the motor task following a SCI and is based on the principles of motor learning. A recent clinical trial suggested that intensive physiotherapy following SCI improves strength and gait in people with AIS C and D lesions even three years after the injury (Jones et al., 2014).

Recent advance in exoskeletal systems may change the outlook of musculoskeletal interventions after SCI in the near future.

Stem cell implantation

Stem cell therapy in SCI is a major research interest area, and several stem cells have been tested in animal SCI models. These cell types include embryonic stem cells (pluripotent), and mesenchymal cells (multipotent) harvested from the fat, bone marrow, umbilical cord, lining of the nasal cavity and tooth pulp. Although embryonic stem cells are pluripotent and have the ability to differentiate into any tissue when implanted, their use is limited due to ethical issues and the fact that the patients require immunosuppression. Mesenchymal cells, on the other hand, are multipotent and do not require immunosuppression. However, recent research does not give insight into their ability to differentiate and repair nerve cells. Recently induced pluripotent stem cells have been developed. These are mature cells genetically manipulated to become nerve cells. These are harvested from a patient's tissue and therefore do not require immunosuppression. Their use is limited in the acute phase of spinal cord injury due to the time involved in genetic manipulation (Doulames and Plant, 2016). There is also a theoretical risk of random mutations with the genetic manipulation.

The use of stem cell therapy is limited due to the severe risks that the newly implanted cells can pose in the spinal cord environment. Large randomized controlled trials are needed to ensure safety and efficacy of stem cell treatment in SCI. There are several ongoing clinical trials in the United States and Europe using neural stem cells, mesenchymal stem cells, and embryonic stem cells (Scope, 2018).

Neural-machine interfaces in SCI

The future of spinal cord injury rehabilitation relies on the research into neural-machine interface (also known as brain-computer interface, BCI, or brain-machine interface, BMI). A neural interface is a direct connection between the nervous system and a reading/stimulating electrode, in turn connected to an external hardware. The electrodes can be either penetrative or superficial. The former can be placed in deep cerebral structures (few centimetres) or in substance of large nerves, an example being deep brain stimulators used for Parkinson's disease; cortical penetrative devices (micrometres to millimetres) are also used and they allow a greater neuronal discrimination. On the other hand, superficial electrodes can be placed on the cerebral cortex (electrocorticography, ECoG) or on the scalp (electroencephalography, EEG). Neural interface electrodes can be implanted anywhere in the nervous system (brain, spine, peripheral nerves) and the myoelectric organs (muscles), potentially enabling a direct communication between any two parts of the system (or with any external neuro-prosthetic device). BCIs can be used to restore function following SCI, by stimulating and recording from either the motor, sensory, and/or autonomic systems and completely bypassing the site of the injury. A well-known example is the Utah array, which has been used in non-human primate experiments and phase 1 human studies to connect the motor and sensory cortex to either muscles or an external neuroprosthetic device in chronic SCI patients.

The priority for functional restoration depends on many factors including the level of the SCI, ASI classification and personal preference (Anderson, 2004; Snoek et al., 2004). For tetraplegic individuals, the priority is some functional recovery of the arm and hand whereas restoration of bladder and bowel function is necessary for SCI at any level. Walking and standing ability is viewed as an improvement in the quality of life for the SCI population (Collinger et al., 2013a).

The most basic form of neural-machine interface is functional electric stimulation (FES), which helps to stimulate weak muscles after SCI. FES can be applied through either surface electrodes or penetrative devices. The surface electrodes tend to stimulate the muscle itself whereas the implanted devices can target the muscles or the nerve innervating a particular group of muscles. Theoretically, FES can aid in improving upper limb function, standing, and walking following SCI. Several external FES systems are being used in clinical trials to improve grasp in SCI patients (Collinger et al., 2013b). Implantable FES systems require skills and extensive surgical interventions before they can be of any use.

Epidural and intraspinal stimulation of the spinal cord, to improve walking in incomplete SCI, is based on the fact that there are central pattern generators in the spinal cord capable of providing rhythmic movements of the legs without requiring any sensory feedback (Collinger et al., 2013b). A few clinical trials are looking at epidural spinal cord stimulation to improve walking in people with incomplete SCI (Herman et al. 2002; Huang et al., 2006).

Neural-machine interface has also been used to improve bladder control following SCI. Sacral anterior root stimulation, through an implanted pacemaker, can help to achieve continence and improve quality of life. The stimulation is beneficial for a selected group of complete SCI patients where conservative management of detrusor overactivity has failed. The commercially available stimulation system consists of an external part and an implanted device. The external stimulator is placed over the implanted device to achieve general stimulation of the anterior sacral root. The stimulation is usually combined with dorsal rhizotomy to prevent reflex bladder and sphincter contractions. SARS with dorsal rhizotomy is also helpful in treating autonomic dysreflexia and DESD (Martens and Heesakkers, 2011). However, dorsal rhizotomy limits the use of SARS in incomplete SCI as it will lead to loss of other pelvic

sensations (Martens and Heesakkers, 2011). Most recently afferent pudendal nerve stimulation is gaining momentum as an alternative to SARS and dorsal rhizotomy. This is useful in patients where reflex pathways for bladder control are intact. It is a relatively simple procedure and does not require a combination of dorsal rhizotomy. Further research is ongoing in creating closed-loop system targeting both afferent and efferent pathways to the bladder and providing a semi-independent system (Chew et al., 2013).

There are several other projects that are currently in preclinical trials including intracortical microstimulation to restore sensations, electroencephalographic (EEG) based brain-computer interfaces, brain-computer interface (neural signals decoded to operate a device and also provide feedback to the user about the brain activity), brain-computer interface using ECoG activity (recorded through subdural or epidural electrodes for precise functional localization). Advances in computer technology, in future, will translate into implants and devices that are easy to use, implanted without major complications, and cosmetically acceptable for patients.

Introduction

Clinical neurophysiology provides valuable information in neurosurgery, serving as: a diagnostic tool that can quantify type and severity of damage to the central and peripheral nervous system, a means of monitoring the safety of structures within and around the surgical site, and a method to map structures. As such it aids in identifying structures (e.g. finding sacral nerve roots within a spinal lipoma or nuclei within the thalamus), assessing functional integrity (e.g. motor pathways from cortex to any relevant accessible muscle), and monitoring their function while surgery occurs near to structures (e.g. VII while retracting during trigeminal microvascular decompression, and in scoliosis surgery) providing guidance for technical operative steps (e.g. for selective dorsal rhizotomy).

Intraoperative monitoring is not new, though the advances in equipment and technique of recent years have seen an explosion in the useful ways that neurophysiology can aid the neurosurgeon and protect the patient. The development of techniques to localize epileptic foci and map eloquent cerebral cortex in the 1950s (Penfield and Jasper, 1954) produced major scientific advances as well as revolutionizing epilepsy surgery. Since the 1960s Tasker in Toronto, and Gillingham in Edinburgh, were recording from microelectrodes in the human thalamus to guide movement disorder surgery. Pioneers such as Møller have extended the applications of neurophysiological monitoring in skull base surgery (Møller et al., 1981; Møller et al., 1982; Møller and Jannetta, 1983).

This chapter describes neurophysiological mapping and monitoring, and the different tools that are useful in different situations.

Normal neuron physiology–basic principles

Neurons consist of a neuronal body, dendrites, and an axon. The dendrites and body process information from other neurons, while the axon initiates self-propagating electrical signals (the action potential) in response to such information, which cause the release of neurotransmitters at the synapse. The synapse is the junction where two neurons in close proximity are able to transfer information. The basics of normal neuron physiology are shown in **Figure 71.1**.

Action potential/membrane potentials

An action potential occurs when the cell membrane is depolarized to a threshold value. The resting membrane potential is around –60–70 mV. This potential is caused by differences in ion concentration between intra- and extracellular fluid. Membrane potential fluctuates in response to external stimuli which alter permeability to specific ions. Such stimuli can consist of electrical current across the membrane, or the action of neurotransmitters in the extracellular fluid. These stimuli cause the opening of specific ion channels, increasing the permeability of the membrane to that ion and driving the membrane potential towards the equilibrium potential for that ion.

Neurotransmitters that increase membrane permeability to sodium or calcium cause depolarization (membrane potential moves towards 0 mV), while increased permeability to potassium or chloride causes hyperpolarization (membrane potential moves away from 0 mV). The threshold value for an action potential is around –60 to –50 mV. At this threshold, a cascade of voltage gated sodium channel activation leads to a sudden increase in sodium permeability causing a rapid change in membrane potential which propagates along the membrane at speeds of up to 100 m/s in myelinated axons. An action potential can also be generated if a current is applied externally; spontaneous and externally generated volleys of nerve impulses are both useful in clinical testing.

Synaptic function

The synaptic cleft measures around 20 nm. When an action potential arrives at the presynaptic membrane, neurotransmitters are released into the synaptic cleft and bind to receptors on the postsynaptic membrane, opening ion channels, and triggering a change in voltage across the membrane. Thus, electrical changes in the presynaptic membrane can bring about changes in the postsynaptic membrane. Gamma aminobutyric acid (GABA) is the most common inhibitory neurotransmitter. GABA binds to GABA A receptors which open chloride channels, hyperpolarizing the postsynaptic membrane, or GABA B receptors which are linked through G-proteins to potassium channels that act to hyperpolarize the postsynaptic membrane. Glutamate is an excitatory neurotransmitter which binds to the N-methyl-D-aspartate (NMDA) receptor, AMPA receptor, and kainite receptors. These receptors open cation channels that allow sodium, potassium, or calcium ions in to the postsynaptic neuron,

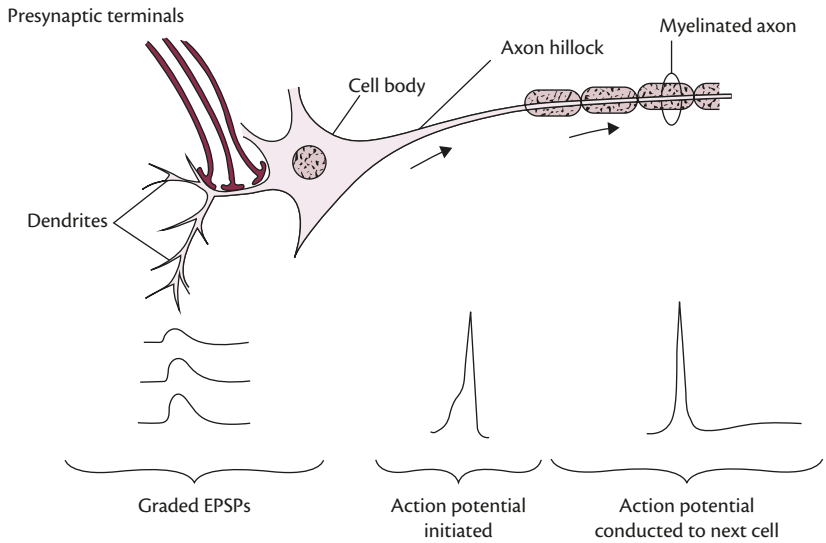

Fig. 71.1 Neuronal electrical activity from its initiation by excitatory postsynaptic potentials (EPSPs) to its transmission as an action potential to another area.

causing membrane depolarization. The neurones can be activated or inhibited by input from dentrites of other neurons.

Classification of types of nerve fibres

Peripheral nerve fibres are classified based on diameter, conduction velocity, and myelination state. The A fibres are larger diameter and myelinated, and have high conduction velocity (10–100 m/s). They are subdivided into:

A alpha fibres in muscle spindles and Golgi tendon organs.
A beta fibres in cutaneous mechanoreceptors, and as secondary muscle spindle receptors.
A gamma fibres are motor neurons controlling muscle spindle activation.
A delta fibres conduct fast painful stimuli as free nerve endings.

B fibres have smaller diameter and are myelinated. They are autonomic nerves with a conduction velocity of up to 15 m/s. C fibres are small and unmyelinated. Conduction velocity is hence lower, up to 2 m/s. They transmit slow pain signals and temperature.

Principles of neurophysiology relevant to neurosurgery

Electroencephalogram

The electroencephalogram (EEG) records variations in electrical activity from different areas of the head, and can be recorded through the scalp, from the cortical surface using, for example, subdural strips or grids (electrocorticography, ECoG) or from depth electrodes within the brain (stereoencephalography, SEEG). It represents a compound electrical field that originates mainly from postsynaptic potentials. The electric field is measured in the form of a voltage difference between two points, and each channel of an EEG represents the difference between two specific sites. These can be averaged to a single common reference point or measured between EEG electrodes. The '10–20' system is commonly used but does not always provide adequate anterior temporal coverage and so is often supplemented with additional electrodes.

Figure 71.2 shows the surface EEG from an adult patient who presented with seizures: standard 10–20 electrode positions used—odd numbers left, even right: F = frontal, Fp = frontopolar, P = parietal, O = Occipital, T = Temporal X1-X2—spare channel, used here for electrocardiogram (ECG) lead 1. Normal 'alpha' rhythm seen, for example, in channel 16 (T5-O1): the slow activity in channels 9, 10, and 11 is the result of damage from an underlying glioma in this region. The 'compressed spectral density' top right here does show the location of the slow activity—measured at position of green line in this trace—but such frequency maps can be misleading at times with surface EEG recordings.

Scalp EEG records mainly from cortical gyri and does not give details of deep brain structures such as the hippocampus and basal ganglia, though slow activity can overly tumours (Fig. 71.2), and frontal slow activity in particular can reflect deep midline damage. It can show the location of areas of abnormal function such as seizure foci or space occupying lesions, or show the degree of abnormal function. Spatial resolution is low, and changes often non-specific, but time resolution is superior to functional imaging. Scalp EEG can be a guide to depth of anaesthesia, and is used in intensive care. Head injured patients may show subclinical seizures. In one study, of 144 monitored head injured children, 30% showed seizure activity correlating with duration of ITU stay (O'Neill et al., 2015).

EEG can also monitor some vascular procedures such as in aneurysm surgery and carotid endarterectomy. Continuous EEG shows immediate asymmetries produced by ischaemia and although somatosensory evoked potential (SSEP) can be more sensitive, nevertheless with SSEP it takes time for averaging to record the warning changes. EEG 'raw' or processed 'cerebral function analysing monitor' (CFAM) showing an acute drop in activity can be a sensitive guide for the need of shunt insertion during carotid

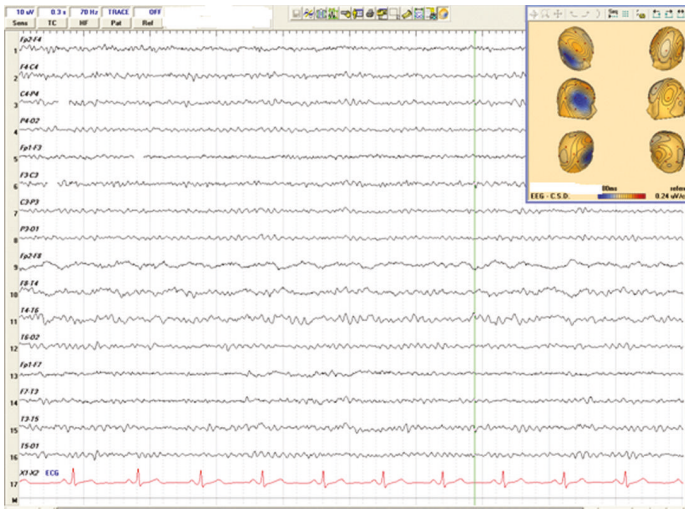

Fig. 71.2 Surface EEG from an adult patient who presented with seizures.

endarterectomy. As the CFAM displays the previous two seconds of processed EEG continuously, the response is almost immediate. EEG or cerebral function monitor can give a guide to the establishment of satisfactory burst suppression if barbiturates are used to reduce cerebral activity.

Electrocorticography (ECoG) and stereo electroencephalography (SEEG) is used for defining epileptogenic foci in the workup for, and during, epilepsy surgery. Recording seizure onset and spread during video telemetry guides the planning of surgery, and at times in theatre may be used to guide extent of resection. In addition to recording through such electrodes, stimulation can be performed to map cortical function or provoke seizures (Cossu et al., 2012). Single pulse electrical stimulation (SPES) can be used as an active technique to demonstrate areas of cortical excitability (Valentín et al., 2002). Use of such techniques is used to guide surgery in complex epilepsy cases.

Evoked potentials

An evoked potential (EP) is an electrical signal generated in response to an external stimulus. This should be contrasted with the spontaneous potentials recorded during investigations such as EEG and electromyography (EMG). These can test a huge range of pathways including motor evoked potentials (MEP), somatosensory evoked potentials (SSEP), visual evoked cortical potentials (VEP), brainstem auditory evoked potentials (BSAEP), and electroretinography (ERG). Most are attenuated or blocked completely by anaesthetic agents, with the best results in theatre being obtained by total intravenous anaesthetic with propofol and remi-fentanyl. Muscle paralysis blocks MEPs and EMG, although if paralysis is administered during intubation it has usually worn off by the time monitoring is required.

Motor evoked potentials (MEP)

MEPs can be recorded wherever distal muscle is accessible, down to the level of S3, and can be used in patients under general anaesthesia to reduce risk of damage to corticospinal tracts during cranial (and spinal) surgery (Fig. 71.3). Responses are recorded in theatre with a contralateral 'homunculus of needles', preferentially using muscles with the largest cortical representation. A representative scheme comprises:

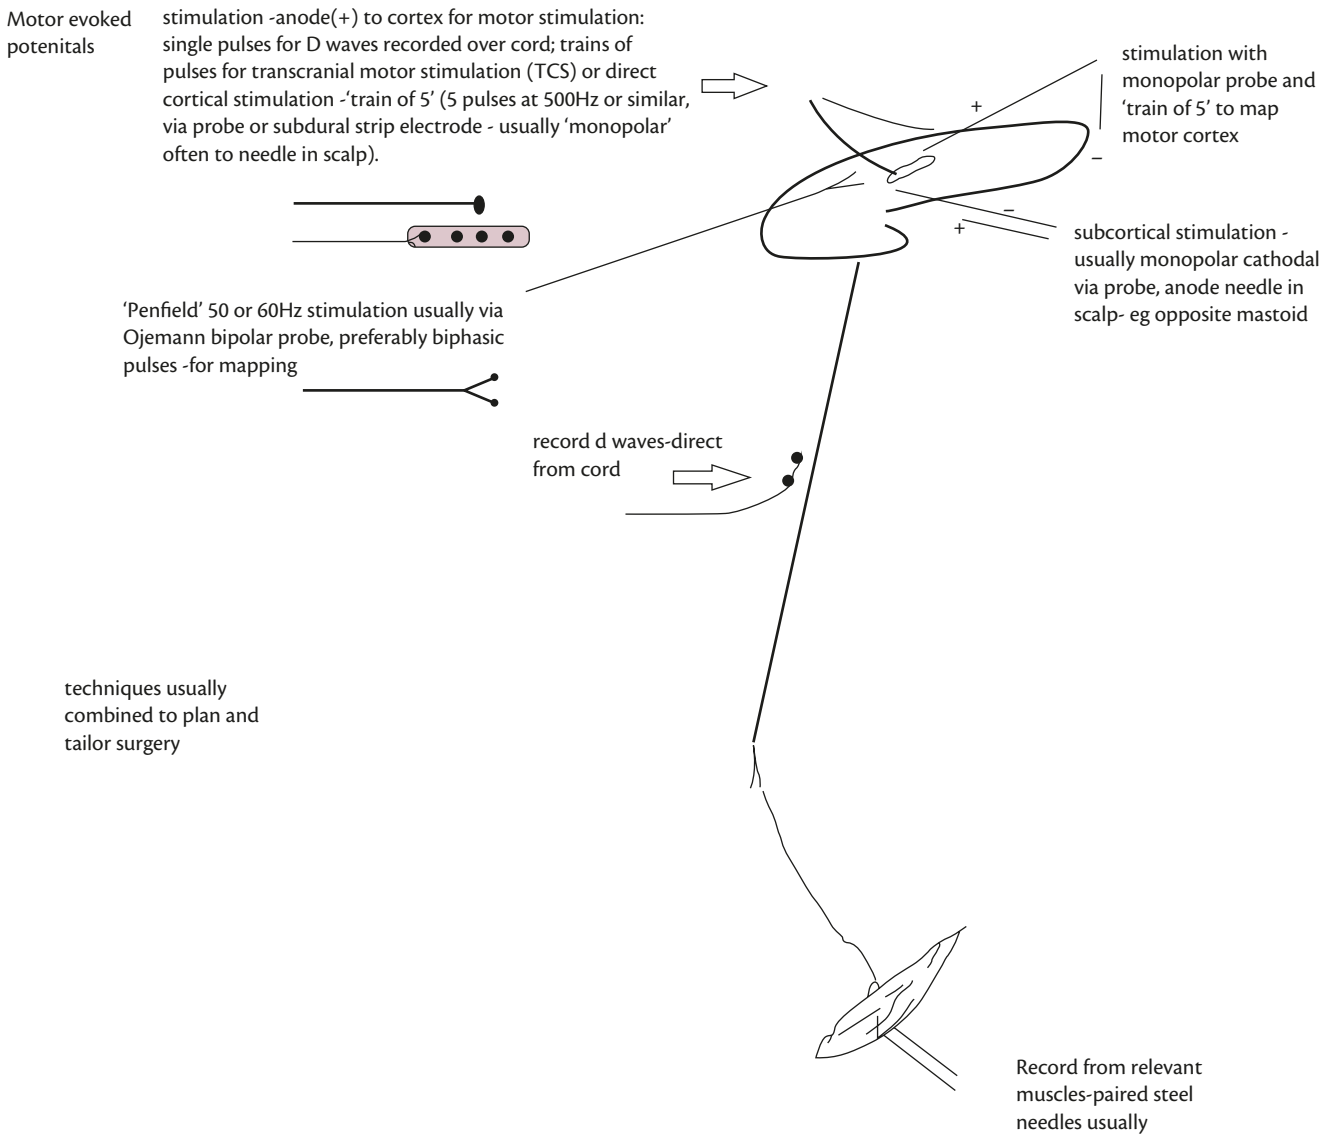
- Mentalis
- Deltoid or biceps
- Extensor digitorum communis
- Abductor pollicis brevis
- Abductor digiti minimi
- Vastus medialis
- Tibialis anterior
- Abductor hallucis

Recordings are commonly from paired needles in the muscles supplied by the relevant pathways, or from along the motor pathway distal to the motor stimulus—termed D waves (direct waves) recorded directly from the spinal cord with electrodes placed in the subarachnoid or the epidural space. D waves are usually elicited with single transcranial stimuli in anaesthetized subjects and they are the most reliable guide to damage to the corticospinal pathways in spinal surgery, but if electrodes move false positive results can occur (Ulkatan et al., 2006).

Stimulation used includes transcranial electrical or magnetic stimulation, direct cortical, subcortical, corticospinal tract (including intraspinal) and peripheral nerve stimulation. Magnetic stimuli can be used preoperatively to map motor and speech areas. During anaesthesia trains of electrical stimuli are normally employed. A 'train of 5' is commonly used, consisting of five pulses with an interpulse interval of 2–4 ms. Taniguchi described stimulation of primary motor cortex with these high frequency (300–500 Hz) pulses to map motor cortex with a monopolar probe, and monitor the corticospinal tract under anaesthesia—usually from a subdural strip electrode contact on the cortex (Taniguchi et al., 1993). In awake procedures the cathode is better located in an anaesthetized area of scalp (e.g. the vertex). Motor tract monitoring under anaesthesia is also feasible during insular glioma resection—first locating motor cortex using SEP phase reversal with a subdural strip, then using contact over the motor cortex to stimulate (as anode—a scalp electrode as frontal cathode). Motor responses can be evoked during resection, allowing therapeutic action to be taken (rest, irrigation, papaverine) if MEPs deteriorate during surgery (Neuloh et al., 2007a). Stimulation of the facial colliculi with a probe gives recordable responses in the face and tongue and may be used to navigate the floor of the fourth ventricle if it is distorted, and to define the midline and safe entry zones to brainstem tumours (Sala et al., 2007). In spinal surgery motor responses from corticospinal tract stimulation can indicate medial pedicle breach: or adjacent corticospinal pathways in intramedullary tumour procedures.

Somatosensory evoked potentials (SEPs)

Peripheral stimulation evokes a response that can be recorded proximally within the nervous system (Fig. 71.4). For example, stimulation of the median or posterior tibial nerves can be recorded at the nerve roots, over the spinal cord, in the brainstem, and the sensory cortex. Median somatosensory response (SEP) is elicited by electrical stimuli—about 200 stimuli applied at the wrist—giving responses normally detectable by averaging at Erb's point, over the cervical spine, and cortex. Latency increases and reduced amplitude of responses indicate pathology at all levels of wrist-cortex.



Motor evoked potenitals
stimulation -anode(+) to cortex for motor stimulation: single pulses for D waves recorded over cord; trains of pulses for transcranial motor stimulation (TCS) or direct cortical stimulation -'train of 5' (5 pulses at 500Hz or similar, via probe or subdural strip electrode - usually 'monopolar' often to needle in scalp).
stimulation with monopolar probe and 'train of 5' to map motor cortex
+
–
–
+
subcortical stimulation - usually monopolar cathodal via probe, anode needle in scalp- eg opposite mastoid
'Penfield' 50 or 60Hz stimulation usually via Ojemann bipolar probe, preferably biphasic pulses -for mapping
record d waves-direct from cord
techniques usually combined to plan and tailor surgery
Record from relevant muscles-paired steel needles usually

Fig. 71.3 Motor evoked potentials—stimulus can be transcranial: usually magnetic for preoperative mapping, electrical transcranial 'train of 5' in theatre for monitoring entire pathway. Applied via a subdural strip or probe direct to cortex when accessible: localization of motor areas at cortical and subcortical levels via probe stimulation. Recording distally can be over cord (D waves) or more usually muscle (MEPs): for spinal work recording from a muscle above the surgery acts as a control.

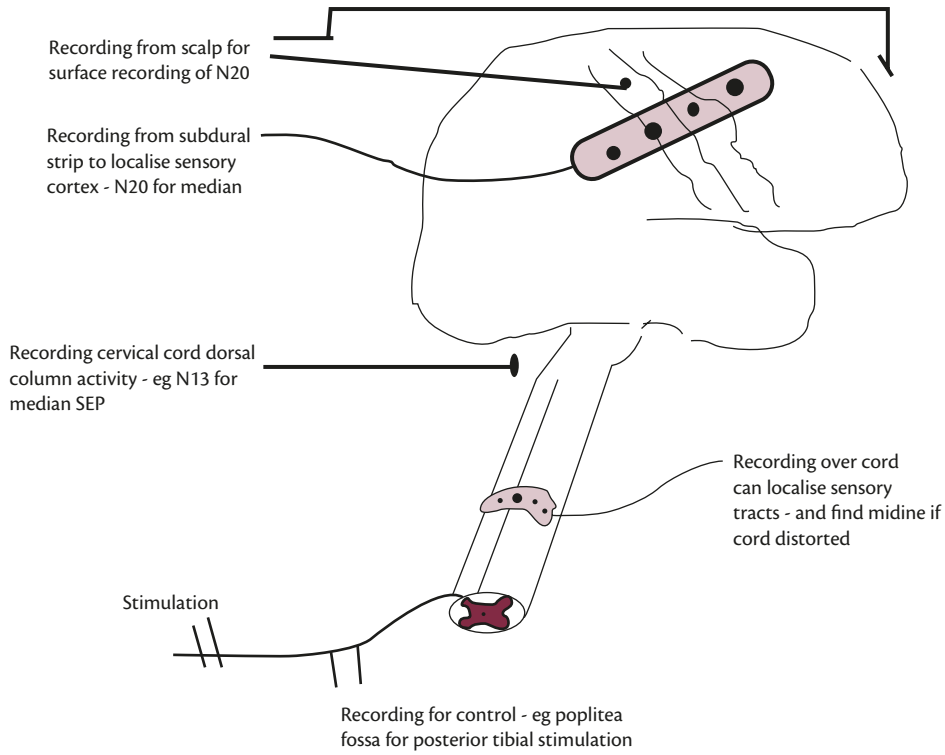
The response from sensory cortex, a negative waveform at 20 msec (N20), like the EEG, localizes sensory cortex, and is an indicator of cortical function. The N20 can be lost with ischaemia from vascular spasm (e.g. in aneurysm or insular surgery). In the ITU if the median SSEP cortical response is lost, but the subcortical (e.g. cervical N13) response present, it suggests cortical function is compromised and a poor outcome probable. The equivalent cortical response from posterior tibial stimuli at the ankle gives a cortical P40 response. Posterior tibial responses travel in the gracile fasciculus; recording this response over the cord from left and right ankle stimuli gives a guide to the midline of the cord and can be useful to find safe entry if anatomy is distorted over intramedullary tumours. This is mainly used to monitor posterior column function in the cord in spinal procedures rather than motor function. Stimulation over the back of the cord, can give sensory responses at ankle and scalp (and motor in leg muscles), as an alternative technique (Quinones-Hinojosa et al., 2002; Yanni et al., 2010).

Loss of responses during cord or cortical surgery must be appropriately interpreted and does not always predict loss of function. Changes may occur due to retraction, vascular events, or dislodged stimulating or recording electrodes. Pressure due to poor limb positioning can result in plexus palsies, also detected by loss of response, reversible with adjustment of the relevant limb.

Recording below and above the surgical site aids interpretation. As several roots are stimulated single root damage might not be detected by SSEPs. In brachial plexus surgery two level lesions can occur. If stimulation of a proximal nerve stump can elicit a cortical SSEP, there must be continuity of some contributing fibres at root level indicating that all roots cannot be avulsed.

Brainstem auditory evoked potentials

Intraoperatively click stimuli are applied via an insert earpiece. About 1000 EEG responses are averaged, with electrodes normally placed at the mastoid and vertex. The normal response gives five



Recording from scalp for surface recording of N20
Recording from subdural strip to localise sensory cortex - N20 for median
Recording cervical cord dorsal column activity - eg N13 for median SEP
Recording over cord can localise sensory tracts - and find midine if cord distorted
Stimulation
Recording for control - eg poplitea fossa for posterior tibial stimulation

Fig. 71.4 SSEP. Peripheral nerve stimulation (commonly median or posterior tibial). Visible twitch confirms stimulation: control recording a useful check (e.g. cubital fossa or erbs for median, popliteal fossa commonly for posterior tibial): recording possible over cord, in brainstem, any accessible locations to cortex, where a negative response on the posterior bank of the Rolandic sulcus coupled with a positivity on the motor bank can be used to locate somatosensory cortex by a phase reversal when recorded from subdural strip. It is also worth noting that recording over cord: stimuli to cord here can generate both sensory responses at ankles, or cortical responses, to localize midline.

early waves with III and V often the clearest. Potentially damaging manipulations or retraction of the auditory nerve increases the latency of waves III and V. V increase more than 0.9 ms gives a measurable alteration of audiogram: 50% amplitude loss and 1 mSec latency shift of wave V normally is considered likely to show postoperative hearing deficit. Reducing retraction or resting usually allows the response to recover.

The main applications of BAEPs are in cerebellopontine angle procedures such as trigeminal neuralgia, acoustic neuroma, and hemifacial spasm surgery. A direct response to a 500 Hz tone can be recorded directly in theatre and locate auditory fibres within an acoustic neuroma (Butler et al., 1995). Click stimuli can also be recorded with electrodes directly on the nerve in theatre to localize and assess function.

In head injury, longer latency auditory evoked responses are good indicators of outcome (Fischer et al., 2008).

Nerve conduction studies (NCS)

Measurement of conduction velocity along a peripheral nerve can test motor, sensory, and reflex pathways. NCS should always be interpreted in the appropriate clinical context.

Components of the study include:

1. The motor component (M wave), measured by stimulation of a peripheral nerve and recording from a muscle innervated by that nerve (e.g. abductor pollicis brevis for the median nerve). Measurements include latency (time from stimulation to recording) and amplitude, and are affected by lesions in the anterior horn cell body, axon, Schwann cells, neuromuscular junction, or the nerve itself.
2. The sensory component, measured by recording from another point on the nerve rather than from muscle. Sensory amplitudes are smaller than motor amplitudes.
3. The F-wave results from an antidromically conducted action potential in the motor axon which, on arrival at the spinal cord, causes the anterior horn cells to fire and cause a late muscle contraction. The F-wave latency measures conduction between limb and spine, rather than within a segment of the limb, and both afferent and efferent action potentials are carried in the motor axon.
4. The H-reflex study is another form of late response that effectively measures the muscle stretch reflex. For example by stimulating the tibial nerve in the popliteal fossa and recording over soleus, can be used to distinguish L5 (H-reflex present) and S1 (H-reflex absent) radiculopathies.

The amplitude of an orthodromic sensory nerve action potential (SNAP) gives a measure of the number of functioning sensory axons. Thus, the ulnar SNAP is reduced not only with ulnar problems at the elbow, but also with any other postganglionic damage to C8 fibres (e.g. generalized diabetic neuropathy or thoracic outlet syndrome). Findings must be interpreted in the clinical context. In brachial plexus injury, sensory amplitudes are a guide to severity, root level, and pre- or postganglionic location. It should be noted that the distal part of a severed nerve still functions for about a week before Wallerian degeneration occurs. Responses recorded the day

after injury must not be misinterpreted. Cervical problems usually give abnormality proximal to the ganglion, so despite a numb hand, sensory potentials are preserved.

Conduction block will occur with pressure on a nerve (e.g. ulnar or peroneal neuropathy). Changes with increasing pressure will initially give conduction block, then localized slowing: as axons die, amplitudes reduce with sensory axons affected before motor.

Motor conduction studies (Fig. 71.5) give responses (compound motor action potentials—CMAPs) from muscles, where amplitude reflects the number of axons/muscle fibres activated. Small responses are seen in axon loss and muscle wasting while latency from distal stimulation point increases with local demyelination (e.g. carpal tunnel syndrome, Guillain Barre, and reinnervating fibres after nerve section).

Repetitive stimulation stresses the neuromuscular junction and can be used to look for myasthenia and related conditions (Kimura, 2001).

NCS aids diagnosis of entrapment neuropathies such as carpal tunnel syndrome (CTS). Local entrapments of nerves commonly produce localized slowing of conduction (see Fig. 71.5). Clinical diagnosis can be misleading in CTS, with accuracy of clinical referral about 50%, and nerve conduction studies should be performed prior to offering surgery. Severity depends on the degree of median nerve slowing compared to the equivalent ulnar velocity across the wrist (Fig. 71.5). Sensory velocity slowing is the most sensitive finding, with motor latency only increased in more severe disease (Bland, 2016).

For ulnar nerve compression localization, reduced motor velocity around the elbow and amplitude drop (50% drop = conduction block), and the 'inching' technique can localize ulnar entrapment preoperatively (Kimura, 2013). The latter technique used intraoperatively has shown the location of localized slowing, and improved outcomes (Kim et al., 2003).

Electromyography (EMG)

Electromyography (EMG) measures the electrical activity of muscle membranes from surface electrodes or needle electrodes. Voluntary muscle contraction recruits motor units with good activation giving a full 'interference pattern' (Fig. 71.6A). If there is axonal loss within a nerve, full voluntary muscle contraction will generate fewer units, or even a single unit, firing at high rates due to abnormal recruitment (Fig. 71.6B).

In nerve injury, the presence of even a single firing unit confirms the presence of at least one axon in continuity with the muscle. This is valuable in assessment of plexus injuries, or as evidence that reinnervation is occurring. With complete denervation lasting for around three weeks, the muscle membrane develops 'denervation hypersensitivity' and recordings will show spontaneous activity such as fibrillation and positive sharp waves (Fig. 71.6C). Spontaneous discharges can also occur in pathologies including myotonia and myositis. The variation of firing of different muscle fibres within a motor unit gives a measure of the 'jitter'. This increases with unstable end plates (e.g. in myasthenia, or with reinnervating unstable terminal axons). The distribution of abnormal muscles on EMG, in conjunction with the clinical and nerve conduction findings, can distinguish and localize pathologies such as radiculopathy, entrapment, and peripheral neuropathy, motor neurone disease, and multifocal conduction block.

EMG can prove useful in theatre when a motor nerve that supplies an accessible muscle is at risk of injury. A free running EMG can display activity in both visual and audible form so irritation to a nerve will alert the surgeon. For example, a pair of needles in a facial muscle will record a discharge when the facial nerve is irritated during acoustic neuroma resection. The response is not linear, so initial discharges may be brief while further insults may give longer lasting discharges for many minutes. Type of discharge varies, and correlates with severity of nerve insult-in facial nerve monitoring during vestibular schwannoma resection the detection of the A train (a pattern of high frequency and homogenous appearance) in muscles supplied by the facial nerve, is a reliable indicator of facial nerve paresis postoperatively (Prell et al., 2007).

Intraoperative monitoring

Intraoperative single cranial nerves monitoring

CN II

The optic nerves and visual pathways may be monitored by flash stimuli giving visual evoked responses that can be recorded from the occipital cortex (Sasaki et al., 2010). Responses can be recorded from optic tracts in anaesthetised patients. In the awake patient stimulation of the optic tract causes phosphenes, while visual pathway stimulation within association cortex can elicit formed visual memories.

CN III, IV, V, VI, VII, IX, X, XI

These cranial nerves may be monitored with free running and stimulated EMG, using both monopolar or bipolar probe stimulation. For the third, fourth, and sixth nerves, the needles are inserted into the extraocular muscles.

Trigeminal nerve EMG is normally recorded from masseter, but free running and stimulated EMG only assesses the motor component of the mandibular division. The blink reflex can test sensory pathways—single stimuli awake, in theatre monitored by trains of stimuli. In the cavernous sinus, V1 and V2 can be detected by stimulation from a probe intraoperatively, recording from facial muscles (Al Masri et al., 2014): trains of stimuli may best elicit the R1 blink reflex response here.

The facial nerve can be localized using stimulation before it is visible during vestibular schwannoma surgery. However, if the nerve is severed, stimulation distal to the injury will still give a response. In addition, spread of excessive stimulation—'current jump'—can be misleading, or conversely stimulus applied to pooled saline may result in current shunting and a failure of stimulation.

In trigeminal microvascular decompression for trigeminal neuralgia VIII is at risk—mainly from retraction—thus the auditory evoked response is the main nerve monitored.

In hemifacial spasm the irritation that produces the spasm alters the 'lateral spread' of a response like an F-wave (e.g. stimulation of the facial zygomatic branch giving responses in the mandibular branch supplied muscle mentalis until the irritating vessel is removed). When this is lifted from the seventh nerve, the 'lateral spread response' is modified and usually vanishes. The response resolving suggests a good outcome likely. As in trigeminal neuralgia, retraction on the eighth nerve can affect hearing—the BAEP is thus often monitored here.

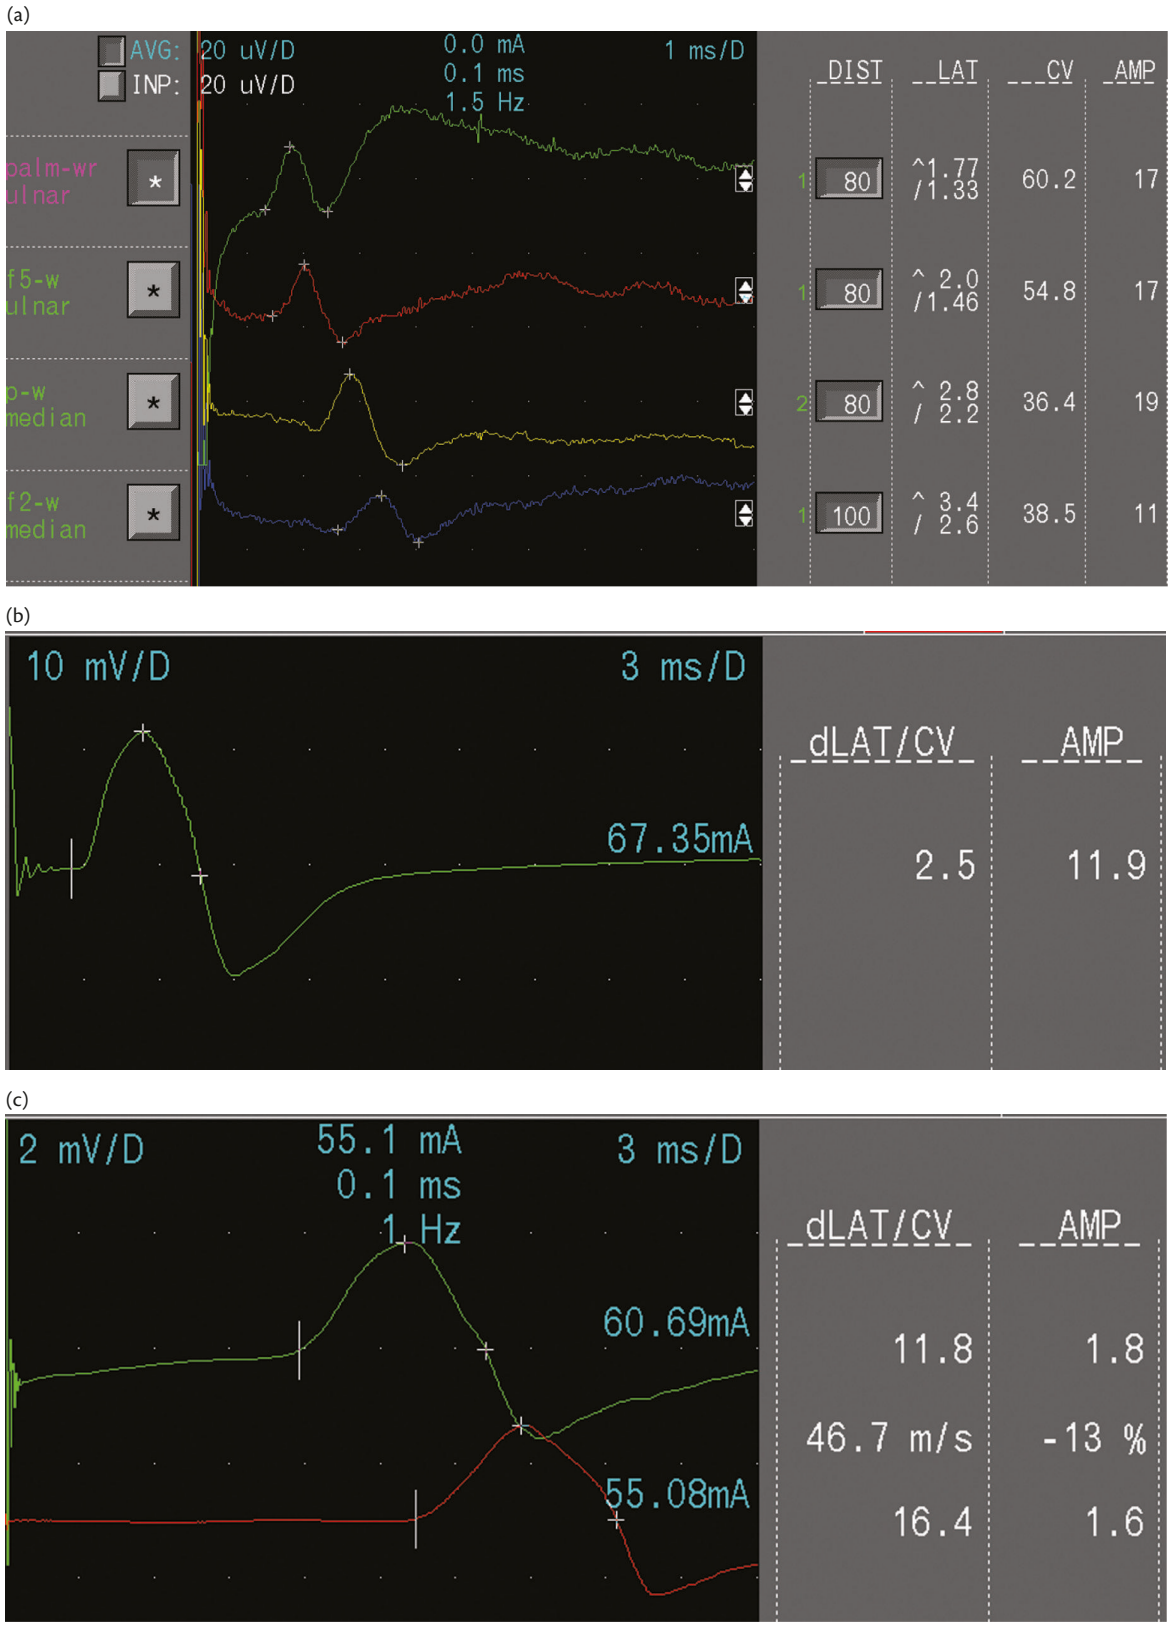


Fig. 71.5 (A) Palm to wrist velocity of 36.4 M/Sec significantly slower than the equivalent ulnar value of 60.2 M/Sec, and finger to wrist median value at 38.5 M/Sec also significantly slower than ulnar at 54.8 M/Sec. (B) With normal median distal motor latency (ii) (wrist to abductor pollicis brevis) this is a mild carpal tunnel syndrome. (C) This subject has median motor response delayed at 11.8 mSec from stimulation at wrist—more severe carpal tunnel syndrome. Second response, from stimulation at elbow, permits median motor conduction to be checked elbow to wrist. (Note other nerves tested gave normal responses -i.e. not part of a generalized problem.)

Fig. 71.6 (A) Normal EMG interference pattern in biceps. (B) Severe reduction of interference pattern to a discrete unit. (C) Fibrillations and positive sharp waves in a largely denervated abductor pollicis brevis, suggesting a postganglionic C8/T1 lesion.

VIII nerve may be monitored with BSAEP in very small acoustic neuroma tumours: direct recording from auditory fibres also possible. Responses are often unrecordable with compromised hearing on the affected side. If the tumour is larger brainstem may be monitored by BSAEP from the other ear, and long tracts by SSEPs.

Transcranial motor stimulation can give responses from cranial nerve supplied muscles, conforming continuity of their cranial nerves: stimulation artefact is a problem—long latency responses recorded from throat muscles (e.g. cricothyroid, vocalis, hypoglossus, palate) can be easier to record than the direct response—some may reflect part of speech pathways, possibly swallowing. Single stimuli of same intensity are used as controls, as high current levels may activate distal portions of peripheral nerves (i.e. response not transcranial, activating nerve distal to procedure). For some muscles (e.g. vocalis) special fine 'hookwire' electrodes are useful, and less easy to dislodge during long theatre cases. Surface EMG recordings can have specific uses (e.g. laryngeal electrodes applied via surface of an endotracheal tube pick up response from vagal innervated throat muscles), but surface recordings are less able to demonstrate high frequency irritable discharges.

Cortical mapping including awake craniotomy

Cortical mapping is mainly performed to assess motor and speech function. In tumour surgery near eloquent cortex mapping and monitoring of motor function can be assessed in anaesthetised or awake patients, speech function is monitored during awake craniotomies. Mapping motor and speech areas can also be performed preoperatively with functional imaging and magnetic stimulation, which can be combined with intraoperative localization for best outcomes in surgery on/near eloquent cortex (Bello et al., 2008).

Mapping to find safe entry zones, and continuously monitoring motor pathways and locating corticospinal tracts subcortically can be of value both to guide surgery and detect spasm of perforating vessels. To confirm main motor area, 50 or 60 Hz electrical stimulation was used by Penfield and Jasper (1954)—either with bipolar or monopolar stimuli—but most now prefer the 'train of 5' method as described by Tanaguchi and Schramm in 1993.

Motor cortex stimulation normally uses five anodal pulses at 500 Hz. A probe with 2 mm ball at end as the anode is held on cortex and the cathode as a separate electrode such as a needle inserted into the forehead, or vertex as in Figure 71.3). This short high

frequency train appears less likely to induce seizures, and a lower charge is required, than the 50 Hz method. Responses to stimuli can be recorded with paired steel needles inserted into a 'homunculus' of muscles contralaterally and the best responses are commonly seen from muscles with largest cortical representation, that is, typically abductor pollicis brevis, abductor digit minimi (or first dorsal interosseous). We commonly employ these, with mentalis, deltoid, or biceps, extensor digitorum communis, vastus medialis, tibialis anterior, abductor hallucis. In subcortical (including spinal) dissection a probe is used to give cathodal stimulation, with other electrode as anode, for direct stimulation of corticospinal tracts.

This is a simple reliable technique that can show main motor areas in an anaesthetised or awake patient. The motor cortex can be localized by SSEPs showing the Rolandic sulcus (phase reversal, usually from contralateral median stimuli), and motor area localization is confirmed by direct stimulation. SSEP gives a negativity 20 msec after stimulation over the sensory posterior bank of the Rolandic sulcus and a positivity over the anterior bank, localizing the motor cortex. A four-contact (or longer six- or eight-contact) strip electrode placed across the Rolandic sulcus thus can be used to localize motor and sensory cortex. Further mapping can be performed with stimuli from a probe where appropriate. The strip is left in this area and a contact over the motor cortex is stimulated repeatedly to give monitoring of motor tracts throughout. This method developed by Neuloh et al. (2007b) gave excellent results in insular tumours—where vascular spasm may compromise motor pathways. Some 44% of his cases showed deterioration in MEP responses. If these were lost rest, irrigation, and papaverine, restored responses in 29%, but if they did not return, a neurological deficit occurred.

Where a tumour dissection runs below motor areas, mapping of tracts with subcortical stimulation is useful using cathodal, monopolar probe, train of five stimulation. Cathodal stimuli can also be used to localize corticospinal tracts from within spinal tumours (Quinones-Hinojosa et al., 2002).

Awake surgery gives the best patient feedback, and is useful for speech, vision, higher function, and motor monitoring, but it is not suitable for all patients. Motor evoked responses also seen with 'Penfield' 50–60 Hz stimulation—usually with an Ojemann bipolar stimulator in awake procedures, for speech and motor localization (Szelényi et al., 2011). This is more likely to give seizures than 'train of 5', though either can, particularly if stimulation is excessive. These can be treated by irrigation with cold saline/ringer on the cortex. Train of five motor stimulation for an awake patient is as described earlier and a lower current is required. This does not usually cause distress if the cathode is placed in an anaesthetised area (e.g. vertex). Several papers now show significantly better outcomes in awake surgery when tumours are in eloquent areas (Sacko et al., 2011) with more complete excision and with fewer deficits. Large stimuli produce a visible contraction, but smaller stimuli can give easily recordable responses via the needles. When testing a positive response is sought first, giving a threshold before trusting 'negative' stimulation sites. If possible, EEG should be assessed to detect after discharges and detect seizures early. If mapping performed with too high a current there is increased risk of seizures, and the stimulus spread may result in excessive caution and incomplete tumour removal. The seizure risk overall is 4.9% (Serletis and Bernstein, 2007), treatment in this situation normally being by irrigation with cold saline on the seizing cortex. Excessive chemical seizure control from the anaesthetist can render the awake patient too drowsy to cooperate with the awake procedure.

Some speech pathways may be detected in asleep patients by 'train of 5' stimuli eliciting long latency responses in cricothyroid (Deletis et al., 2011), and similar responses may be seen in the palate and tongue.

Supplementary motor area damage gives profound weakness which in general resolves spontaneously over a period of days or weeks. Damage to this area can be detected by inability to perform planned motor tasks (Nakajima et al., 2015), for example, opposing specific digits: this can affect ipsilateral as well as contralateral hands. In theory, if the motor responses are intact from cortical stimulation recording directly from contralateral muscles, and voluntary activation fades, the supplementary motor cortex is being excised. Motor recovery should occur in about a month. Premotor motor area surgery can leave permanent deficit—cortical and subcortical stimulation in awake subjects can again minimize deficit (Rech et al., 2017).

Visual pathways can be located in awake subjects by stimulation eliciting flashes, colours, or visual field changes. In asleep subjects, flashes of light can evoke responses from visual pathways recorded with microelectrodes from optic tract below globus pallidum during deep brain stimulation surgery.

Huge variation exists in areas relevant for speech (Ojemann, 1979). Speech arrest with 50 Hz stimuli is the simplest test, but picture recognition and verb generation test other important components of speech (procedures reviewed in Rofes et al., 2017).

Thus, train of five stimuli give fewer seizures, and are more effective in most situations

Neurophysiology for functional procedures and microelectrode recording

Deep brain stimulation 'DBS' has now evolved to become a major area of neurosurgery. The physiological mechanism responsible for the effects of DBS remain unclear, and different patterns of stimulation have different effects at different targets. Stimuli modulate the activity of adjacent cells or fibres. McIntyre at el suggest depolarization blockade, synaptic inhibition, synaptic depression, and stimulation-induced modulation of pathological network activity' as the four general hypotheses of the effects (McIntyre et al., 2004).

Electrodes implanted, usually with four contacts, can provide a variable stimulus leading to the function at the target area being disrupted with currents passing in various ways between these implanted electrodes. Variable frequencies and currents can be programmed in to modify the effects.

Currently the main targets for movement disorder surgery are the thalamus (mainly for tremor), the globus pallidus (mainly for dystonias or Parkinson's disease), the subthalamic nucleus (for Parkinson's disease) and the more recent pedunculopontine nucleus (again for Parkinson's disease). For Neuropathic pain, targets include VPL of thalamus and periventricular grey matter. Stimulation of the PVG gives a sensation of warmth in the affected region, while VPL gives paraesthesia. Motor cortex stimulation for pain targets the motor cortex and also the anterior cingulate gyrus (Boccard et al., 2014). Numerous other targets include the nucleus accumbens for obsessive compulsive disorder and the hypothalamus for eating disorders.

Neurophysiology can be involved in accurate definition of the targets and in the correct placing of electrodes. Functional procedures

are frequently performed in awake subjects. Stimulation is employed as a means of localization of the target, determining the therapeutic window and determining the proximity of adjacent structures and avoidance of stimulation-induced side effects such as proximity to internal capsule from thalamus giving muscle contraction. In addition, impedance measurement or microelectrode recordings can be considered for guidance of tissue traversed by the electrodes.

Microelectrodes give information about the activity of the target area, but the location of the target electrode is what is critical requiring good imaging, and good targeting technique with either microelectrode or impedance methods. Extracellular microelectrodes are mainly used during DBS surgery to record action potentials from adjacent neurons. White matter shows only occasional spikes, while grey matter shows more continuous activity with patterns that vary from one location to another. This is a useful technique to determine the precise location of targets such as the subthalamic nucleus (STN) in surgery for Parkinson's disease (Fig. 71.7). Spontaneous discharges with frequencies at about 40 Hz which are normally recorded from the STN are increased in Parkinson's disease and reduced in Huntington chorea. The increased firing rate of excitatory glutamatergic STN neurones are responsible for the increased firing in inhibitory GABA-ergic output of GPi resulting in inhibiting thalamic or brainstem targets and thus reduced motor activity in Parkinson's disease. For dystonia, the globus pallidus is often targeted with the subject asleep, as vigorous movement gives technical difficulties. GPi recording in dystonia shows diminished spontaneous discharges evident as change from a tonic to a phasic pattern of the pallidal neurones discharges. This in turn results in reduced inhibition of the thalamus and increased activity in the motor and premotor cortex. The discharge pattern of the advancing activating electrode changes with its location from the putamen, GPe and GPi. Flashes of light can evoke responses from visual pathways and can be recorded with the microelectrode from the optic tract below globus pallidum. Thalamic recordings from Vim may show tremor related rhythmic burst activities.

These neurophysiological techniques were essential to locate targets when imaging technology was not able to demonstrate them clearly. Advances in imaging have resulted in successful DBS implantations without neurophysiological information, although such methods remain controversial (Ashkan, 2008).

Motor and sensory monitoring in spinal surgery

For spinal surgery 'multimodal' monitoring is best practice (Kothbauer et al., 1997). Motor, somatosensory, and EMG techniques are commonly combined. Since the 1970s SSEPs were used in scoliosis surgery (Nash et al., 1977), but could not reliably predict damage to motor pathways. 'Mulimodality monitoring' with motor evoked potentials recorded from peripheral muscles or from the back of the cord (D waves), SEPs, and free running and stimulated EMG. These techniques are considered particularly useful for intramedullary tumours, also being applied in extramedullary tumours, and even for simple decompressive surgery (Ney et al., 2015).

In spinal and conus surgery, again single peripheral nerves can be at risk. EMG activity from irritation of the supplied muscles, and response to a stimulating probe, is currently the main guidance available to the surgeon, but transcranial stimulation is also useful to confirm continuity, and monitor cord function.

Conus tumours and cauda equina surgery can be complex. In complex spinal lipoma surgery neurophysiology is a 'sine qua non' (Pang, 2015). The concentric stimulating probe is recommended with 10/sec stimuli, 0.3–3 mA for roots, or up to 2 mA on the cord. In addition, peroneal and posterior tibial SSEP recording, multiple muscles for EMG and MEP, particularly including sphincters, which are also used for the bulbocavernosus reflex monitoring (Skinner and Vodušek, 2014).

Pedicle screws insertion may risk breaching the pedicle wall. If the screw track is close to the nerve roots, stimulation applied along this track or through the inserted screw can generate a muscle twitch from the stimulated root, or lower segmental levels if the breach is medial and cord is stimulated. Monitoring requires reliable stimulation, and reliable muscle recording. The muscle must be innervated from the tested root and nerve and muscle must function. Recording can be tricky in obese patients if the muscle cannot be easily accessed with the paired recording needles. It is particularly a problem in thoracic levels.

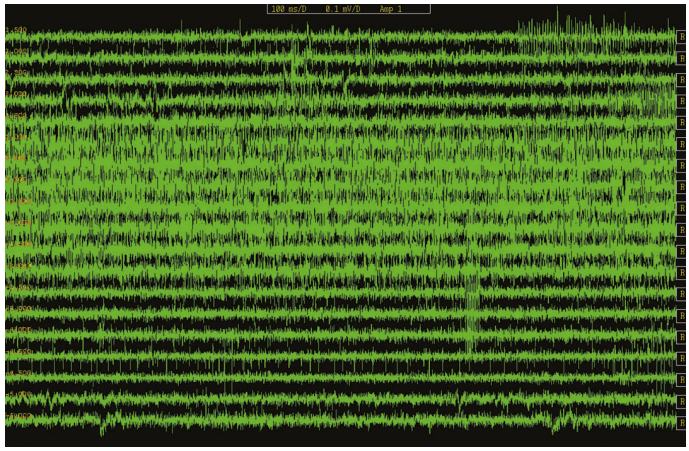

Fig. 71.7 Multicellular activity as recorded with a microelectrode passing through the subthalamic nucleus (STN). Each trace is recorded in sequence as the electrode descends, thus top traces originate deep to STN, with some regular firing cells (top right) probably arising from substantia nigra: increasing activity in the centre where rapidly firing STN cells make a sound through the amplifiers like 'ripping velcro'. Deep brain stimulating lead should be positioned to straddle this zone.

Entrapment syndromes

Grainne Bourke and Mobin Syed

Introduction

Peripheral nerve entrapment syndromes are common (Table 72.1). In the upper limb, carpal tunnel syndrome (CTS) accounts for about 90% of entrapment neuropathies. It has an annual incidence of 0.1–0.35% and a reported prevalence between 1% and 7% in the European population (Bongers et al., 2007; Dang and Rodner, 2009). This is far greater than the incidence of ulnar nerve syndromes (0.03%), radial nerve syndromes (0.003%) or meralgia paresthetica (4.3 per 10 000 person-years) (Nordstrom et al., 1998; van Slobbe et al., 2004; Latinovic et al., 2006). Due to the prevalence of CTS in the working population age group the economic effects are significant (Foley et al., 2007).

Pathophysiology

All nerves glide through specific pathways as they pass peripherally to their target organ. It is these pathways composed of bone, ligament, fibrous tunnels, muscle origins and insertions that not only enable effective nerve movement and gliding but also are the potential source of nerve compression. For example, it is the cubital tunnel 'pulley system' (intermuscular septum, arcade of Struthers, epicondylar groove and origin of the flexor carpi ulnaris) that allows for effective movement of the ulnar nerve about the elbow with excursion of 9.8 mm and 14.5 mm in the forearm during flexion and extension of the elbow (Wilgis and Murphy, 1986). However, it is these same structures which we divide to relieve nerve compression.

Anatomical deformity secondary to pressure and alteration of epineural blood flow inducing nerve ischaemia have both been shown experimentally to be induced by nerve compression. The changes seen are dependent on the duration and degree of applied pressure. Early changes induce endoneural oedema altering intraneuronal transport. The increased endoneural pressure disrupts micro-neural circulation resulting in dynamic ischaemia of the nerve. Clinically these microanatomical changes correlate with intermittent paraesthesia and increased sensory thresholds (Ochoa et al., 1972; Rempel et al., 1999; Mackinnon, 2002).

Progressive compression leads to localized demyelination resulting in persistent paraesthesia, numbness, and changes in dexterity. Further prolonged pressure progresses to diffuse demyelination with axonal degeneration manifesting clinically as muscle wasting, permanent sensory abnormalities, and pain (Rempel et al., 1999).

Connective tissue elements, both within and surrounding each nerve, increase where each nerve crosses a joint. This change can contribute to the symptoms of compression as alteration in blood flow to this surrounding sleeve can lead to fibrosis and thickening thus promoting nerve compressive symptoms and interfering with the natural intraneural and extraneural gliding mechanisms (Rempel et al., 1999; Mackinnon, 2002).

Double crush

The double crush concept, first proposed by Upton and McComas in 1973, involves compression along the course of the nerve, insufficient to cause symptoms but leaving the nerve more susceptible to a secondary site of compression. It is then this two-level compression that then yields symptoms. Relieving the nerve compression at one of the sites might be enough to provide symptomatic relief and traditionally the more distal site is addressed first (Upton and McComas, 1973).

Carpal tunnel syndrome

Aetiology

In most patients, the aetiology of CTS remains idiopathic. Histologically these patients have been shown to have increased oedema and fibrous thickening with little inflammation. The compression being greatest at 1 cm distal to the distal wrist crease corresponding to the thickest point of the transverse carpal ligament (Ikeda et al., 2006). Several other local aetiologies which can potentially increase the pressure inside the carpal tunnel have been reported; lipomata, ganglia, haemangiomata, and anatomical anomalies such as a proximal lumbrical origin, Palmaris brevis, or persistent median artery.

Systemic conditions such as diabetes mellitus, rheumatoid arthritis, hypothyroidism, acromegaly, and chronic renal failure predispose patients to carpal tunnel syndrome. In children,

Table 72.1 Entrapment neuropathies of the upper limb with sites of compression (sites listed distal to proximal)

Nerve affected	Location: compression syndrome	Anatomical entrapment
Median	Wrist: carpal tunnel	Under the transverse carpal ligament
	Proximal forearm: pronator syndrome	Compression between the two heads of Pronator Teres or fibrous arch of flexor digitorum superficialis
Anterior Interosseous nerve	Proximal forearm: anterior interosseous nerve	Compression between the two heads of pronator teres or fibrous arch of flexor digitorum superficialis
Ulnar	Wrist	Guyon's canal
	Distal arm/elbow: cubital tunnel	Between the two heads of flexor carpi ulnaris, ligament of Osborne, arcade of Struthers
Radial	Forearm\ Elbow: posterior interosseous entrapment	Arcade of Froshe, between the heads of supinator

muco-polysaccharidosis should be excluded. Pregnancy remains a transient cause with up to 45% of women being affected during the third trimester.

Anatomy of the carpal tunnel

The carpal tunnel is an osseofascial tunnel bounded by the carpal bones and the transverse carpal ligament. This strong fascial structure takes origin from the hamate and triquetrum on ulnar side and tubercle of trapezium and scaphoid on the radial side. The median nerve along with the deep and superficial flexor tendons to the digits and flexor pollicis longus travel through it from forearm to hand. Knowledge of the variation in the anatomy of the median nerve is important during surgical decompression. Considerable variations in the anatomy of the motor branch and palmar cutaneous branch have been reported with extra ligamentous pattern of motor branching being most common (46–90%) while the other less common patterns being subligamentous (31%) and transligamentous (23%).

Clinical presentation

A diagnosis of CTS is established on the evaluation of clinical symptoms, signs, and provocative tests (Table 72.2). Classical symptoms include night time wakening with numbness, tingling in the median nerve distribution and weakness in the thenar muscles. Similar symptoms are reproduced on actions which alter the pressure\volume ratio of the carpal canal such as holding a steering wheel while driving or holding a book while reading. Consensus expert agreement on the clinical diagnostic criteria has been validated by Graham et al. in 2006 (Graham et al., 2006) (Box 72.1).

Perhaps the most commonly used sign is that of Tinel-Hoffmann. This clinical sign describes the tingling felt in the sensory distribution of an injured nerve on percussion. The sensitivities for this sign are poor while the specificity is high for identifying CTS (i.e. a patient is likely to have CTS if they have both a positive Tinel's sign and a history suggestive of CTS), however a negative Tinel's does not exclude the diagnosis (Davis and Chung, 2004). Other

Table 72.2 List of common provocative tests

Nerve	Site of entrapment	Provocative test and explanation of positive test
Median	Carpal tunnel	Tinel-Hoffman's sign: percussion over the carpal ligament produces sensory symptoms in median nerve distribution (circa 1915) Phalen's sign: flexing of the wrist while the forearm is vertical induces symptoms in less than a minute (1966) Reverse Phalen's: extension of the wrist induces symptoms in less than 1 minute Durkan's: direct compression over CT for 30 s with appearance of symptoms in any of the radial digits-sensitivity of 89% and specificity of 96% when performed with calibrated device (1994)
	Proximal Forearm	Pronator teres: onset of symptoms on resisted pronation with elbow in extension Lacertus fibrosus: symptoms on resisted elbow flexion Flexor digitorum superficialis arch: symptoms on resisted middle finger flexion
Ulnar	Guyon's canal	Pressure proximal to Guyon's canal Reverse phalens: extension of the wrist induces symptoms in less than 1 minute
	Cubital tunnel	Tinel's sign: tapping over the Cubital tunnel produces sensory symptoms in ulnar innervated digits Flexion of elbow Pressure proximal to cubital tunnel

provocative tests include Phalen's, reverse Phalen's and Durkan's (Table 72.2). Threshold sensory testing using Semmes-Weinstein filaments and assessment of two-point discrimination are also useful sensory tools (Gelberman et al., 1983). These may demonstrate sparing of the palmar skin as this is supplied by the palmar cutaneous branch which does not travel through the carpal canal.

Investigation

Investigations should be modelled around excluding differential diagnoses including cervical radiculopathy and peripheral neuropathy and evaluating predisposing conditions such as hypothyroidism, diabetes, and inflammatory arthritis. These include blood tests, electrodiagnostic studies, and imaging modalities.

Electrodiagnostic tests can support clinical diagnosis. However, they are only positive if there is demyelination or axonal loss. Those cases where there is intermittent ischaemia and a reversible conduction block will not produce abnormal nerve conduction values. In diabetic patients nerve conduction values are more abnormal.

Neurophysiological grading scales for CTS have been described. Nerve conduction findings correlate with a score for clinical characteristics. Other correlations that were demonstrated included those between the severity of disease and older age groups, mild disease was more common in young females (Padua et al., 1997; Bland, 2000).

In practice nerve conduction evaluation is used for cases where the combination of history and clinical assessment is inconclusive but suggestive of CTS. They are also used for cases of recurrent CTS again to confirm the diagnosis.

Box 72.1 Final list of unweighted clinical diagnostic criteria

Numbness and tingling in the median nerve distribution
Nocturnal numbness
Weakness and/or atrophy of the thenar musculature
Tinel's sign
Phalen's test
Loss of two-point discrimination
Ameliorating/exacerbating factors*
Improvement by splinting and/or steroid injection
Worsening with activities such as driving and strenuous hand use
Coexisting medical conditions*
Pregnancy
Diabetes
Hypothyroidism

**These factors did not contribute significantly to the logistic regression model.*

Ultrasound to determine the cross-sectional area, elasticity, local tissue kinematics, and Doppler studies to study flow characteristics have been proposed as non –invasive modalities. Sensitivities of up to 97.9% have been described which are comparable if not better than those ascribed to nerve conduction studies (85%) (McDonagh et al., 2015).

Anatomical MRI may be indicated to evaluate abnormal median nerve or carpal canal anatomy, including intraneural and extraneural tumours, and vascular anomalies. The role of MRI diffusion tensor imaging is currently under evaluation and as yet is not defined.

Treatment

Non-operative

Modification of the underlying disease such as inflammatory arthritis can relieve symptoms for some patients. CTS resolves in the majority of cases when associated with acromegaly once the condition is successfully treated and has been reported to occur mostly within 6 weeks.

Non-operative strategies such as wrist splints are effective in relieving symptoms and are useful in pregnancy and in early presentation of symptoms in young women. However, evidence supporting night splinting and the comparable benefit of splints compared to other treatment modalities is lacking (Page et al., 2012).

There is evidence to show that methylprednisolone injection has benefit in relieving symptoms up to 10 weeks postinjection but in a randomized placebo-controlled study 75% of patient went on to surgical decompression after steroid injection within 1 year (Atroshi et al., 2013).

Certain other non-surgical treatments have been trialled which include laser therapy, iontophoresis, electroconvulsive therapy, heat therapy, diuretics, and non-steroidal anti-inflammatories; there is however insufficient evidence in support of these.

Injection technique

This is a sterile procedure. The median nerve sits between and deep to the flexor carpi radialis and the palmaris longus just proximal to the wrist crease. The palmar cutaneous branch leaves the nerve on the radial side and travels adjacent to the nerve and does not enter the carpal tunnel (Fig. 72.1).

A combination of one millilitre of steroid and one millilitre of local anaesthetic is used. Triamcinolone acetonide 10 mg per millilitre is most commonly used. Insert the fine bore needle through the skin, directed at 30°, at the level of the wrist crease and just ulnar to the palmaris longus tendon. Draw back on the syringe to confirm the needle is not located intravascularly. There should be no resistance while injecting the fluid. Ask the patient to tell you if they are experiencing tingling or pain, as this means the needle location could be intraneural and should be withdrawn. Complications of injection include intraneural and intravascular placement of the steroid mixture, both of which have serious sequelae.

Operative

This is indicated when non-surgical treatments have failed or when the presentation is with advanced nerve compression (i.e. with loss of sensation or motor deficit). Surgery involves release of the transverse carpal ligament which can be done either open or as an endoscopic carpal tunnel decompression.

Open carpal tunnel decompression is the most commonly practised technique. It is a local anaesthetic procedure in adults and can be performed with or without adrenaline. In the later a tourniquet is needed to ensure good visibility of structures.

An incision is made over the carpal ligament in line with the radial border of the flexed ring finger, parallel to the thenar crease extending proximally to the distal wrist crease. The skin and soft tissues are retracted using self retaining retractors as the carpal ligament is divided under direct vision (Fig. 72.2). This enables the identification of any anatomical variations and avoids injury to the motor branch. A single layered skin closure is performed with absorbable sutures. A simple dressing is applied to enable full mobilization of the hand although it is usual to provide some local pressure over the operation site with advice to elevate the hand for the next 48 hours.

Endoscopic carpal tunnel release was first described by Chow using two ports in 1989. The benefits were immediately apparent: rapid recovery, decreased scarring, and lower postoperative pain (Chow, 1989). Agee modified the access using a single incision technique to view the plane between the flexor synovium and the carpal ligament. This later technique aids in visualization of the deep surface of the carpal ligament (Agee et al., 1994). It can be performed under local anaesthetic, but regional anaesthesia is probably more common.

Carpal tunnel release—open or endoscopic

Both the techniques are practised extensively. There is still controversy in the literature about which technique is best. The key factors to consider in deciding the most appropriate for each healthcare system include complications, time to return to work, cost of equipment, and theatre time and technical expertise.

Historical evidence supports an increased incidence of neurovascular complications and a steeper learning curve in endoscopic carpal tunnel release. A recent multicentre systematic review and meta-analysis did not concur with the higher complication rate (Vasiliadis et al., 2015). Patients having an endoscopic carpal tunnel release have an earlier return to work with less scar tenderness and greater grip strength. They do however have more transient

Fig. 72.1 The median nerve (yellow) sits between and deep to the flexor carpi radialis and the palmaris longus just proximal to the wrist crease. The palmar cutaneous branch 9 purple) leaves the nerve on the radial side and does not enter the carpal canal.

postoperative neurological symptoms. At 6 months the outcomes are no different to open carpal tunnel decompression (Sayegh and Strauch, 2015).

Studies have not shown a substantial difference between the procedural cost of the techniques provided the cost of equipment is disregarded for endoscopic carpal tunnel release (Sayegh and Strauch, 2015). However, for the employed group there is a statistical difference in the time to return to work (8 days earlier in the endoscopic group), which does have a cost advantage for industry (Saw et al., 2003). Thus endoscopic carpal tunnel release should be considered in patients keen on early return to work if appropriate equipment and technical expertise are available.

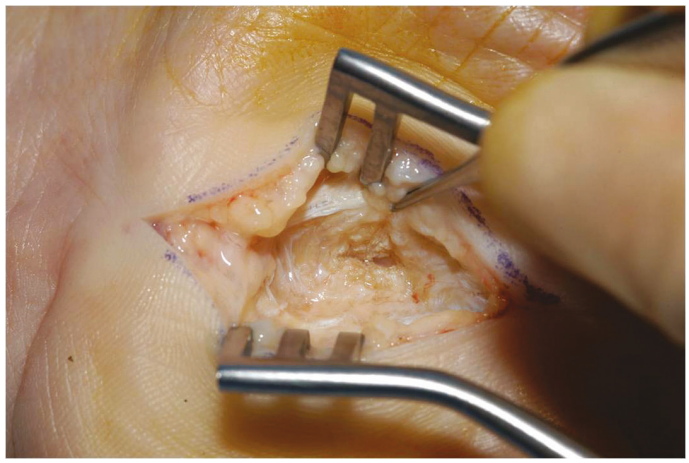

Fig. 72.2 The skin and soft tissues are retracted using a self-retaining retractor as the carpal ligament is divided under direct vision. Layers from superficial to deep; skin, subcutaneous fat, palmaris longus fascial extension, carpal ligament and, at the base, a small opening showing the contents of the carpal canal.

Outcomes and complications

Overall surgical release has good outcomes in 75% but 8% of patients are worse. Patients who have steroid injections have a 70% initial response rate but can relapse with time. A further steroid injection can be equally effective (Bland, 2007). In those over 70 years release does not result in complete relief of symptoms or recovery of function but patient-reported outcomes were statistically better (Leit et al., 2004).

The most common complication with open carpal tunnel decompression is pillar pain reported in about 25% of patients. This is followed by stiffness and swelling. Other reported specific complications include injuries to the motor branch, the palmar branch, or the main trunk of the median nerve and tendon adhesions. Recurrence of symptoms is noted in about 20% of the patients.

Cubital tunnel syndrome

Aetiology

Cubital tunnel syndrome is the second most common compression neuropathy after CTS. It is the most common entrapment neuropathy at the elbow, and it is more common in men. It has an incidence of 20.9 cases per 100 000 person-years (Mondelli et al., 2005). Cigarette smoking is a risk factor probably related to its pathophysiological effects on the micro circulation rather than the mechanical effects of elbow motion to enable the smoking action (Bartels and Verbeek, 2007). Retro epicondylar compression is seen more commonly in young administrative workers, while compression due to the humeroulnar aponeurosis is seen in manual workers (Omejec and Podnar, 2016). Predisposing systemic conditions are similar to those described for CTS.

Anatomy

The most proximal site of compression is the arcade of Struthers which is a condensation of the deep brachial fascia extending onto the medial intermuscular septum about 8 cm proximal to the medial

Fig. 72.3 The ulnar nerve travelling between the flexor and extensor compartments of the arm, traversing the epicondylar grove where the roof has been removed for visibility. The ulnar nerve is seen entering the forearm between the heads of the flexor carpi ulnaris.

epicondyle. The cubital tunnel has as its roof a thick fascial condensation extending from flexor carpi ulnaris (FCU) to the arcuate ligament of Osborne while the ulnar collateral ligament forms the floor. The nerve tunnel continues between the two heads of FCU and the deep flexor pronator aponeurosis (Fig. 72.3).

Clinical presentation

The symptoms include tingling or altered sensation in the little and ulnar border of the ring finger and the dorsum of the ulnar aspect of the hand. Patients complain of numbness on wakening and exacerbation of symptoms with elbow flexion. Late presentations are in the form of loss of sensation of the ulnar innervated digits and wasting of the intrinsic muscles. The later differentiating proximal compression at the elbow from distal compression at the wrist in Guyon's canal. The diagnosis is clinical with confirmation by provocation tests (Table 72.2).

Investigations

Investigations to exclude underlying systemic conditions are as described for CTS mentioned earlier. Imaging modalities that can be helpful include X-ray, ultrasound, and MRI. These are helpful not only in defining the anatomy of the nerve itself but also in excluding bone deformity, tumours, and other soft tissue anomalies that predispose to compression.

A combination of short segment nerve conduction studies combined with ultrasound can localize the area of compression to retroepicondylar or within the humeroulnar aponeurotic arcade (Omejec and Podnar, 2016).

Treatment

Non-surgical treatments

Non-operative strategies include splinting, physiotherapy, and activity modifications. This is the treatment of choice in the absence of muscle wasting or persistent numbness. Half the patients treated will have relief of symptoms (Dellon, 1989).

Surgical

Patients with muscle weakness, persistent numbness, or those with significant symptoms, who have failed to improve with non-operative strategies should be offered surgery.

The surgery is performed with the aid of a tourniquet under local or regional anaesthesia. Surgical options include simple decompression (open or endoscopic), anterior transposition (submuscular or subcutaneous) and medial epicondylectomy.

Common to all techniques is the rearrangement of the nerve's anatomical tunnel to allow easier gliding and eliminate areas of potential or actual compression. The nerve is released from proximal to distal as follows: ligament of Struthers; ligament of Osborne; and the FCU fascia. The nerve is dissected free along its entire length in the tunnel ensuring protection of the branches to FCU and medial and posterior cutaneous nerves of forearm.

There is significant controversy regarding the techniques and between *in situ* release versus transposition and the plane of transposition (submuscular, intramuscular, or subcutaneous). Where transposition is considered studies suggest equivalent results with *in situ* release itself. If the nerve has a propensity to subluxation in flexion following the release than transposition can be considered as more than 90% success has been reported with *in situ* decompression alone with transposition reserved for patients with unresolved symptoms.

Endoscopic decompression

Endoscopic cubital tunnel release has been reported using a small incision approach with outcomes and complications similar to open approach while avoiding a larger scar with the added benefit of early return to work. There are however no larger randomized studies relating to this approach.

Medial epicondylectomy

This is a technique originally described by King and Morgan for post-traumatic ulnar neuritis and subsequently extrapolated to patients with cubital tunnel syndrome. The philosophy behind this approach is that it allows for some degree of anterior transposition while avoiding significant dissection to mobilize the ulnar nerve. Cadaveric studies have a shown significant reduction in strain on the ulnar nerve with epicondylectomy as compared to *in situ* release alone (Hicks and Toby, 2002). Overzealous resection can result in an unstable medial elbow especially if a portion of the medial collateral ligament is resected (Efstathopoulos et al., 2006). The procedure involves following an *in situ* release of the tunnel, subperiosteal exposure of the epicondyle and osteotomizing the apical portion

(about 20%) ensuring the attachment of the medial collateral ligament is maintained. Persistent elbow pain has been reported in up to 45% of patients undergoing medial epicondylectomy.

Meralgia paresthetica

Aetiology

Entrapment of the lateral cutaneous nerve of the thigh as it passes from the pelvis to the lateral thigh is called meralgia paresthetica. It is more common in men. and overweight patients.

It may be related to anatomical variability of the nerve as it passes through the fascial tunnel leaving it susceptible to compression with variation of movement. It has also been associated with prone positioning in spinal surgery and as a complication of bone graft harvesting from the iliac crest and anterior pelvic procedures.

Clinical presentation

Patients present with pain, tingling, and paraesthesia in the anterolateral thigh. The lateral cutaneous nerve does not have any motor component, so the symptoms and signs are only sensory. Symptoms are aggravated by external compression with clothing or belts, hyperextension of the hip, and standing for prolonged periods.

Provocative tests reproduce the tingling and pain; for example, Tinel-Hoffman, which is pressure over the nerve as it passes adjacent to the anterior superior iliac spine. A helpful diagnostic test is to inject some local anaesthetic into the site of the positive Tinel-Hofmann's test. If the patient then experiences relief of symptoms and associated numbness in the distribution of the nerve, then the diagnosis is confirmed.

Investigations

The diagnosis is clinical. However, nerve conduction studies and ultrasound are the most useful investigative tools were the clinical evaluation is inconclusive. Other imaging modalities such as MRI are helpful to exclude the differential diagnoses of proximal spinal nerve compression, intraneural and extraneural tumours.

Non-operative

Non-operative strategies include removal of external compressors such as tight clothing or belts, losing weight, and anti-inflammatory medication.

Ultrasound can not only be used for diagnosis but also as a treatment modality. Ultrasound-guided steroid injection can be performed either directly or indirectly (Onat et al., 2016).

Operative

Surgery for meralgia paresthetica is indicated for those cases that have failed non-operative strategies but where significant symptoms persist. It is also useful for those cases with symptoms after previous pelvic surgery.

Surgery has a dual role in both diagnosis and treatment. Exploration and neurolysis is effective. In cases where the nerve is tethered or embedded in scar tissue options for importing normal tissue with the potential for nerve gliding should be considered.

Historical evidence in the literature suggest that neurectomy can be as effective if not more effective that neurolysis in some cases (de Ruiter and Kloet, 2015).

Other entrapment neuropathies

Other entrapment neuropathies that are seen within clinical practice include compressions of the radial nerve (radial tunnel syndrome, posterior interosseous nerve palsy), median nerve at the elbow (pronator syndrome) and compression of the ulnar nerve at Guyon's canal (Kumar and Bourke, 2016). More proximal nerves such as the suprascapular nerve and long thoracic nerve can also be subject to entrapment around the shoulder girdle. These entrapments can be more difficult to diagnose as there are no cutaneous sensory components to assess and patients present with pain aggravated by movement of the shoulder. Detailed discussion about these less common entrapment syndromes is beyond the scope of this chapter.

Summary

Nerve entrapment syndromes such as carpal tunnel and cubital tunnel syndrome are common. They can affect all age groups. They do have financial implications as they effect the working population and require time off work for rehabilitation and recovery after surgical release.

The diagnosis of nerve entrapment is based on evaluation of clinical symptoms and signs and reproduction of these with provocative manoeuvres. Ultrasound is probably the most useful imaging modality in current practice as it allows dynamic assessment during movement. Electrodiagnostic tests are also valuable but are best used as an adjunct to clinical examination.

Supraclavicular brachial plexus and peripheral nerve injuries

Jonathan Perera and Marco Sinisi

Introduction

Injury to the supraclavicular brachial plexus (SBP), is very rare and normally associated with traumatic injury. SBP injury (SBPi), causes significant physical impairment, but also psychological and stigmatic problems.

Epidemiology

The incidence of traumatic brachial plexus injury (BPi), is extremely difficult to ascertain due to worldwide variance, under-reporting, and the lack of recognition of milder injuries. Goldie and Coates (1992) showed that approximately 500 cases of brachial plexus injury take place in the United Kingdom each year principally as a result of road traffic collisions.

As road safety in general is improving, as shown by Keep in 2013, the amount of high-energy accident survivors in the United Kingdom is increasing. Between 1990 and 2012 there has been a 66% decrease in the number of people killed in road traffic accidents and a 62% decrease in severe injury. Most SBPis are caused in motor vehicle collisions with most series quoting upwards of 60% (Allieu and Cenac, 1988; Azze et al., 1994; Doi et al., 2000). Reviewing the statistics available SBPis are predominately caused in high-energy polytrauma motorcycle accidents in young men and are associated with long-bone fractures and head injuries. Even though motorcyclists only account for 1% of road users in the United Kingdom, they account for 20% of all road fatalities and serious injuries, with approximately 7000 serious injuries per year (Clarke et al., 2003; Rhee et al., 2011; Keep and Rutherford, 2013). Even though the number of these incidents is high, SBPi accounts for only 1% of polytrauma patients, the incidence has been reported by Allieu in 1988 to be between 0.3 to 6.3 cases/100 000/year.

Narakas's rule of sevens

There are seven '70% statistics' regarding BPis, namely 70% of cases involve road accidents, 70% of these accidents are motorcyclists, 70% of these patients present with combined injuries, 70% of these lesions are supraclavicular, 70% of these lesions involve at least one nerve root avulsion, 70% of these avulsions involve a C7, C8, or T1 level nerve root, and 70% of patients with avulsions develop chronic pain (Narakas, 1985).

Mechanism of injury

As with all medical diagnoses, SBPi types and severity can be diagnosed with an accurate history. It is vitally important to understand the mechanics leading to the injury. Important factors are the anatomy, the magnitude of the force and the vector of the force. Stretching of more than 12% of a nerve or more than 8 hours of ischaemia will result in severe nerve injury. The force required to avulse cervical nerve roots is as little as 200 newtons. The nerve root exiting angles are very important, as different forequarter positions at the time of impact will result in differing force vectors and therefore differing injury. A typical injury would be the arm and head or neck being pulled away from each other, with the arm being pulled below horizontally resulting in an upper plexal injury, versus the arm being pulled above horizontally and a resultant lower plexal injury.

A dislocated shoulder is a significant injury and can be a risk factor for supra or infraclavicular brachial plexus, (ICBP), injuries. Injury is usually to the upper trunk affecting predominately the suprascapular and axillary nerves. Many of those who get combined injuries also have an abnormal band of fascia connecting the pectoralis minor to the thoracic wall. This effectively narrows the space for the exiting SBP into the ICBP and means these patients are more susceptible to injury. Using an average male of 70 kg as an example and a deceleration period over 1 second, it is easy to calculate the starting speeds to generate the force described. In order to avulse a nerve root starting speeds of only 5 mph would be required, if the force is imparted on the SBP.

Anatomy and injury classification

The brachial plexus is formed by five spinal nerves C5 to T1. The nerve roots exit from the spinal cord and emerge in the posterior

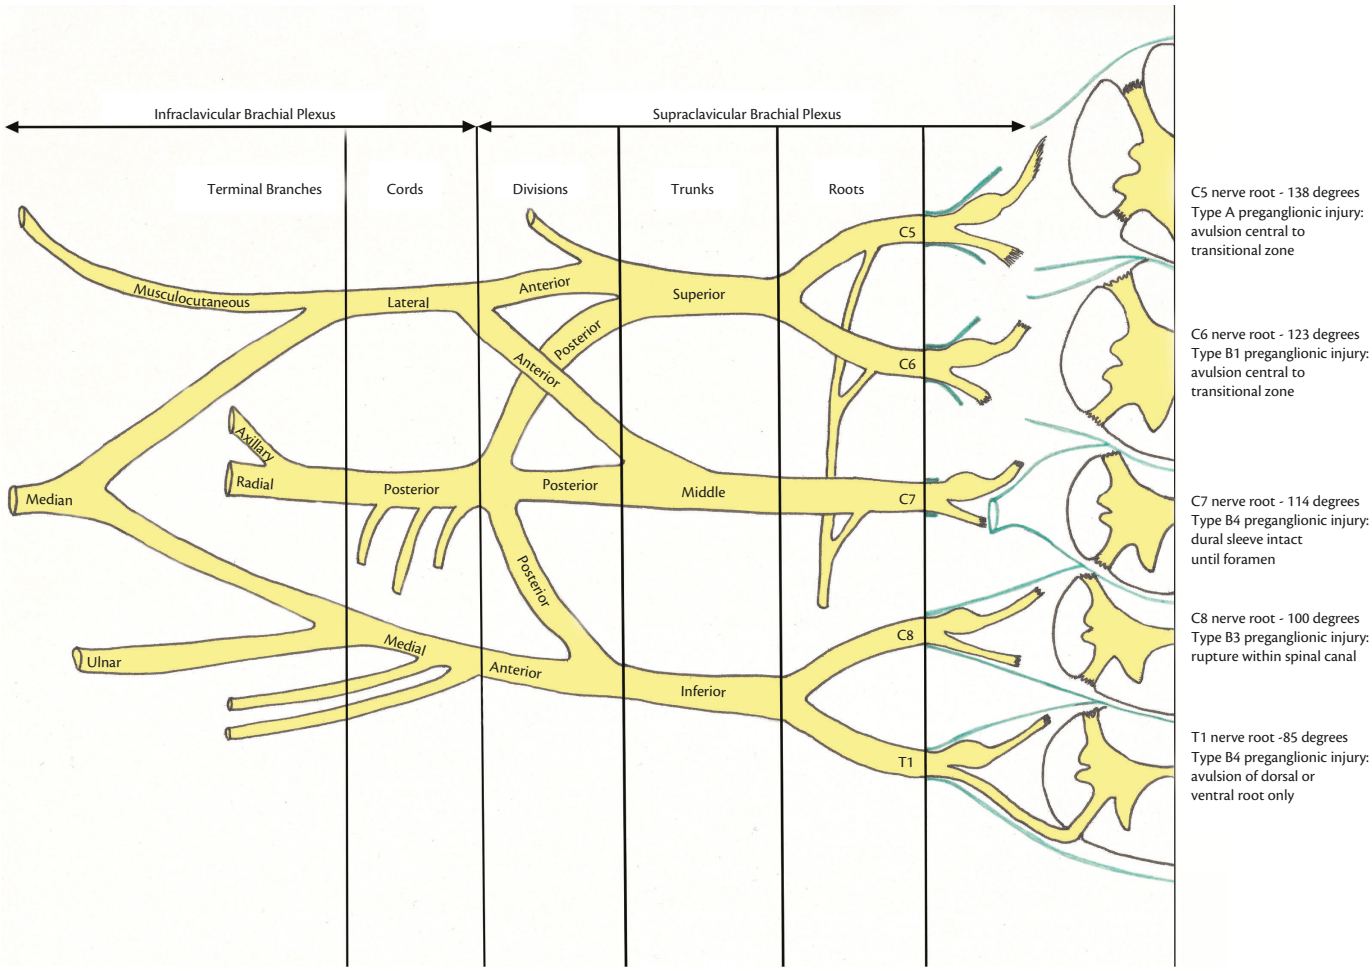

Fig. 73.1 Schematic drawing of the brachial plexus and nerve roots in addition to the root angles and the differing types of preganglionic nerve avulsion.

Courtesy of Mr Jonathan R. Perera.

triangle of the neck where they then form the upper (C5–C6), middle (C7), and lower trunks (C8–T1); see Figure 73.1. Sometimes a contribution from C4 can be present and therefore the plexus is named 'prefixed' sometimes a contribution from T2 is present and therefore is named 'postfixed'.

The SBP lies superior to the clavicle, and includes the roots, trunks, and divisions of the brachial plexus. It does not include the cords and branches, which is the ICBP. SBPi also include those injuries from further proximal and therefore can also be subdivided into pre- and postganglionic injuries, proximal and distal to the dorsal root ganglion (DRG).

The preganglionic injuries have been further classified by Birch in 2011 into five types, namely A, which is an avulsion central to the transitional zone, (TZ); B1, which is distal to TZ; B2, which has an intact dural sleeve; B3, which is root rupture within the spinal canal without DRG displacement or dural rupture; and finally B4, which is avulsion confined to dorsal or ventral roots (Fig. 73.1).

With avulsion injuries the DRG remains intact and therefore no Wallerian degeneration of the sensory nerve takes place and these patients will not have a positive Tinel's sign (Tinel, 1915). Direct and indirect nerve injury has been subdivided by the Seddon Classification (Seddon, 1942), as shown in Box 73.1. This classification applies to axonal injury, not injury of the whole nerve. The Sunderland Classification (Sunderland, 1951) defines first- to fifth-degree injuries by splitting Seddon Class III into three further divisions: preservation of the perineurium, preservation of the epineurium, and complete nerve transection.

Box 73.1 Classification of nerve injury

Class I: Neuropraxia—interruption of conduction without loss of axonal continuity and preserved supportive structures.
Prognosis: normally rapid and complete (days, weeks).

Class II: Axonotmesis—disruption of axonal continuity and its myelin with intact endoneurium.
Prognosis: variable, generally good, with worse prognosis for proximal injuries and injuries that do not re-implant in the muscle.

Class III: Neurotmesis—disruption of all nerve layers. Recovery is not possible without appropriate surgical intervention. It is a total severance or disruption of the entire nerve.

Prognosis: poor especially without intervention; normally incomplete.

Erb's point is the site where C5 and C6 form the upper trunk of the brachial plexus. It occurs halfway along the posterior border of the sternocleidomastoid muscle, from which all the cutaneous branches of the cervical plexus exit superficially (lesser occipital, greater auricular, transverse cervical, and supraclavicular nerves). This is clinically particularly important as it is at this location where forces applied to the upper forequarter and head and neck of a patient converge, commonly causing SBPi. Total plexal injury and especially those SBPi affecting the lower plexus are often associated with a Horner's syndrome (ptosis, miosis, anhidrosis, and enophthalmos). This is due to the simultaneous injury of the sympathetic trunk with preganglionic injury as well as direct spinal, head, or vascular injuries as described by Rhee in 2011. Other injuries that can sometimes worsen the presentation, confuse the diagnosis, or be initially missed are: arterial injury to the axillary; subclavian and vertebral vessels; fractures, dislocations, and muscle injuries of the forequarter.

Clinical presentation

There are three separate distinct patterns of injury that may occur in isolation or combination, namely: SBPi with preganglionic injury, SBPi with postganglionic injury, and ICBPi.

Preganglionic or avulsion injuries classically present with severe, crushing, unremitting, shooting pain in an insensate arm. The pain is usually along the dermatome of the injured spinal nerve. Kato in 2006 described a cohort where more than 50% of avulsion patients had significant pain occurring by 24 hours and 90% by 6 weeks postinjury. Patients with a preganglionic injury have a negative Tinel's test. Other signs of preganglionic injury will be injury to nerves branching at or around the root level (long thoracic, dorsal scapular, and phrenic nerves) and dysfunction of the associated muscles.

Conversely patients with an SBPi, postganglionic injury will have a positive Tinel's test, no Horner's syndrome, no serratus anterior, rhomboid, diaphragmatic dysfunction and will have absent sensory nerve action potentials, (SNAPs) on nerve conduction studies. Erb's palsy or upper brachial plexopathy (C5, C6) leaves a characteristic posture referred to as the 'waiter's tip' position, namely, shoulder adduction and medial rotation, elbow extension, and forearm pronation. Klumpke's palsy or lower brachial plexopathy (C8, T1) results in elbow flexion, forearm supination, extreme wrist extension, and clawing of the hand as a result of weakness in the small muscles of the hand. Both Erb's and Klumpke's palsy have been described as a result of birth injury from forceful depression or elevation of the shoulder, respectively, however they also occur in adults from a similar mechanism of injury.

Investigations

The main imaging investigations of choice for SBPi are magnetic resonance imaging (MRI), computed tomography (CT), and myelography.

Magnetic resonance imaging scans of the SBP and the cervical spine are extremely useful in SBPi but interpretation of the SBP portion can be challenging with conventional MRI. Since the 1990s two new magnetic resonance sequences have been discovered and implemented namely magnetic resonance neurography (MRN) as described by Filler et al. in 1993 (Filler et al., 1993) and magnetic resonance myelography (MRM) as demonstrated by Ramsbacher in 1997 (Ramsbacher et al., 1997). These sequences can be used to assess both pre- and postganglionic nerves in the SBPi. MRN requires MRI machines of 3-Tesla or more. MRN can provide an excellent form of non-invasive imaging of any peripheral nerve. MRM is useful to assess the preganglionic SBP, which is also non-invasive and just as efficient as traditional myelography in detecting injuries at this level. MRM does not require contrast medium injection into the spinal canal or radiation. Combining these two imaging modalities together can revolutionize the diagnosis and management of SBPi, especially in non-specialist centres.

CT and CT angiography are very important imaging modalities, especially when imaging polytrauma patients. Most trauma units will have quick, easy access to these scans near to the accident and emergency department. Once the patient has been stabilized, they can be safely scanned for life and limb threatening injuries. Vascular injury and/or haematomas, which are common in SBPi, will cause a significant fibrotic reaction around the SBP. This, on top of the initial injury, can be enough to cause a permanent conduction block, without surgical intervention.

Traditional myelography using fluoroscopy and CT myelography both require intradural injections. Myelography is a very useful imaging modality for assessing nerve root avulsions and to look for subsequent meningoceles or pseudomeningoceles. The lower nerve roots of the SBP can be difficult to distinguish due to the artefact created by the lower cervical and upper thoracic spinal vertebrae.

Plain X-rays

Plain X-rays are a quick and easy imaging technique, for example, a chest X-ray may show a raised hemi-diaphragm indicating a phrenic nerve injury as well as demonstrating thoracic trauma. Cervical spine X-rays may show transverse process fractures indicating nerve root avulsion injuries. Forequarter X-rays may reveal humeral, scapula, clavicular fractures, and shoulder girdle injuries, which are associated with SBPi and ICBPi.

Electrodiagnostic testing

In SBPi electrodiagnostic testing is an excellent adjunct to a thorough sensory and motor examination and imaging. Like other test modalities, electrodiagnostics require an experienced clinician to perform the testing and interpret it correctly. The tests used are predominately electromyography (EMG) and nerve conduction studies (NCS) as summarized in **Table 73.1**. EMG is used to evaluate the electrical activity of muscle during rest and during activity. Denervated muscle changes can be seen as early as 1 week after an injury (Dumitru and Zwarts, 2005) and the speed with which this change can be detected is inversely related to the nerve length. The longer the axons, the longer the Wallerian degeneration will take and so the proximal muscles will show EMG changes sooner, with the distal muscles taking 3–6 weeks to demonstrate denervation. When significant nerve injury has taken place, there will be EMG changes immediately but only a skilled Neurophysiologist will be able to detect this. EMG and NCS can both be used to demonstrate an injured nerve segment, but they will not show axonal transection. SNAPs and motor unit action potentials (MUAPs), are both important for distinguishing pre- and postganglionic nerve injuries. SNAPs are preserved in lesions proximal to the dorsal root ganglion

Table 73.1 Approximate EMG and NCS findings in nerve injury

	Conduction velocity	MUAPs	CMAPs	SNAPs	To be aware
Neuropraxia	Maintained	None	Normal Slight reduction proximally	Reduced	Permanent conduction slowing due to thinner internodes
Axonotmesis	Reduced	None	Reduced proportional to axonal loss	Reduced	Positive sharp waves and fibrillations
Neurotmesis	Nil	None	Reduced proportional to axonal loss	Absent	

therefore preganglionic injuries will have normal SNAPs with abnormal MUAPs (Table 73.1).

Histamine test

This test is not routinely performed due to the improvements in BPi imaging and diagnosis. An intradermal injection of histamine will normally cause a triple response as follows, a red reaction due to direct capillary dilatation followed by a wheal due to fluid extravasation from increased permeability of vessels and a flare of redness in the surrounding area which is caused by arteriolar dilatation mediated by the axon reflex in the sensory nerve distribution.

The histamine test can be used to distinguish between pre- and postganglionic lesions. In a preganglionic lesion the afferent axons remain intact therefore a normal triple response with flare will be seen. In a postganglionic lesion the sensory cell body and axon are not connected, and the afferent axons are degenerated therefore only the initial redness and the wheal are seen, the flare response is absent.

Management

While open SBPi needs to be dealt with urgently, there are differing opinions on when to operate in the management of a closed SBP injured patient. The benefits of early intervention include pain relief and improved outcomes although occasionally a delay in going to theatre can help to allow the inflammation to settle down (Kato et al., 2006; Birch, 2011; Birch, 2015; Hems, 2015). There have always been two main trends of thought with regards to SBPi operating, one operating early, and the other delayed until all acute problems have settled (Birch, 2015; Hems, 2015). The middle period is affected by the inflammatory phase of the original injury and tends to give poorer outcomes (Hems, 2015). Late phase repairs can also improve outcomes after the inflammatory phase had settled down (Hems, 2015). The main aims of reconstruction are to achieve the best forequarter function and relieve pain. Kato et al. (2006) found that the earlier that an operation is performed, the greater the patient's pain relief, partly due to the functional recovery which reduces pain in early surgery (Fig. 73.2).

Much like with an open injury, a vascular injury also needs to be operated on immediately. Bleeding, infection, and haematoma formation will cause significant fibrosis. This can be so severe that the normal tissue planes can disappear and the whole plexus can form a wall of scar tissue making surgery impossible. The history of the injury is very important as the level of energy imparted upon the SBP relates to the injury severity and its likely recovery. All complete lesions require exploration, as they are extremely unlikely to recover spontaneously. Pain, which occurs in many patients, is a debilitating problem that can impair their subsequent rehabilitation with physiotherapy and occupational therapy.

Distraction therapy with employment or regular exercise regimes can provide extremely effective pain relief and the more normal the routine the better (Birch, 2015). It can be clearly seen that patients returning to work earlier tend to have less pain and better outcomes with the same injuries (Kato et al., 2006; Birch, 2011). The severity of the pain predicts whether avulsion has taken place (Parry, 1980; Kato et al., 2006; Birch, 2011).

The operation

Position and skin incision

The patient is positioned in a beach chair position using a head ring with the head slightly extended about 5–10° and tilted approximately 10° to the contralateral side. The head position is very important in order to gain enough exposure of the brachial plexus, particularly at the root level, which is unattainable without this head extension. The thorax must be elevated to 30°, by tilting a split table. See Figure 73.3.

In order to achieve a complete exposure of the brachial plexus at the supraclavicular region we think that it is enough to perform a Langer's line neck incision starting 1–2 cm above the medial clavicle and extending posteriorly for about 10–15 cm, (Langer, 1861). This can avoid an incision along the sternocleidomastoid muscle and gives enough space for dissection of the plexus from the root level to the divisions of the trunks.

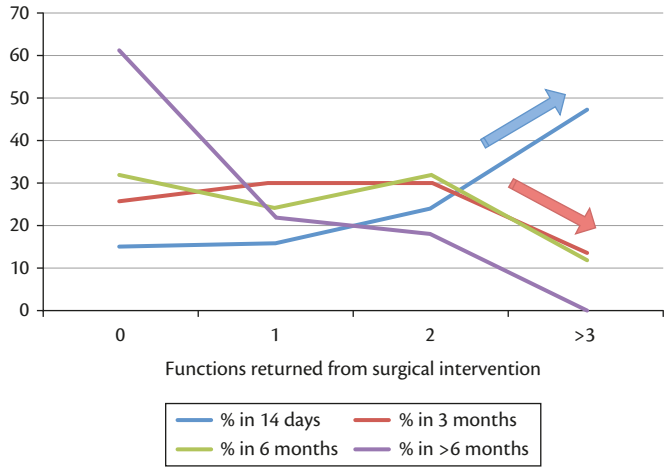

Fig. 73.2 Graph drawn with data from Birch and the Royal National Orthopaedic Hospital Peripheral Nerve Injury Unit which shows clear differences in outcome when operating within 14 days of SBPi compared to waiting more than 6 months.

Data from Birch R; 2011; Peripheral Nerve Injury Unit, Royal National Orthopaedic Hospital.

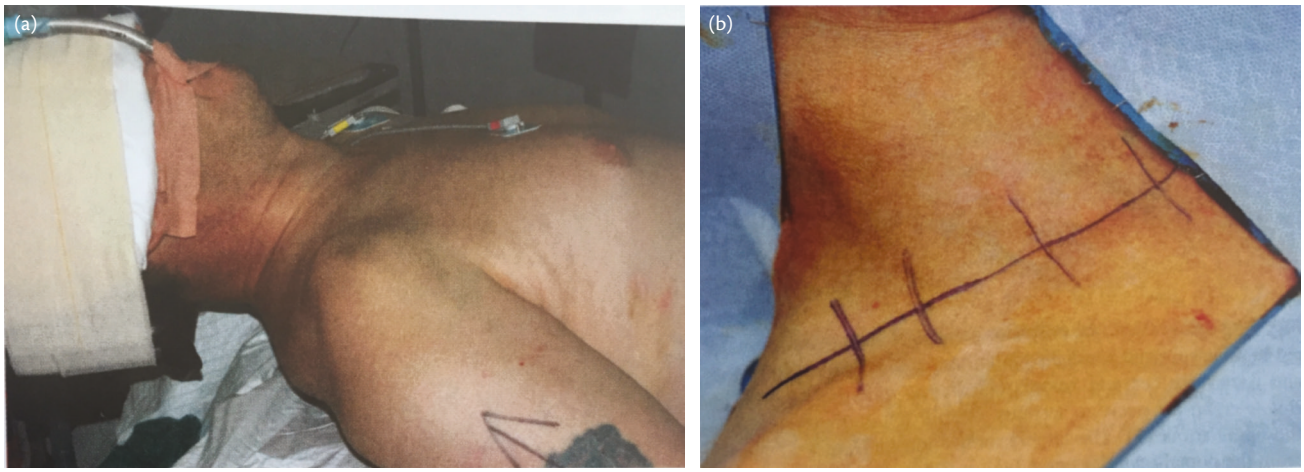

Fig. 73.3 Patient positioning for the transverse supraclavicular approach to the brachial plexus with overall position and marked incision line.
Reproduced with permission of Medtronic, Inc.

The dissection must be carried out by sectioning the platysma and by identifying the anterior surface of the sternocleidomastoid muscle medially, the supraclavicular branches of the cervical plexus, external jugular vein laterally, and the greater auricular nerve superiorly. At the end of this dissection a Joll's thyroid retractor can be used to keep the operative field open.

Dissection between sternocleidomastoid muscle and external jugular vein is carried out to mobilize the vein and retract it laterally. Sometimes mobilization, ligation, and division of the vein is required. Going deeper with the dissection between these structures the next to be identified is the omohyoid muscle. This is the only transverse muscle in this region and has to be dissected free from surrounding structures. It is then sutured with an absorbable strong suture, in order to repair it at the end of the operation. The fat pad and transverse cervical vessels have to be divided and reflected. These vessels are thin walled and can only be cauterized. Occasionally these vessels are much bigger, particularly if stasis is present.

The next step is to identify the phrenic nerve, which lies on the anterior surface of the scalenus anterior. Sometimes in a traumatic injury to the brachial plexus, particularly after many months from the injury, there is a lot of fibrosis here and the dissection is difficult. The dissection of the phrenic nerve leads to the C5 nerve root.

In a few cases, a C6 contribution to the phrenic nerve may be present. The root of C5 just after its exit from the foramen gives a branch posteriorly, which is the dorsal scapular nerve supplying the rhomboid muscles and 1–2 cm from its origin it joins C6 to constitute the upper trunk. On the lower surface of C6 there is the long thoracic nerve, which runs obliquely through the middle scalene muscle, and is constituted by branches from C5, C6, C7, and occasionally C8.

After dissecting the C5 and C6 roots, the upper trunk can be demonstrated posterolaterally and just before the anterior and posterior divisions the suprascapular nerve is identified. After this dissection inferior dissection is carried out to identify the middle and lower trunks. Between the upper trunk and the middle trunks runs the dorsal scapular artery with a transverse direction, relative to the plexus.

The middle and lower trunks are found inferior and slightly anterior to the upper trunk. To identify the trunks up to the level of the roots it is often required to divide part of the anterior scalene. It is very important to trace the subclavian artery, especially when there is a lot of scar tissue after significant traumatic injury. The subclavian vein at this level lies anterior to the scalenus anterior and inferior to the subclavian artery and all the veins passing transversely regarding the brachial plexus have their origin here. Therefore, it is vitally important never to pull too much on these veins otherwise they can be damaged as they enter the subclavian vein and even the subclavian vein itself may be traumatized.

The dissection of the three main trunks will reveal all the anterior and posterior divisions. The anterior divisions of the upper and middle trunk gather to form the anterolateral cord, the anterior division of the lower trunk constitutes alone the anteromedial cord and all the posterior divisions together give the posterior cord.

Reconstruction

Common reconstructive techniques for SBPi are direct repair, nerve transfers, and nerve grafting to give major forequarter function back to the patient. Ultimately either a working nerve or working fascicles are transferred to the nerves that do not function. There are many options for nerve transfer, but the options are limited by locations of donor and recipient nerves. After nerve transfer patients are expected to gain at least grade 3 power Medical Research Council (MRC, 1976).

Common nerve transfers include the spinal accessory nerve to the suprascapular or axillary nerves, the radial nerve fascicle to the axillary nerve, the ulnar nerve, and/or median nerve fascicle to the musculocutaneous nerve and the intercostal nerves to the musculocutaneous, axillary, radial, median, or ulnar nerves. Common nerve donors include the medial cutaneous nerve of the arm and or forearm and the sural nerve.

Nerve root reimplantation should be done within four weeks of the injury. As most of the injuries will be traumatic avulsions the roots themselves will be damaged so severely that direct repair cannot take place without fascicular grafting. Grafting is usually performed using fibrin glue or the nerve is sutured to the pia mater. The muscle power expected is weaker than prior to the injury, more than power 3 on the MRC grading scale may take over a year to achieve. However, the further distal the muscles the weaker they are. There

have been cases where great results have been seen with near normal wrist and hand function attained (Htut et al., 2007).

Free functional muscle transfer is a rare operation where a muscle free flap, along with its arterial supply, venous drainage, and motor nerve supply, are harvested and re-implanted into a new location. A common donor muscle would be gracilis and in brachial plexus injury it is used for regaining elbow flexion or finger flexion (i.e. replacing biceps or flexor digitorum profundus). This procedure is usually performed by plastic surgeons and requires micro-anastomosis of the vessels as well as the nerve repair. It requires careful planning and patient selection due to the risks involved. If successful it can provide useful function and grade 4 power to the patient (Doi et al., 1998).

Peripheral nerve injuries

Peripheral nerve palsies are common and the management of them can be simple as long as your clinical examination and subsequent diagnoses is accurate. They are generally related to acute and chronic compressions or traumatic injuries. Sometimes described as distal brachial plexal injuries, with the most common being median and ulnar nerves but radial and common peroneal nerve palsies being important as well. The general functions and findings of these nerves can be summarized in Table 73.2.

Once the diagnosis has been established then the appropriate treatment can then be commenced. Sometimes this can be fairly easy, with good outcomes, and others not.

Surgery is often required especially if there is a non-advancing positive Tinel's sign at the sight of the nerve entrapment. Surgical decompression is the easiest and if done correctly has the best outcome, carpal tunnel decompression being the most obvious. An extremely important factor in a good outcome is having excellent allied health professionals (occupational therapists and physiotherapists), who can assess and rehabilitate the patients afterwards.

Repair is performed using a microscope or loupes with fine nylon suture material and fibrin glue. Either an epineural repair or fascicle group repair are utilized. Peripheral nerves cannot be repaired under tension as this will fail. In these situations, nerve grafts are required and commonly sural or antebrachial cutaneous nerves, as they are cutaneous nerves only. If there is no chance at direct repair or the distance too long there are innumerable nerve and tendon transfers which can be undertaken to provide useful limb function.

Table 73.2 Summary table of the important nerve compressions in both the upper and lower limbs

Nerve	Common site of palsy	Muscles affected	Sensation	Key examination
Median nerve (C5–T1)	Delto-pectoral fascia; Supracondylar Process + Ligament of Struthers; Carpal Tunnel;	**L**umbricals 1&2 **O**pponens pollucis **A**bductor pollucis brevis **F**lexor pollucis brevis Wasting thenar bulk	Radial predominately volar 1st three webspaces	Thenar wasting Phalen's and Durkin's tests
AIN (C5-T1) from median	Kiloh-Nevin; superficial arch of FDS; lacertus fibrosus; superficial head of pronator teres	Flexor digitorum profundus radial half; pronator quadratus; flexor pollicis longus	n/a	Unable to make OK sign; weak resisted pronation
Ulnar nerve (C8–T1)	Cubital tunnel syndrome (5 sites); Guyon's canal	Lumbricals 3 and 4 All interossei Adductor pollicis Deep head of Flexor pollicis brevis Wasting hypothenar bulk	Ulnar/4th webspace	Froments test Hypothenar + 1st DIO wasting Wartenberg's and Jeanne's sign
Radial nerve (C5–T1)	Accessory subscapularis-teres-latissimus muscle; subscapular artery; triangular interval; lateral intermuscular septum;	Triceps brachii Aconeus Brachioradialis Extensor carpi radialis longus/brevis Supinator Entire posterior compartment, extensors, and abductor pollicis longus	Lateral/posterior upper arm and elbow and hand—radial dorsal predominately 1st three webspaces	Classical wrist drop depends on level
PIN from radial	Radial tunnel syndrome	Extensor carpi radialis brevis (normally from radial nerve) Extensor digitorum communis Extensor digiti minimi Extensor carpi ulnaris Supinator Abductor pollicis longus Extensor pollicus brevis Extensor pollicus longus Extensor indicis proprius	Sensory fibres to dorsal wrist capsule, no cutaneous	Pain Finger metacarpal extension weakness Wrist drop
Common peroneal nerve (L4–S2)	Above knee; fibula neck; below knee	**Deep:** Anterior compartment: Tibialis anterior extensor Halluces longus extensor Digitorum longus Peroneus tertius **Superficial:** Lateral compartment: Peroneus brevis and longus	Lateral sural nerve (L2–3) upper lateral-calf/knee Superficial peroneal (L4–S1) calf and dorsum of foot—lateral border Deep peroneal (L4/5) 1st webspace only	Foot drop TA, EHL, and extensor digitorum longus (EDL) weakness in varying degrees

Conclusion

SBPi is a significantly disabling diagnosis, normally affecting young healthy adult patients. Urgent referral, assessment, and intervention are often required for the best outcomes. Nerve injury has previously been seen as irreversible but with modern swift intervention this is not the case. It is always advisable therefore to refer the patient as soon as possible to a peripheral nerve specialist.

Peripheral nerve tumours

Rikin Trivedi and Vincent Nga

Introduction

Peripheral nerve sheath tumours (PNSTs) encompass a spectrum of well-defined clinicopathologic entities, ranging from benign tumours to high-grade malignant peripheral nerve sheath tumours (MPNSTs). While the majority of PNSTs arise sporadically, there are well known inherited conditions that predispose an individual to developing PNSTs such as neurofibromatosis type 1 (NF1), neurofibromatosis type 2 (NF2), schwannomatosis, and Carney complex (Rodriguez et al., 2012).

The neurosurgeon is often consulted to diagnose and manage tumours involving the peripheral nerves of the extremities and trunk. Most tumours involving the peripheral nervous systems encountered would be that of benign tumours of the nerve sheath. This chapter focuses on the pathology, diagnosis, management, and outcome of benign and malignant peripheral nerve sheath tumours.

Classification

PNSTs may be divided into benign and malignant variants. Several distinct benign subtypes have been well recognized, including that of schwannoma (neurilemmoma, neurinoma), neurofibroma, and perineurioma. Several changes have been made to the WHO classification of tumours of the nervous system in 2016 (**Table 74.1**) (Louis et al., 2016). These includes classifying melanotic schwannoma as a distinct entity, incorporating hybrid nerve sheath tumours, as well as designating two subtypes of MPNST: epithelioid MPNST and MPNST with perineurial differentiation.

The aetiology of PNSTs is unknown. The tumours may arise sporadically or in association with hereditary disorders, notably neurofibromatosis type 1 (NF1) and neurofibromatosis type 2 (NF 2). Both of these disorders are inherited in an autosomal dominant fashion, with NF1 being a mutation on chromosome 17 and NF2 a mutation on chromosome 22. NF1 patients in particular are predisposed to multiple neurofibromas and MPNSTs. NF2 on the other hand predominantly affects the spine and the cranial nerves.

Schwannoma

Schwannoma are benign neoplasms of Schwann cell origin. The gross appearance is characterized by well encapsulated spindle cell tumours with distinct Antoni A areas (compact spindled) and Antoni B components (hypocellular and microcytic), hyaline vessel walls, and nuclear palisading. Unlike neurofibromas, schwannomas arise within the nerve sheath and displace the fascicles as opposed to enveloping them. Tumour cells are strongly immunopositive for S-100 protein with abundant pericellular collagen type IV. Recent described markers frequently positive in schwannomas include podoplanin (Jokinen et al., 2008), calretinin (Fine et al., 2004), and SOX10 (Nonaka et al., 2008).

The schwannoma variants include that of conventional, cellular, plexiform, and melanotic schwannomas. Cellular schwannoma, although relatively uncommon, is an important variant to recognize because of its high cellularity, fascicular growth pattern, increased mitotic activity, and occasional locally destructive behaviour. Important clues to the diagnosis include a well-formed capsule containing lymphoid aggregates, presence of foamy histiocyte aggregate, and diffuse strong S100 protein and pericellular collagen IV expression. Of note, diffuse S100 protein expression is exceedingly uncommon in spindled MPNST. Cellular schwannoma may have higher local recurrence (5–40%) but for practical purposes lack malignant potential and never metastasize. Plexiform schwannoma is a distinctive subtype that usually occurs in superficial locations and is defined by an intraneural nodular pattern of growth. More problematic are the rare plexiform schwannomas that arise in deep anatomic locations as they demonstrate increased cellularity and mitotic activity. The presence of widespread S100, collagen IV immunoreactivity is reassuring. Melanotic schwannoma is a rare, distinctive, potentially malignant neoplasm, characterized by epithelioid cells with marked accumulation of melanin. The presence of psammoma bodies is associated in approximately half the cases with Carney complex (Carney, 1990).

Comparative genomic hybridization (CGH) analysis of sporadic and NF2-associated schwannomas has shown that the loss of 22q sequences is the most frequent imbalance. The NF2 tumour suppressor gene codes for schwannomin (merlin), a cell membrane protein that functions in the intercellular signalling pathway and helps mediate growth arrest.

Neurofibromas

Neurofibromas are benign unencapsulated tumours composed of spindle cells dispersed in fibromyxoid stroma. They appear tan-white

Table 74.1 2016 WHO Classification of peripheral nerve sheath tumours

Benign peripheral nerve sheath tumours	Malignant peripheral nerve sheath tumours
Schwannoma Cellular schwannoma Plexiform schwannoma Melanotic schwannoma Neurofibroma Atypical neurofibroma Plexiform neurofibroma Perineuroma Hybrid nerve sheath tumours	Epithelioid MPNST MPNST with perineurial differentiation

with a glistening cut surface in gross specimens. A crucial histological feature that distinguishes them from schwannomas is that the tumour involves the cross section of the nerve fascicle; hence it lacks a surgical cleavage plane between the normal nerve fibres and the tumour. Their growth pattern is either as a well-demarcated intraneural type or through diffuse infiltration of soft tissue at extraneural sites. They are relatively common, particularly at superficial cutaneous sites, where they present as localized, pedunculated growths. The proportion of S-100 positive cells is variable.

Three specific clinicopathological subtypes based on architectural growth patterns have been described, namely localized, diffuse, and plexiform neurofibromas. The localized cutaneous neurofibroma is the most common and occurs sporadically in most cases. Diffuse neurofibromas are characterized by a plaque-like enlargement and usually occur in the head and neck region. Approximately 10% of cases are ultimately proven to be associated with NF1. The plexiform neurofibroma represents the rarest form and is almost always associated with NF1. It is defined by the involvement of numerous adjacent nerve fascicles and often shows an admixture of areas resembling localized and diffuse-type neurofibromas microscopically. It has a potential for malignant degeneration and is a recognized precursor for MPNST in NF1 patients. The mutation in the *NF1* gene is located at 17q11.2 locus and codes for neurofibromin, an intracellular signalling protein that contributes to inactivating the Ras-GTP signalling cascade and upregulates the cyclic adenosine monophosphate (cAMP) levels. The absence of functional neurofibromin increases cell proliferation and survival.

Perineuriomas

Perineuriomas are benign neoplasms with advanced perineural differentiation. Two distinct types are recognized; intraneural and soft tissue. Intraneural perineuriomas are characterized by the solitary expansion of peripheral nerves, due to involvement of one of more nerve fascicles. Histologically, they show 'pseudo-onion bulbs', which are composed of complex perineural cell proliferation extending into the endoneurium and concentrically surrounding the individual nerve fibres and endoneural capillaries. Soft tissue perineuriomas in contrast almost always lacks an associated nerve, are usually well circumscribed, and may have a capsule. Typical histological findings are slender cells with very delicate, overlapping elongated cellular processes, arranged in loose fascicles. The neoplastic cells express vimentin and epithelial membrane antigen but are negative for S-100 protein, desmin, muscle-specific actin, and CD34.

Hybrid nerve sheath tumours (HNSTs)

HNSTs are a recently recognized entity in the 2016 WHO classifications of peripheral nerve tumours. These include neurofibroma/perineurioma, schwannoma/perineurioma, and neurofibroma/schwannoma hybrid tumours. In the reported cases, the tumour locations are almost exclusively in the digits and extremities. The tumours tend to be solitary in nature, and located in the dermis and subcutis. Atypical sites such as the colon have been previously reported (Lang et al., 2012).

Malignant peripheral nerve sheath tumours (MPNSTs)

MPNSTs are malignant tumours arising from a peripheral nerve or in extraneural soft tissue and showing nerve sheath differentiation. Malignant spindled tumours in NF1 patients should be considered MPNST until proven otherwise. MPNSTs may also arise in the postirradiation setting. Frequent histologic findings include fascicles of alternating cellularity, whorls, palisades, or rosette-like arrangements, perineural and intraneural spread when the tumour is associated with a nerve, subendothelial accentuation of tumour cells, and large areas of geographic-like necrosis (Hruban et al., 1990).

The S-100 protein is expressed in 50–70% of these tumours and most cases are immunopositive for TP53. Although MPNSTs lack a distinctive cytogenetic signature that allows for a specific diagnosis, molecular alterations (including epidermal growth factor receptor (EGFR) amplification and deletions of NF1 or CDKN2A) are supportive of the diagnosis in the appropriate setting.

Epithelioid MPNST is a distinctive, rare subtype of MPNST that is characterized by a predominance of large epithelioid cells. These tumours are more common in superficial sites and in contrast to conventional MPNSTs, express S100 protein strongly, and are typically diffuse. The great majority of MPNST arising within pre-existing schwannomas are of epithelioid type.

Plexiform neurofibromas, in particular, are the main recognizable benign precursors to MPNST in NF1. Malignant transformation into MPNSTs of schwannomas is a much rarer phenomenon, and usually takes the form of epithelioid change, angiosarcoma, or a tumour with a primitive small cell component. MPNSTs may also rarely arise in ganglioneuromas or ganglioneuroblastomas and even less commonly in phaeochromocytomas.

The CGH data indicates that gain in distal 17q and loss of 13q14-q21 is common in MPNST. Additional frequent changes reported are gain of 5p, 7, 8q, and loss of 9p sequences.

Clinical presentation

All ages and both sexes may be affected by PNSTs. Sporadic MPNSTs are most common between 40 and 50 years of age. While those occurring in association with NF1 are diagnosed 10 years earlier. MPNSTs account for approximately 5–10% of all soft tissue sarcomas. Although rare in the general population, MPNSTs arise in 5% to 42% of patients with NF1.

Patients with PNSTs usually present with a visible or palpable mass, pain, weakness, sensory alterations, or sometimes a mass is found

as an incidental finding on imaging studies, but most peripheral nerve tumours are first noticed as asymptomatic lumps. Palpation of the mass might elicit dysesthesia or paraesthesia. Involvement of motor nerves might produce weakness or more commonly subtle functional impairment with fine motor tasks. Autonomic dysfunction may manifest as changes in texture, colour, and temperature of the skin or in the amount of sweat produced. The patient should be examined specifically for stigmata of NF1 (café au lait spots, neurofibromas, Lisch nodules, optic glioma, axillary/inguinal freckling, distinctive skeletal abnormalities, and family history).

Any rapid increase in size or rapid symptom progression should raise the suspicion of cyst formation, haemorrhage or malignant transformation, and the patient will need to be investigated accordingly.

Investigation

Historically, the diagnosis of peripheral nerve tumours was based on history, clinical examination, and electrophysiological studies. While computed tomography (CT) is able to demonstrate intrinsic calcifications and secondary skeletal changes, MRI has emerged since the 1980s as the gold standard for imaging peripheral nerve tumours. MRI permits detailed visualization of soft tissue at high resolution and can demonstrate the presence of a mass, the anatomy of the involved peripheral nerves and their relationship to adjacent major structures such as blood vessels. High-resolution MR neurography (MRN) offers improved resolution and contrast that facilitates identification of the precise location, shape, size, and resectability of peripheral nerve tumours.

MRI also provides clues to the nature of the tumour and can help distinguish benign and malignant lesions. Benign nerve sheath tumours are often isointense or slightly hyperintense on T1, hyperintense on T2 (Fig. 74.1) and heterogeneously enhancing. The majority of neurofibromas and a portion of schwannomas display increased central and decreased peripheral T1 signal intensity (termed 'target sign') and an opposite pattern on T2 signal intensity. In contrast, MPNSTs tends to heterogeneously enhance, are less discrete, and more likely to have areas of haemorrhage or necrosis. A rapid increase in tumour size on serial imaging suggests malignant transformation.

Metabolic imaging using ^{18}fluorodeoxyglucose (^{18}FDG) positron emission tomography (PET) can add valuable information regarding the tumour grade. ^{18}FDG PET/CT is currently the most efficient imaging modality in the detection of MPNST in NF1 patients. An SUV_{max} (maximum standardized uptake value) ratio greater than 1.5 provides a 98.8% negative predictive value, and a 61.5% positive predictive value. However, in view of the false positives rate, it is not specific enough to make an NF1 related MPNST diagnosis (Combemale et al., 2014). A recent study of 26 NF1 patients with suspected MPNST, who underwent stereotactic PET/CT (tumour/liver binding ratio SUV_{max} ratio greater than 1.5) core biopsy technique, has shown a diagnostic accuracy rate of 96% (Brahmi et al., 2015).

Electrophysiological studies such as electromyography (EMG) and nerve conduction studies (NCS) are often obtained in patients with peripheral nerve tumours. EMG studies and NCS may assist in localization, detect subclinical deficits, and document baseline function for future comparison. These studies are especially useful in plexus level tumours involving multiple nerves to the extremities.

Management

As benign PNSTs are usually slow growing, intervention is not warranted until symptoms appear. The indications for surgical resection include that of pain, neurologic symptoms, concern for malignancy, cosmesis, and for histological diagnosis. Plexiform neurofibromas should be monitored closely for changes in size or development of symptoms. Tumours with imaging findings suggestive of benign PNSTs do not require biopsy unless there are unusual clinical features.

Histological diagnosis should be sought when diagnostic uncertainty arises. Because of the elevated risk of malignant transformation in NF1, there should be a low threshold for percutaneous biopsy when there is rapid tumour growth or rapid onset of pain. Tissue sample can be obtained via fine-needle aspiration or with needle core biopsy. Performing the biopsy with PET/CT stereotactic

guidance should be considered in order to reduce the false negative rate of suspicious lesions.

Surgical excision of a PNST can be performed under general, regional, or local anaesthesia (**Figs. 74.2, 74.3,** and **74.4**). Use of muscle relaxants must be avoided because these agents prevent intraoperative neurophysiological monitoring and stimulation. The patient is positioned to provide maximal exposure of the peripheral nerve in question. The skin incision is made over the course of the nerve beginning 2–4 cm proximal and extending 2–4 cm distal to the tumour. Dissection is performed though the subcutaneous tissues to expose the underlying lesion with meticulous haemostasis. Exposure of the nerve begins within an area of normal anatomy and extends into the area of tumour. It is important to identify the normal proximal and distal limits of the tumour. Loupe magnification or an operating microscope is often required to delineate the tumour, which may require internal neurolysis to identify the fascicles coursing over the tumour.

A nerve stimulator is applied to help identify afascicular entry points. An afascicular dissection plane is established by gently elevating and separating the fascicles from the tumour capsule. Internal debulking of the tumour with ultrasonic aspirator may facilitate dissection in very large tumours. Intraoperative EMG recordings provide feedback alerting the surgeon to overaggressive fascicle manipulation.

Non-functioning (as determined by stimulation) single fascicles seen entering and exiting a schwannoma may need to be divided to remove the tumour. Most schwannomas can be rolled out of their capsule and removed *en bloc*. It is not necessary to remove the tumour capsule of schwannomas as it is not associated with tumour recurrence. In contrast, fascicles enlarged by neurofibromas are often

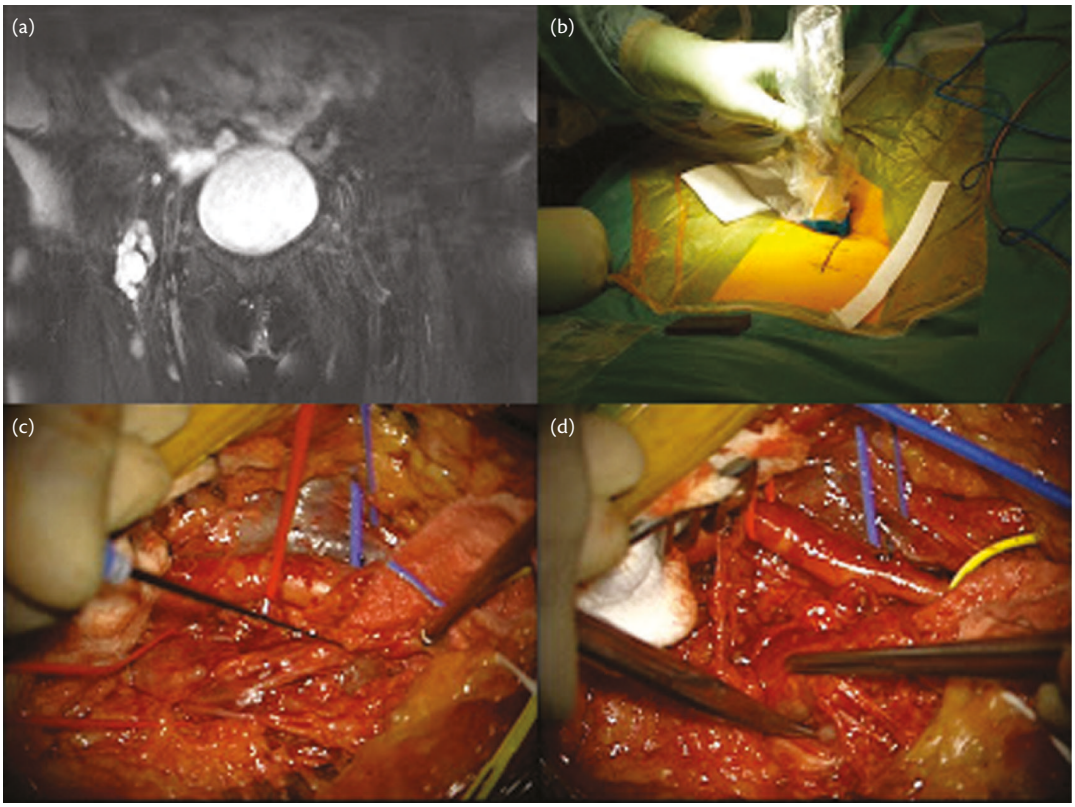

Fig. 74.3 Right genitofemoral nerve sheath tumour. (A) T1-weighted magnetic resonance imaged showing a contrast enhancing well-circumscribed tumour arising from the right genitofemoral nerve. (D) Excision of the tumour performed using sharp dissection and microsurgical techniques.

still functioning and removal of the tumour inevitably requires sacrifice of one or more fascicles. Nerve grafting should be considered on occasions when a significant fascicle is sacrificed. The sural nerve commonly serves as the donor nerve; alternatives include the medial antebrachial cutaneous nerve or the sensory radial nerve. The surgical goal in extensive plexiform neurofibroma is often debulking to alleviate symptoms caused by neural compression. Frozen sections should be obtained to determine if a malignancy is present. Wound closure is then performed in layers with care taken not to entrap nerves in a tight compartment.

In MPNSTs with localized disease, complete surgical extirpation with clear margins is the treatment of choice. This is crucial even in large, non-extremity malignant tumours, as often seen in NF1 patients, for which extensive gross total resection would be associated with significant morbidity. Data supports the independent prognostic importance of complete surgical excision (Dunn et al., 2013). In most cases of large (>5 cm) high-grade extremity sarcomas, adjuvant radiation is advocated to reduce local recurrence. This however needs to be carefully discussed with all NF1 patients in view of the heightened risk of radiation-induced sarcoma. Although there are

no randomized trials examining adjuvant chemotherapy specifically in MPNST, adjuvant chemotherapy remains a consideration for motivated patients. The recently reported SARC006 phase II trial conducted by the Sarcoma Alliance for Research (SARC) evaluated the role of chemotherapy with doxorubicin, ifosfamide, and etoposide in 48 locally advanced metastatic MPNST patients. It revealed encouraging disease stabilization rates with responses accruing from neoadjuvant chemotherapy, that rendered subsequent local therapy feasible, in most patients with localized disease (Widemann et al., 2013).

Tumours of the brachial plexus represent an unusual disease, involve unfamiliar surgical territory for many neurosurgeons and hence present as a clinical challenge. The management of these tumours requires not only an understanding of the complex anatomy of the brachial plexus but also an appreciation of the appropriate surgical approach to the various tumours that may be encountered. The surgical recommendation is to use an anterior supraclavicular approach to treat tumours on most of the roots and trunks. The infraclavicular approach is used for lesions involving the cords and distal plexal elements. A posterior approach is utilized for tumours involving spinal nerves at the intraforaminal level, the C8-T1 roots, and the lower trunk. The posterior approach is also recommended in patients who present with residual or recurrent tumour or who have undergone radiotherapy.

Regardless of the approach selected, the operative steps for resection of most neural sheath tumours are similar. Briefly, the proximal and distal extent of the tumour is identified, and the tumour is isolated from the surrounding neurovascular structures. Involved and uninvolved fascicles at both the proximal and distal poles are identified by interfascicular dissection, intraoperative stimulation, and recording. These techniques are used to distinguish functional from dysfunctional fascicles so that non-functional fascicles may be sacrificed. The tumour is gradually dissected away and adherent but displaced fascicles and then lifted off the residual nerve. Finally, the capsule is sharply trimmed away from the remaining fascicles (Das et al., 2007).

Outcomes

Most benign PNSTs are amenable to complete excision and recurrence is infrequent. Unless a benign PNST is massive or has been previously operated on, complete excision can be achieved with little or no injury to the parent nerve.

MPNSTs are known to have high metastatic potential and poor prognosis. Reported long-term outcomes vary widely across multiple series, with 5-year survival ranging from 15% to 50%. Large tumour size at presentation (>5 cm) has been the most consistent adverse prognostic factor across all series. Other reported factors include tumour grade, surgical margin status, local recurrence, truncal location, and heterologous rhabdomyoblastic differentiation. While nuclear p53 expression, AKT, and TOR pathway activation, and MET activation have been associated with inferior outcome, to date there remains no well-defined or widely reproducible molecular prognostication factors (Farid et al., 2014)

The risk of MPNSTs in NF1 is estimated to be between 8% and 13% over a patient's lifetime and they are known to be one of the most frequent causes of death in patients with NF1. Several large series have reported significantly worse outcomes for MPNST arising in the setting of NF1 compared to sporadic tumours, with poorer responses to cytotoxic chemotherapy and 5-year survival up to 50% worse. A meta-analysis of several European studies, however, has suggested that while NF1 may have been a negative prognostic factor in studies before year 2000, this effect was subsequently lost possibly because of overall better surveillance and more rapid intervention at earlier stages of the disease in patients with NF1, and from improvements in imaging and diagnostic techniques (Kolberg et al., 2013).

In the setting of advanced or metastatic MPNST, outcomes are generally poor. The Response Evaluation Criteria in Solid Tumours (RECIST) response rate was reported to be 21% in a multi-institution retrospective study pooling MPNST patients from across multiple soft tissue sarcoma trials (Kroep et al., 2011).

Principles of deep brain stimulation

Erlick A.C. Pereira, Alexander L. Green, and Tipu Z. Aziz

Introduction

The notion that illness can be ameliorated by electrical stimulation predates both Sir Victor Horsley's and Harvey Cushing's early twentieth century establishment of neurological surgery as a discipline and Benjamin Franklin's late eighteenth century discovery of static electricity and its effects upon muscle. First accounts date back to the ancient Roman empire when a freed man of Emperor Tiberius with painful gout stepped upon a torpedo fish. The electrocution administered relieved his gout considerably, leading the local physician Scribonius to recommend the treatment for painful gout and headache (Kellaway, 1946; Gildenberg, 2005). Not until nineteenth century animal experiments elicited movement by electrical stimulation of the brainstem and cerebral cortex did electrical brain stimulation became a noteworthy scientific endeavour (Flourens, 1824; Fritsch and Hitzig, 1870; Morgan, 1982). Horsley, the father of British neurosurgery, was first to apply electrical stimulation directly onto the human brain in the 1880s, using the technique to identify eloquent cortex and guide tumour resections (Vilensky and Gilman, 2002).

Alongside pioneering neurostimulation techniques, Horsley's other great advance enabling deep brain stimulation (DBS) was his invention, together with Clarke, of apparatus enabling stereotaxis (Horsley and Clarke, 1908). Stereotaxis uses a frame fixed to the head to localize cerebral structures with reference to a brain atlas via an external coordinate system calculated in relation to skull or brain landmarks. In 1947 Spiegel and Wycis adapted the Horsley-Clarke apparatus to humans for stereotactic neurosurgery (Spiegel et al., 1947). While irreversible lesioning surgery by chemical injections or thermocoagulation soon became the norm, many pioneers favoured reversible DBS during surgery to confirm they were on target (Hassler et al., 1960; Spiegel, 1982).

DBS emerged as a clinical tool from a nexus of translational research initiatives. Implantable neurostimulatory devices were developed by engineers such as Roger Avery and Thomas Mortimer in collaboration with surgeons and industry (Sweet and Wepsic, 1968; Mortimer et al., 1970). Intraoperative stimulation was used to produce functional maps of the sensory thalamus and other deep brain structures (Tasker et al., 1982). Knowledge of the functional anatomy of deep brain structures was increased by animal research and empirical observations from ablative neurosurgery in humans (Gildenberg, 2005; Gildenberg, 2006; Pereira and Aziz, 2006). Intermittent DBS was successfully trialled first for cancer pain in the 1950s and 1960s (Heath and Mickle, 1960; Gol, 1967) then for trigeminal neuralgia and other chronic pain syndromes targeting the thalamus, internal capsule and periaqueductal grey matter in the 1970s (Adams et al., 1974; Hosobuchi et al., 1973; Hosobuchi et al., 1977; Richardson and Akil, 1977). Throughout the last four decades, DBS for pain has continued to be undertaken by experienced specialists, its indications expanding to include stroke, amputation, multiple sclerosis, plexopathies and failed back surgery syndrome among others (Pereira and Aziz, 2014).

Despite its intraoperative use throughout the epoch of the 1950s to 1970s for localization during lesional and resective surgery for epilepsy (Spiegel et al., 1950), and movement disorders with observations of improvement in Parkinsonian tremor and dyskinesia (Hassler et al., 1960; Alberts et al., 1965; Bechtereva et al., 1975), therapeutic DBS did not promulgate to these indications until the late 1980s. Key factors obviating its use were the success of drug treatments for these conditions—phenytoin, carbamazepine, and valproate for epilepsy and levodopa for Parkinson's disease (PD) (Cotzias et al., 1967), established efficacy and surgeon experience with ablative and resective surgery in both PD and epilepsy (Cooper, 1956; Svennilson et al., 1960; Jensen, 1975), and cumbersome early neurostimulator models both less reliable and at greater risk of damage and infection than current technologies (Mullett, 1987).

Over a decade after its first use in pain (Hosobuchi et al., 1973), implantable DBS of the thalamus was performed to suppress tremor in PD refractory to drug treatments (Benabid et al., 1987). Primate-based research identified the subthalamic nucleus, a basal ganglia structure, as a putative brain target for both ablation and DBS (Bergman et al., 1990; Aziz et al., 1991). Alongside the resurgence of thalamic and globus pallidus internus lesional surgery (Narabayashi et al., 1984; Laitinen et al., 1992), together with advances in the miniaturization and reliability of neurostimulator technology, the scientific discoveries from primate research cultivated a renaissance in neurosurgery for PD in the 1990s and in particular for the popularization of DBS over the last decade as the neurosurgical therapy of choice for medically refractory PD with several other disorders of movement, pain, and affect becoming candidates for treatment. **Table 75.1** summarizes current indications for DBS and their anatomical targets.

Table 75.1 Indications for deep brain stimulation and popular deep brain structures targeted

Indication	Deep brain targets
Parkinson's disease	Globus pallidus interna, subthalamic nucleus
Dystonia	Globus pallidus interna
Tremor	Ventralis intermedius thalamic nucleus, zona incerta
Depression	Subgenual cingulate cortex, anterior limb of internal capsule
Obsessive-compulsive disorder	Anterior limb of internal capsule
Tourette's syndrome	Ventromedial thalamus, anterior limb of internal capsule, globus pallidus interna
Epilepsy	Anterior thalamic nucleus, centromedian thalamic nucleus
Cluster headache	Posterior hypothalamus
Chronic pain	Ventroposterior thalamus, periventricular and periaqueductal grey matter

Stereotactic surgery

Horsley and Clarke invented stereotaxis as 'a means of producing lesions of the cerebellar nuclei which should be accurate in position, limited . . . in extent, and involving as little injury as possible to other structures' (Horsley and Clarke, 1908). Legend has it that while gazing up at the stars and contemplating his place in them, Clarke conceived an apparatus through which probing intracranial instruments could be inserted that could be clamped to an animal's head by laterally placed skull pins, bars attached to plugs inserted into the external auditory meatus and further bars resting upon the nose and orbital margins, fixing it to a Cartesian coordinate system. They coined the term 'stereotaxic' from the Greek words 'stereos' meaning 'solid' and 'taxis' meaning 'arrangement'. 'By this means every cubic millimetre of the brain could be studied and recorded' (Horsley and Clarke, 1908; Pereira et al., 2008).

Stereotactic surgery has three fundamental concepts. Firstly, that the brain is a geometric volume in a (usually Cartesian) coordinate system, secondly that suitable reference points (such as the commissures) can be defined within this volume to calculate surgical targets and thirdly that appropriate surgical instruments can navigate the coordinate system to operate upon such targets.

Geometry and reference points

Any point in the head can be described in space by considering the head as fixed in three orthogonal planes intersecting at a given reference zero point. Thus, the distance lateral to the zero (x), anterior to it (y), and vertically above it (z) can be quantified in mm.

Visible targets in the brain can be described in terms of their distance from the zero reference point in x, y, and z directions when the head is fixed into a stereotactic frame (or frameless system). These include the subthalamic nucleus and globus pallidus interna targets for Parkinson's disease with modern MRI imaging. Invisible targets such as the ventral intermediate thalamus can be grossly targeted either in terms of their known distance from deep brain landmarks such as the mid-commissural point or using stereotactic atlases. The use of the anterior and posterior commissures (AC-PC) as part of a completely intracerebral reference framework was first described by Jean Talairach (Talairach et al., 1957). Stereotactic atlases are compiled from multiple fixed brain specimens sliced parallel to the reference planes and stained to highlight deep brain nuclei or fibres of passage. Schaltenbrand's atlas compiled from brains sliced orthogonal or in parallel with the AC-PC line is most commonly used (Schaltenbrand and Wahren, 1977). It can be helpful to some surgeons if either direct or indirect targeting is combined either with clinical assessment of the awake patient intraoperatively or electrophysiological recording by multiple microelectrodes or from the DBS 'macroelectrode' lead to increase efficacy.

Instruments

Most stereotactic systems comprise a coordinate frame and targeting device. The frame has a rigid, metallic 'base-ring' platform fixed to the skull to prevent displacement, usually by four pins penetrating its outer table. Common frames in usage are the Cosman-Roberts-Wells (CRW) (Fig. 75.1) which has its zero in the centre of the frame and Leksell which has its zero in the upper, posterior, right hand corner with 100, 100, 100 mm being its x, y, z centre. Onto the platform, a localizing system can be placed before a computed tomography (CT) or MRI is performed. The position of the head relative to the frame can then be calculated by computer software (and also manually with the Leksell frame) to transform the brain structures of interest into 'stereotactic space', the coordinate system of the frame. N-shaped bars on the localizer enable calculation of z.

Fig. 75.1 CRW Precision™Arc System on its phantom target to check targeting coordinates.

Arc radius, polar, and focal point coordinate systems can be used for stereotactic instruments. Focal point systems brought the patient's head to the framed probe and are hardly used now outside of radiosurgery. Polar coordinate systems solely used by the first stereotactic frames (such as Clarke's modified Horsley-Clarke frame, the Spiegel-Wycis frame, and the Riechert-Mundinger frame still popular in Europe) define probe trajectory in terms of angles and depth. While the target point is defined by Cartesian coordinates, the entry point through the skull chosen when planning gives the azimuth and declination of the probe carrier to target. With target and entry point fixed, the probe trajectory is the straight line between them passing through the arc of the stereotactic frame to a depth fixed by the frame. In modern, commonly used, arc radius systems, the trajectory can be defined by two angles (the arc and ring) and a linear magnitude (the radius or depth). In commonly used arc radius frames (such as CRW and Leksell), a fixed radius semicircular arc can move freely in a Cartesian coordinate system, pivot through 180° anteroposteriorly and its probe holder can translate along the arc in the frontal plane. Thus, the target can be hit from any trajectory as long as the target coordinates and depth remain fixed.

Cartesian phantom target systems (such as that of CRW) contain a pointer that mimics the target and provide a safety check to reduce human error and confirm that the frame is set to the correct target point before it is placed on the head and a probe passed to the intracranial target (Fig. 75.1). Such phantom systems were more important when stereotactic frames used polar coordinates as they provided a safety check between the intersecting angles of the probe carrying frame and the Cartesian target of the phantom—a concomitant error in both is highly unlikely.

Many DBS surgeons use CRW frames and algorithmically fuse stereotactically acquired CT scans to preoperative MRI to reduce spatial distortion of tissue representation by MRI (Fig. 75.2). Others use MRI-compatible CRW or Leksell frames to directly target from a stereotactic MRI, with spatial distortion being less of an issue in modern higher resolution scanners. A few practitioners continue to use CT alone or even ventriculography for DBS and some use computerized frameless systems and even robots that automate the whole process.

DBS hardware

The most regularly used current DBS electrode is quadripolar, having four electrical contacts, each 1.5 mm long and separated by 0.5 mm of insulation. Several stimulation parameters can be altered in DBS. Commonly, stimulation can be monopolar (with the distant pulse generator case acting as the anode) or bipolar over any combination of the four contacts of each electrode and multiple contacts can be specified as anodes or cathodes. Voltage can typically be altered from 0 to 10 v, frequency from 2 to 300 Hz, and width of the square wave pulse from 60 up to 500 μs. Stimulation may be either continuous or cycled between on and off states each of at least 0.1 s duration.

The DBS electrode is secured to the skull and connected to a lead that is tunnelled to the chest or abdomen where a pulse generator (pacemaker) containing the power source is implanted under the skin (Fig. 75.3). Some pacemakers can be transcutaneously recharged.

DBS mechanisms

The prevailing dogma surrounding DBS mechanisms is that high frequency DBS inhibits neuronal firing within its target brain structure and that low frequency DBS excites neurons to fire. The evidence for high frequency 'jamming' comes largely by analogy with lesional surgery such as pallidotomy and thalamotomy which can have similar clinical outcomes. The low frequency driving theory arises from the observation that low frequency DBS worsens some Parkinsonian symptoms and the suggestion that low frequency DBS of the pedunculopontine nucleus in freezing of gait and periaqueductal grey in chronic pain can drive motoric and analgesic

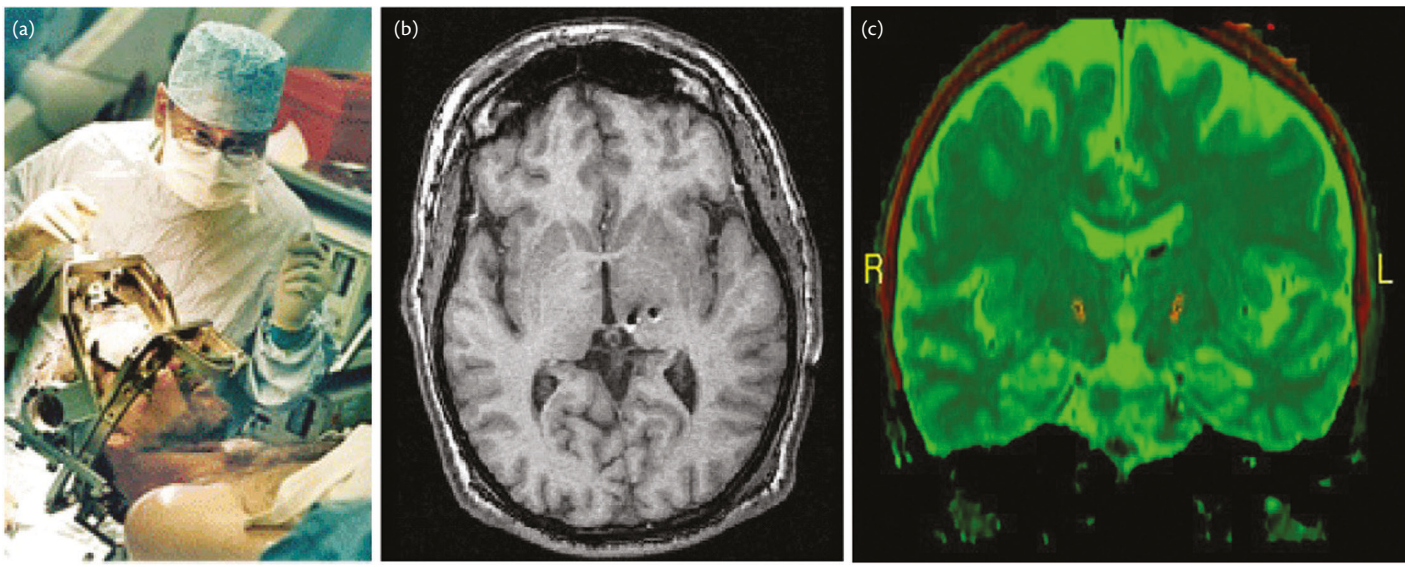

Fig. 75.2 (A) Intraoperative awake deep brain stimulation; (B) axial MRI of deep brain stimulators for pain *in situ*; (C) fused coronal CT and MRI showing subthalamic nuclei targeted in deep brain stimulation for Parkinson's disease.

neural circuits, respectively. Electrophysiological experiments in humans and non-human primates, however, suggest that both low and high frequency DBS can excite target nucleus afferent and efferent neuronal axons as well as fibres of passage (McIntyre et al., 2004).

More fundamental underlying principles of DBS include firstly its effects on the neuron and its components in terms of the electrical activities generated, secondly how those effects propagate through the relevant neural circuitry such as the basal ganglia, thalamus, and cortex, and finally how DBS influences modulatory monoamine and other neurotransmitters in the brain. Here we focus upon the direct electrical effects of DBS upon neuronal physiology as the latter principles of synaptic neurotransmitter release and modulation of neuroanatomic circuits can be considered secondary to this effect.

Local electrical effects

DBS generally excites action potentials in surrounding neuronal tissue (Kringelbach et al., 2007; Montgomery and Gale, 2008). Effective DBS is reliant upon exciting sufficient action potentials in the desired target tissue while limiting spread of electric current to excite action potentials in unintended adjacent structures. Greater current intensity or volume improves outcome but increases likelihood of untoward side effects. Strategies to electrophysiologically tailor the DBS electrical field to each patient are therefore desirable. Varying stimulation parameters such as amplitude and pulse width can also alter the population of neural elements stimulated. Axonal terminals have the lowest threshold, followed by axons, dendrites, and finally neuronal cell bodies. Larger axons respond more to narrower pulse widths of stimulation. Therefore when considering which neurons are activated by DBS, general principles are firstly that neurons further away from the brain electrode are less likely to be stimulated, secondly that axons will be stimulated to give rise to an action potential at lower DBS amplitudes than neuronal cell bodies, thirdly that larger axons will respond to lower stimulus amplitudes than will smaller axons and finally that axons with branching processes will also be activated at lower stimulus amplitudes. The orientation of the neuron relative to the DBS field is also relevant. Those oriented with the voltage gradient are more likely to reach threshold than those lying orthogonal to it. Also interesting is that neurons nearest the DBS cathode are more likely to be activated than those close to the anode, hence the designation of the pulse generator case as anode in monopolar DBS.

Future developments

Currently, most pacemakers deliver stimulation continuously at a fixed rate, in what is a rather simple but nevertheless effective therapy. However, constant stimulation can incur unwanted side effects by spreading to other fibre tracts or by disrupting normal brain signals embedded in pathological activity. Alteration of such 'normal' signals may affect emotion or cognition, for example. By targeting stimulation specifically to abnormal oscillations, it may be possible to apply stimulation intermittently and thus allow normal signals to re-emerge. Indeed, there is evidence that symptom suppression may be better with such intermittent stimulation than with continuous stimulation (Little et al., 2016). Other prospects include a pacemaker with telemetric capabilities, which could aid the identification of pathological markers in various disorders. Pacemakers that respond to posture could also reduce side effects, as in the case of spinal cord stimulation where lower levels of stimulation may be required in the supine position than in the upright position. Such pacemakers use directional accelerometers to determine movement and position.

A good clinical response is sometimes limited by the proximity of the contacts to structures adjacent to the target. An electrode may be placed in the subthalamic nucleus, for example, but if it is too close to the capsule, stimulation will induce side effects within the therapeutic window. To overcome this problem, technology companies have produced alternative electrode configurations, such as splitting the ring contacts into two or three, or even arranging 32 contacts in an array resembling a fish-scale (**Fig. 75.4**). Experimentally, the latter has been shown to offer directionality in the primate (Martens et al., 2011), as well as in a clinical case series in which it was also possible to record local field potentials from multiple contacts for better localization (Bour et al., 2015).

At present, structural MRI is usually used for targeting electrodes. Although not yet fully evaluated, the use of diffusion tensor imaging may improve results by allowing specific parts of a nucleus that are connected to another region or possibly part of a network to be targeted, rather than just the nucleus itself. As demonstrated in tumour surgery, diffusion tensor imaging can be used to identify fibre tracts that, if stimulated, would induce side effects, so that these can be avoided. It is also possible to somatotopically identify the best electrode position within homogeneous structures such as the thalamus (Hyam et al., 2012).

In the realm of molecular and cellular therapies, much translational research is being undertaken but few treatments have demonstrated comparable safety and efficacy to DBS. Clinical trials of neurotrophic factors, stem cells and fetal cell transplants have all been undertaken with limited success (Astradsson and Aziz, 2016).

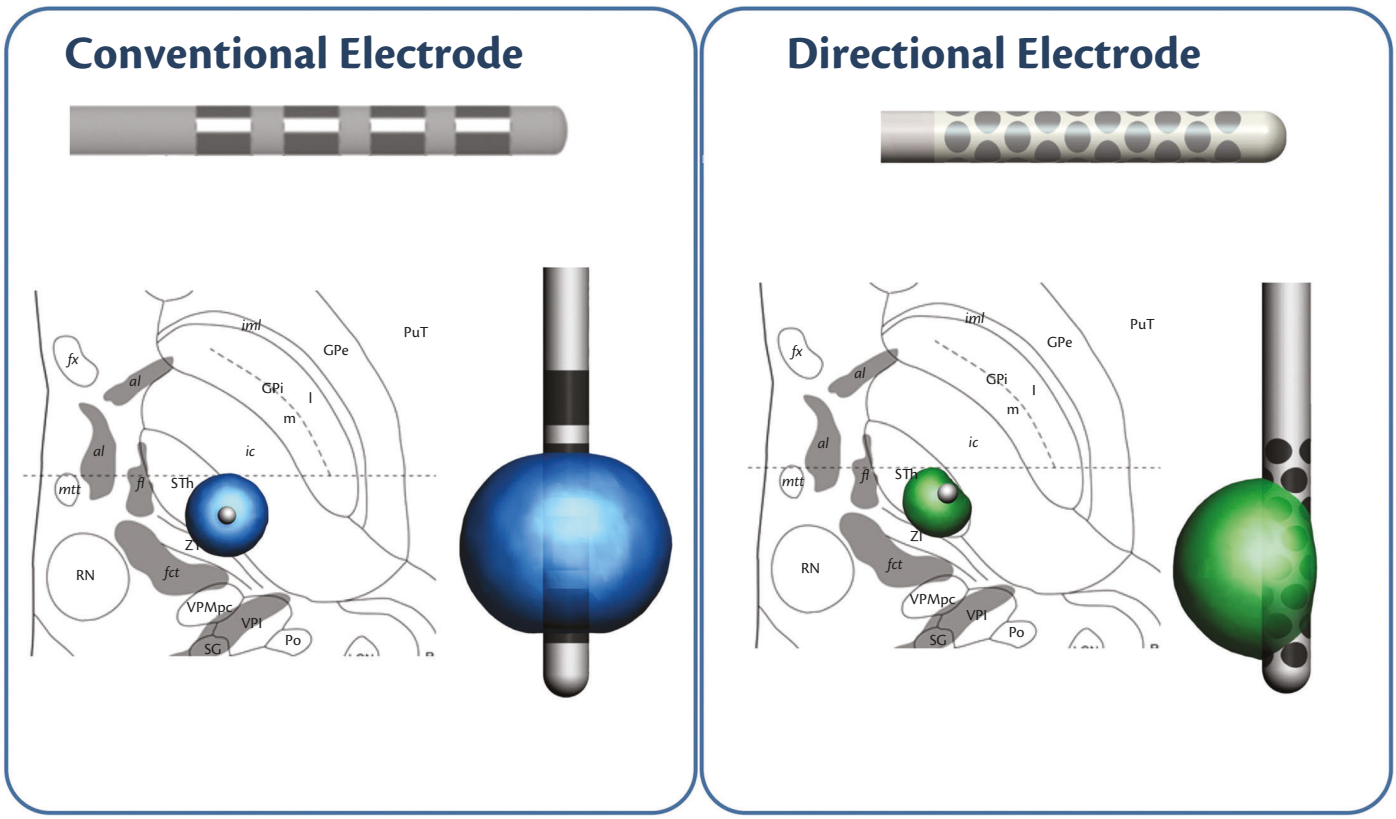

Fig. 75.4 Multicontact array directional electrode enabling optimization of brain nucleus stimulated by DBS. STN, subthalamic nucleus (common Parkinson's disease DBS target); ic, internal capsule.
Reproduced with permission of Medtronic, Inc.

Unilateral DBS does however provide an elegant potential control surgery for contralateral biological therapy implantation (Rowland et al., 2015).

Lesional surgery

Lesional procedures using radiofrequency ablation have been largely replaced by DBS due to its greater safety and its reversibility, but under certain conditions pallidotomy, thalamotomy, and even subthalamotomy remain useful alternatives, especially in the resource limited setting where DBS may not be economically feasible and clinical follow-up might be a challenge (Pereira and Aziz, 2013). Other specific indications include chronic infection complicating past DBS, metal allergies, risk to implanted DBS hardware from falls or obsessive-compulsive head banging or palliative procedures if limited lifespan such as cingulotomy for cancer pain or pallidotomy in severe, advanced Parkinson's disease (Bulluss et al., 2013; Viswanathan et al., 2013). Radiofrequency thermocoagulation of brain tissue with an electrical lesion generator is most commonly performed but requires a burr hole and passage of a rigid probe through the brain to the target to be lesioned. Alternative non-invasive lesioning modalities are gamma knife radiosurgery that has the disadvantage of several months for onset of efficacy and magnetic resonance–guided high frequency focused ultrasound for which there is promising initial clinical evidence (Elias et al., 2013; Witjas et al., 2015).

Conclusions

DBS requires accurate brain electrode placement which usually utilizes a stereotactic frame fixed to the head, although frameless and robotic alternatives exist. For all DBS targets, the relative contributions of local interactions and wider functional neuroanatomical circuitry are yet to be fully elucidated. However, the general principle is that pulsed current passed from an implanted battery generates a local field potential which in turn causes a surrounding population of neurons to individually either reach their thresholds for action potential generation or to hyperpolarize. Such neurons may release neurotransmitters from their synapses and alter deep brain neural circuitry functions controlling movement, seizures, or other behaviours such as reduced pain perception or tics. Alternatives to DBS include lesions by radiofrequency thermocoagulation, gamma knife radiosurgery, or focused ultrasound. Future developments include advances in imaging such as diffusion tensor MRI, fields made steerable by directional electrodes, segmented electrodes, 'smart' adaptive DBS, and the use of stereotactic neurosurgery to deliver molecular and cellular therapies such as gene therapy, neurotrophic factor drug delivery, fetal and stem cell transplants.

Movement disorders

Keyoumars Ashkan and Ismail Ughratdar

Introduction

Movement disorders encompass a broad range of neurological disorders which primarily affect speed, fluency, ease, and quality of movement. They can be broadly categorized (Table 76.1) into those with excess spontaneous movement (hyperkinetic disorders) or those with absent or reduced ability to perform purposeful movement (hypokinetic disorders). Abnormal movements may be rhythmical (e.g. essential tremor) or slow and sustained (e.g. Parkinson's disease). In most cases, the irregular movements cannot be consciously controlled or suppressed.

Clinical assessment and appropriate investigation must be considered carefully as variations from the typical and overlap in presentations between diagnoses can affect treatment modality and success of surgery. A detailed history and directed examination should confirm the diagnosis in the majority, with augmentation as required utilizing electrodiagnostic studies and structural imaging.

In the present chapter the clinical assessment, pathogenesis, and medical therapy of the common movement disorders will be reviewed. A brief description of the surgical management, outcomes, and controversies is also described.

Parkinson's disease

Parkinson's disease (PD) is a chronic, progressive neurodegenerative disorder characterized by bradykinesia, rigidity, rest tremor, and postural instability. It is usually initially unilateral, insidious in onset and is associated with disabling non-motor symptoms such as depression, fatigue, and sleep disorders.

Classification

The term parkinsonism encompasses the motor syndrome described earlier and is classified into four subtypes according to the aetiology:

a. Primary/idiopathic/Parkinson's disease—the commonest form
b. Secondary/acquired (infection, drugs, trauma, vascular)
c. Hereditary parkinsonism (rare)
d. Parkinson plus syndromes—disorder occurs as a secondary effect of another primary neurological disorder (e.g. multiple system atrophy)

Epidemiology

PD is one of the most common neuro-degenerative disorders, second only to Alzheimer's disease. In the United Kingdom, the crude incidence rates range between 8–18/100 000 population/annum and prevalence rates around 108–164/100 000. Both incidence and prevalence are markedly affected by an increase in age. The onset of PD before 50 years of age is rare, but escalates dramatically over the age of 60 affecting approximately 1% of the population. This is likely to increase with an ageing population. With the ever-growing ageing population, the number of people with PD worldwide is projected to double to at least 8.7–9.3 million by 2030 (Dorsey et al., 2007).

Studies have also shown PD to be more common in males than females (1.3:1, prevalence and incidence). Crude prevalence studies suggest that PD is more common in Caucasians in Europe and North America and lowest in African races, though ascertainment bias may account for these differences. For reasons unknown, cigarette smoking and drinking beverages containing caffeine are reported to be protective against PD (Goetz and Pal, 2014).

Pathogenesis

The basic mechanism responsible for the development of PD consists of cellular degeneration of dopaminergic cells within the substantia nigra pars compacta (SNc) resulting in biochemical deficiency of dopamine (Dauer and Przedborski, 2003). There are three pathological hallmarks of PD:

- Lewy bodies—eosinophilic intraneuronal inclusions considered to be markers of neuronal degeneration
- Dopaminergic neuronal death in the SNc is an essential feature of PD and leads to loss of neuromelanin and depigmentation of this structure at post-mortem
- Removal of neuromelanin from dead cells by microglia

Understanding how this relatively selective loss of dopamine leads to parkinsonism requires a detailed understanding of the functional anatomy and neurocircuitry of the basal ganglia. In essence, the pathway 'flows' from the premotor cortex through the striatum and then back to the supplementary motor cortex. Activity in this loop is modulated by the SNc which acts as an accelerator and the subthalamic nucleus (STN) which acts as a brake. In PD, the SNc fails to work and thus the patient slows down and loses motor control.

Clearly, this model represents a gross oversimplification of the pathophysiology of PD. At a more complex level, the STN and SNc

Table 76.1 Classification of movement disorders

Hypokinetic disorders	
Parkinson's disease/ parkinsonism	Idiopathic, secondary (drugs, toxins, infection, trauma, vascular) Bradykinesia, tremor, rigidity, and postural instability
Progressive supranuclear palsy	Vertical gaze dysfunction, extrapyramidal symptoms, and frontal lobe dysfunction
Multiple system atrophy	Parkinsonism, cerebellar, and autonomic dysfunction Rapidly progressive
Stiff person syndrome	Progressive rigidity and stiffness of truncal muscles associated with spasms
Hyperkinetic disorders	
Restless legs syndrome	Irresistible urge to move limbs secondary to unpleasant sensations
Essential tremor	Action/postural tremor Autosomal dominant
Tics/Tourette's syndrome	Sudden, repetitive, non-rhythmic movements (motor) and utterances (vocal) that involve discrete muscle groups
Dystonia	Sustained muscle contractions causing twisting and repetitive movements or abnormal postures
Hemifacial spasm	Involuntary movement of one side of the face
Huntington's disease/ Chorea	Cognitive, movement, and psychiatric disorders
Torticollis	Dystonia leading to asymmetrical position of head/neck
Blepharospasm	Abnormal contraction of both eyelids
Writer's cramp	Task-specific (e.g. writing) focal hand dystonia

functions are mediated via a direct and an indirect pathway (Fig. 76.1). The direct pathway arises from a set of neurons that projects monosynaptically to neurons in GPi and SNr, whereas the indirect pathway arises from a different set of neurons that projects to GPe which is reciprocally linked with the STN. In PD, dopamine deficiency results in increased activity in striatopallidal GABAminergic fibres which inhibits the GPe neurones to the STN. Thus the glutaminergic STN projection to the GPi is stimulated which increases firing to the thalamus (Calabresi et al., 2014).

However, these models do not explain several findings from laboratory or clinical studies and thus in the last decade, theories relating to the pathophysiology of PD have moved from focussing on altered discharge rates to altered discharge patterns and now to excessive synchronization of activity across populations of neurons. In particular, when the brain is aroused and actively engaged in mental activities, it generates beta-waves. Excessive synchronization of basal ganglia neuronal activity in the beta-frequency band at 20 Hz has been implicated in PD (Little et al., 2012). The latter can be detected as undulations of the local field potential and recorded through the macroelectrodes used for therapeutic deep brain stimulation (DBS).

Diagnosis

The diagnosis of PD is usually based upon clinical impression. The UK PD Society Brain Bank criteria (Hughes et al., 1992) (Box 76.1) for diagnosis of probable PD states that bradykinesia must be present alongside one other cardinal symptom (rigidity, rest tremor, postural instability). In addition, an excellent response to dopaminergic therapy is an important criterion for the diagnosis. The response to dopaminergic therapy in other parkinsonian syndromes is reduced or absent compared with the response in PD.

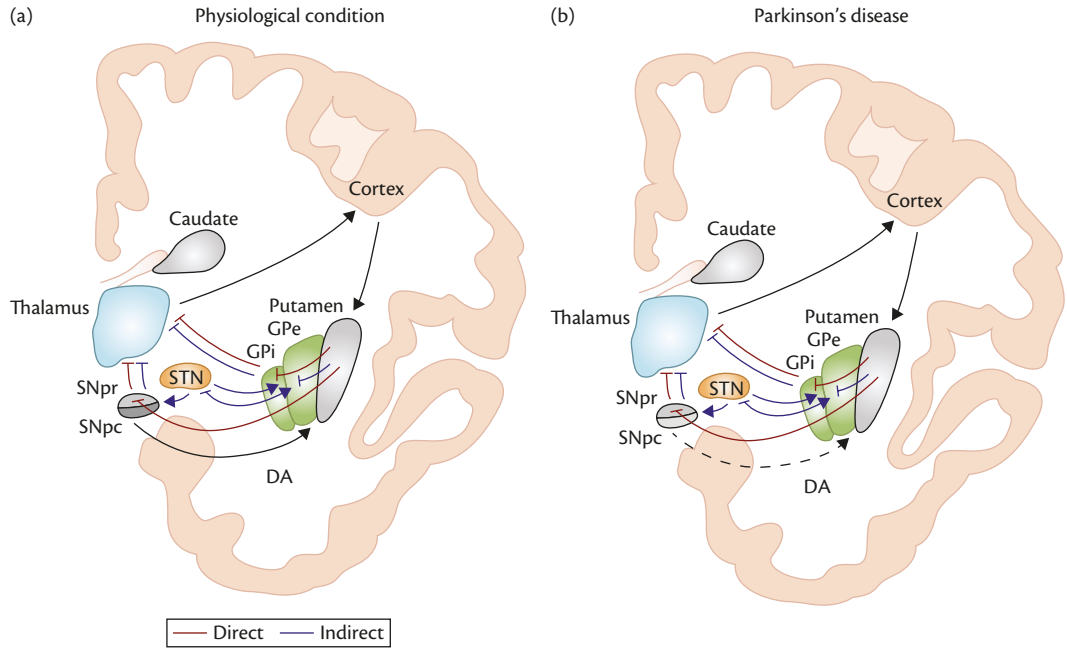

Fig. 76.1 (A) In the physiological condition, dopamine (DA) arising from the SNc is thought to activate D1-expressing striatal MSNs of the direct pathway (red lines) and to inhibit D2-expressing striatal neurons of the indirect pathway (blue lines). The output nuclei GPi and SNr project to the thalamus, which in turn sends efferents that complete the cortico-basal ganglia-thalamo-cortical loop. (B) In Parkinson's disease, degeneration of nigral neurons reduces dopamine receptor stimulation in striatal MSNs. The imbalance between direct and indirect pathways results in the abnormal activation of output nuclei and overinhibition of thalamic neurons projecting to the cortex.

Box 76.1 UK PD Society Brain Bank criteria for diagnosis of probable Parkinson's disease

Inclusion criteria

Bradykinesia (slowness of initiation of voluntary movement with progressive reduction in speed and amplitude of repetitive actions); and at least one of the following:

- Muscular rigidity
- 4–6 Hz rest tremor
- Postural instability not caused by visual, vestibular, cerebellar, or proprioceptive dysfunction.

Exclusion criteria

- History of repeated strokes with step-wise progression of parkinsonian features, repeated head injury, or definite encephalitis
- Oculogyric crises
- Neuroleptic treatment at onset of symptoms
- More than one affected relative
- Sustained remission
- Strictly unilateral features after 3 years or symmetrical at onset
- Supranuclear gaze palsy
- Cerebellar signs
- Early severe autonomic involvement
- Early severe dementia with disturbances of memory, language, and praxis
- Babinski sign
- Presence of cerebral tumour or communication hydrocephalus on imaging study
- Negative response to large doses of levodopa in absence of malabsorption
- MPTP exposure

Supportive (prospective) criteria

Three or more required for diagnosis of definite Parkinson's disease in combination with Step 1.

- Unilateral onset
- Rest tremor present
- Progressive disorder
- Persistent asymmetry affecting side of onset most
- Excellent response (70–100%) to levodopa
- Severe levodopa-induced chorea
- Levodopa response for 5 years or more
- Clinical course of 10 years or more

Reproduced with permission from AJ Hughes, SE Daniel, L Kilford, AJ Lees, Accuracy of clinical diagnosis of idiopathic Parkinson's disease: a clinico-pathological study of 100 cases, *Journal of Neurology, Neurosurgery & Psychiatry*, Volume 55, Issue 3, pp. 181–4, Copyright © 1992 BMJ Publishing Group Ltd.

Neuroimaging is usually non-diagnostic in the evaluation of suspected PD, however magnetic resonance imaging (MRI) of the brain should be performed to exclude specific structural abnormalities and exclude other conditions. In early PD, positron emission tomography may demonstrate decreased tracer uptake in the mid- and posterior putamen of patients although the clinical use is still under debate.

Dopamine transporter (DAT) imaging using single photon emission computed tomography (SPECT) usually reveals reduced radiotracer uptake in the putamen (Fig. 76.2) and to a lesser extent the caudate (often asymmetrically). By contrast, uptake is normal in controls, patients with essential tremor, and drug-induced parkinsonism. Striatal DAT SPECT differentiates between clinically probable PD and essential tremor with a sensitivity of 79–100% and specificity of 80–100% (Vlaar et al., 2007). However, it cannot differentiate PD and most parkinsonian syndromes from one another.

Clinical assessment

A detailed neurological history and examination (Fig. 76.3) is vital to ensure the correct diagnosis and subsequent management. Alternative conditions (e.g. essential tremor), coexisting conditions and reversible causes of secondary parkinsonism (e.g. medications) need to be carefully elicited and thus these patients are best reviewed by neurologists with a specialist interest in movement disorders. Sensory examination tends to be normal and a skin examination maybe recommended given the debate on the possible increased risk of melanoma (Bertoni et al., 2010). Many of the cardinal symptoms will usually be present on examination and should be evaluated thoroughly. Additionally, focus should also be given to non-motor symptoms (Chaudhuri et al., 2006).

Several clinical rating scales are used to measure the severity, monitor progression, and response to intervention. While detailed consideration of these scales is beyond the scope of this book, some of these are commonly used by functional neurosurgeons:

- UPDRS (Unified Parkinson's Disease Rating Scale). This is the most commonly used scale in the clinical assessment of PD and is used to follow the longitudinal course. It comprises six sections assessed using a combination of interview and clinical observations. UPDRS-III is a clinician-scored motor evaluation. Recently a modification by the Movement Disorder Society, MDS-UPDRS has been published with additional emphasis on assessing non-motor aspects of the condition.
- A modified Hoehn and Yahr staging scale is used to describe symptom progression and stage the disease.

Medical therapy

The range of pharmacological treatments available for PD is broad and dependent of careful individualization of patient specific factors (e.g. stage of disease, degree of disability). Most therapies are symptomatic in nature and do not slow/reverse the natural course of the disease. However, several potential neuro-protective agents have shown some promise in animals and/or early human studies and are undergoing further investigation (Stocchi and Olanow, 2003). Non-pharmacologic management of PD, including education, support, exercise, physical/occupational/speech therapy, and nutrition are also helpful to provide holistic care.

The decision to initiate medical therapy in patients with PD is determined by the degree to which symptoms affects the patient's activities of daily living or interferes with work. The main drugs available for the treatment of PD motor symptoms include:

- **Levodopa (L-dopa)** is the most effective drug for the symptomatic treatment of PD and is the drug of first choice, particularly for bradykinesia. Tremor and rigidity can also respond to levodopa therapy, however, postural instability is less likely to do so. Levodopa is combined with a peripheral decarboxylase inhibitor (carbidopa, benserazide) to block its conversion to dopamine in the systemic circulation before it crosses the blood-brain barrier.

A significant number of patients develop levodopa-induced complications such as motor fluctuations, dyskinesia, and dystonia. These

are estimated to occur in at least 50% of patients after 5 to 10 years of treatment (Schrag and Quinn, 2000).

- **Dopamine agonists** (e.g. pramipexole, ropinirole, rotigotine, and injectable apomorphine) may be employed either as monotherapy in early PD or in combination with other drugs for treatment of advanced disease. While dopamine agonists possibly delay the need to initiate levodopa therapy, their use is associated with impulse control disorders (hypersexuality, pathologic gambling) (Weintraub et al., 2006). As dopamine agonists may be associated with fewer motor fluctuations than levodopa, and the evidence suggests that there is a higher incidence of levodopa-related dyskinesia in young-onset PD, it is argued to be reasonable to start therapy with a dopamine agonist in younger patients (age <65 years) after appropriate counselling.
- **MAO-B inhibitors** (e.g. selegiline, rasagiline) are modestly effective as symptomatic treatment for PD, though monotherapy does not produce a functionally significant benefit in many patients. Uncertainty remains about the relative risks and benefits of MAO-B inhibitors, as few trials compared them with other antiparkinsonian medications. Adverse effects include nausea, headache, insomnia, and confusion, especially in older adults (Riederer and Laux, 2011).
- **Anticholinergic drugs**—In PD, dopamine depletion produces a state of cholinergic sensitivity, so that cholinergic drugs exacerbate and anticholinergic drugs improve parkinsonian symptoms. They are most useful as monotherapy in patients under 70 years of age with disturbing tremor who do not have significant bradykinesia or gait disturbance. They also may be useful in patients with more advanced disease who have persistent tremor despite treatment with levodopa or dopamine agonists. Use in older or demented individuals and those without tremor is strongly discouraged.
- **Amantadine** is an antiviral agent with relatively weak antiparkinsonian effect with low toxicity that is most useful in treating younger patients with early or mild PD and also later when dyskinesia becomes problematic. Adverse effects include livedo reticularis, ankle oedema, confusion, hallucinations, nightmares, abnormalities of liver function, and cognitive changes.
- **COMT inhibitors** (e.g. entacapone) are ineffective when prescribed alone, though they may prolong and potentiate the levodopa effect and thus are useful as levodopa extenders. They are predominantly used to treat patients with motor fluctuations who are experiencing end-of-dose wearing 'off' periods.
- **Oestrogen**—Low-dose oestrogen was suggested to be helpful as adjunctive therapy in postmenopausal women with motor fluctuations on antiparkinsonian medication (Liu and Dluzen, 2007). In practice, this is rarely ever used.

Essential tremor

Tremor is an involuntary movement characterized by rhythmic and oscillatory movement of a body part about a fixed point. Essential tremor (ET), previously referred to as benign essential tremor, is the most common neurologic cause of postural or action tremor and commonly affects the finger, hands and arms though may also extend to affect other body parts such as the head and vocal cords. It is distinct from PD but can be misdiagnosed as such.

Epidemiology

ET is thought to affect 0.4–4% of the population with men and women equally affected (Benito-Leon and Louis, 2006). However, head tremor may be more frequent in women, and postural hand tremor may be more severe in men. Approximately 50% of ET cases are familial with an autosomal dominant inheritance pattern.

The prevalence of ET increases with age with bimodal peaks of the age of onset—one in late adolescence to early adulthood and the second in older adulthood. At presentation, the mean age is between 35 and 45 years, though usually manifests by age 65 years and virtually always by age 70 years. Tremor amplitude also slowly increases over time, however, tremor frequency decreases with increasing age. An 8–12 Hz tremor is seen in young adults, and a 6–8 Hz tremor is typically evident in elderly individuals. Although ET is progressive, no association has been found between age of onset and severity or disability. Rare cases of ET have been reported in newborns and infants.

Pathogenesis

The precise pathophysiology of ET remains an enigma with no consistent pathological findings. Various hypotheses from postmortem and imaging studies point either to a cerebellar-brainstem-thalamo-cortical circuit dysfunction or an abnormally functioning central oscillator located in the Guillain Mollaret triangle near the brainstem and involving the inferior olivary nucleus (Helmich et al., 2013).

Genetics

ET is commonly quoted to be familial in at least 50–70% of cases with transmission demonstrating incomplete penetrance in an autosomal dominant fashion. More accurate studies however report anywhere between 17 and 100% of cases being familial and thus due to methodological variations such as ascertainment bias, true figures for familial link may be difficult to determine (Deng et al., 2007). Some cases are sporadic with unknown aetiology.

Clinical presentation

ET is usually described as trembling or quivering movement or sensation and is typically a distal symmetrical postural tremor of the upper limbs, usually of low amplitude with a fairly rapid frequency of 8–10 Hz. Initially it may be transient but usually progresses to become persistent. Factors predicting likely progression include asymmetric tremor and unilateral onset of the initial tremor. The neck muscles may be involved, causing tremor of the head (about 30% of cases), and voice, face, and jaw muscles may also be involved. The frequency of the tremor tends to remain constant, but amplitude is highly variable depending on emotional and physiological state. It does not occur during sleep and the majority report improvement following alcohol ingestion. It may be difficult to distinguish from exaggerated physiological tremor, that caused by hyperthyroidism/fever or tremor due to medications; these causes should always be borne in mind before diagnosing ET.

The tremor can become disabling over time, interfering with a patient's activities of daily living including feeding, dressing, and personal hygiene, thus leading to depression, anxiety states, social handicap, or alcoholism. A small proportion of sufferers may be severely disabled by the condition, affecting their employment and social prospects (Lorenz et al., 2011).

Diagnosis

Like most movement disorders, diagnosis remains largely clinical (Box 76.2). Biochemical investigations (thyroid function, ceruloplasmin) and imaging studies (MRI) are useful to screen for alternative diagnoses. SPECT imaging can support a diagnosis of parkinsonism, hence decreasing the misdiagnosis of ET as Parkinson's disease. Other features to differentiate the tremor of PD and ET are shown in Table 76.2.

Table 76.2 Other features to differentiate the tremor of PD and ET

Clinical features	Parkinson's disease tremor	Essential tremor
Age at onset	>50	Bimodal 2nd and 6th decade
Gender	M ≥ W	M = W
Family history	<10%	>50%
Asymmetry	Unilateral onset	Bilateral
Frequency	4–6 Hz	4–10 Hz
Character	Rest, rarely kinetic	Postural, kinetic
Distribution	Hands, legs, chin, tongue	Hands, head, voice
Associated features	Bradykinesia, rigidity, gait difficulty, postural instability	Nil
Response to: **- Alcohol** **- Levodopa** **- Primidone/ Propranolol**	 No Yes No	 Improves No Yes

Medical therapy

Beta-blockers and in particular propranolol between 60 and 320 mg/day, if tolerated, is the most commonly used medication for the treatment of ET. Side effects include syncope, light-headedness, fatigue, impotence, and bradycardia, which occurred in 12 to 66% of patients in clinical trials (Zesiewicz et al., 2005). Propranolol may be contraindicated in the presence of heart block, asthma, or type 1 diabetes mellitus.

The *anticonvulsant* primidone is also equally effective as propranolol for the treatment of ET. Side effects from primidone are typically more severe at treatment initiation, and include sedation, drowsiness, fatigue, nausea, vomiting, ataxia, malaise, dizziness, unsteadiness, confusion, vertigo, and an acute toxic reaction. Coadministration of a beta-blocker and primidone may provide useful additive therapeutic benefits if side effects are tolerated. Other anticonvulsants that reduce tremor include gabapentin and topiramate.

Alcohol has long been known to ameliorate ET. The use of small amounts of alcohol before meals or social events is not unreasonable and is commonly practised. However, prolonged use can lead to tolerance, with a need for increasingly larger amounts of alcohol to achieve the same effect which can be complicated by the superimposed withdrawal tremor when alcohol is omitted or the risk of liver disease. Concerns for an increased incidence of alcohol addiction in patients with ET are under debate.

Benzodiazepines are reserved as late-line choice for ET due to the potential for abuse, as well as the potential for drug discontinuation to cause withdrawal symptoms and exacerbation of tremor. Furthermore, their efficacy is limited.

Botulinum toxin (BTX) injections have a limited role to play in the management of ET. Modest benefit for limb tremor is associated with dose-dependent hand weakness, while for voice tremor, the side effects may include breathlessness, hoarseness, and swallowing difficulty.

Box 76.2 Movement Disorder Society on tremor

Classic essential tremor (ET) inclusion criteria

- Bilateral, largely symmetrical postural, or kinetic tremor involving hand and forearms that is visible and persistent
- Additional or isolated tremor of the head may occur but in the absence of abnormal posturing

Classic ET exclusion criteria

- Other abnormal signs of tremor, including dystonia
- The presence of known causes of enhanced physiological tremor, including current or recent exposure to tremorogenic drugs, or the presence of a drug withdrawal state
- Historical or clinical evidence of psychogenic tremor
- Convincing evidence of sudden onset or evidence of step-wise deterioration
- Primary orthostatic tremor
- Isolated voice tremor
- Isolated position-specific or task-specific tremors, including occupational tremors and primary writing tremor
- Isolated tongue or chin tremor
- Isolated leg tremor

Bhatia, Peter Bain, Nin Bajaj, et al., Consensus Statement on the classification of tremors. from the task force on tremor of the International Parkinson and Movement Disorder Society, *Movement Disorders*, Volume 33, Issue 1, pp. 75–87, Copyright © 2017 John Wiley and Sons.

Dystonia

Dystonia is defined as a clinical syndrome characterized by involuntary sustained muscle contractions that usually produce twisting and repetitive movements or abnormal postures. Herman Oppenheim in 1911 was the first to describe the condition (Klein and Fahn, 2013). It is a heterogeneous disorder with many presentations and various causes and thus can affect a multitude of functions including movement, speech, posture, visual performance, and mobility. Typically, the abnormal postures are not fixed and slow writhing movements (athetosis) can occur. Living with the condition can be painful and very debilitating.

Classification

Classification systems for dystonia are complex with several systems in place. Early systems divided dystonias into primary for idiopathic and secondary for dystonia associated with another disorders (e.g. cerebral palsy). This system has undergone many iterations with a consensus now classifying dystonia on two axes, clinical and aetiological (Box 76.3) and without the potentially confusing terminology of primary and secondary dystonias (Albanese et al., 2013).

Box 76.3 Classification of dystonia

Axis I. Clinical characteristics

Age at onset

- Infancy (birth to 2 years)
- Childhood (3–12 years)
- Adolescence (13–20 years)
- Early adulthood (21–40 years)
- Late adulthood (>40 years)

Body distribution

- Focal (e.g. writer's cramp, blepharospasm)
- Segmental (involving two or more contiguous regions, craniocervical dystonia)
- Multifocal (two or more non-contiguous regions)
- Generalized (+/– leg involvement)
- Hemidystonia

Temporal pattern

- Disease course
- Static
- Progressive
- Variability
- Persistent
- Action specific
- Diurnal
- Paroxysmal

Associated features

Isolated dystonia or combined with another movement disorder

- Isolated dystonia
- Combined dystonia

Occurrence of other neurological or systemic manifestations

- List of co-occurring neurological manifestations

Axis II. Aetiology

- Nervous system pathology
- Evidence of degeneration
- Evidence of structural (often static) lesions
- No evidence of degeneration or structural lesion
- Inherited or acquired
- Inherited
- Autosomal dominant
- Autosomal recessive
- X-linked recessive
- Mitochondrial

Acquired

- Perinatal brain injury
- Infection
- Drug
- Toxic
- Vascular
- Neoplastic
- Brain injury
- Psychogenic

Idiopathic

- Sporadic
- Familial

Epidemiology

There is estimated to be approximately 70 000 adults and children in the United Kingdom who suffer with some form of dystonia, which equates to a prevalence of 1 in 900. Though difficult to quantify accurately, according to minimum prevalence estimates, primary dystonia should be considered the third most frequent movement disorders after ET and Parkinson's disease.

Genetics

Genetic forms of the disease are important to recognize clinically and also provide valuable information about possible pathogenic mechanisms within the wider disorder. Hereditary dystonia is classified either by the gene underlying the condition or by reference to an ever-expanding list of dystonia loci, of which there are currently over 20. The DYT loci system were assigned in chronological order based on appearance of reports in the medical literature and in theory once the underlying genetic cause was known, the locus was supposed to be removed. However, in practice this has not occurred and thus dystonia loci and gene names appear interchangeably (e.g. DYT1/TOR1A) (Charlesworth et al., 2013).

DYT1/TOR1A is responsible for early onset dystonia and is inherited in an autosomal dominant fashion with reduced penetrance. The offspring of an affected individual or an asymptomatic individual known to have a TOR1A mutation have a 50% chance of inheriting the disease-causing mutation and 30–40% chance of developing symptoms.

Pathogenesis

The underlying pathogenesis for dystonia remains unclear. Interestingly in DYT1 dystonia most of the studies report no overt neurodegeneration or cell loss. One study has described ubiquitin and torsin A-positive inclusions within the brainstem. Functional MRI studies have implicated the pedunculopontine nucleus as part of dystonia 'metabolic network'.

In secondary dystonias the pathology is linked to basal ganglia structures, though several studies point to a cerebellar outflow problem. While progress has been made to pin down the exact pathophysiology much work remains to be done to refine these hypotheses.

Diagnosis

Though diagnosing dystonia can be difficult due to its variability in presentation, wide aetiology, and overlap with other movement disorders, it is a clinical diagnosis and thus best assessed by a neurologist with a special interest in movement disorders. Family history is important as up to 44% of patients have relatives with similar movement disorders. A careful drug history to rule out secondary causes is also vital.

Blood tests including liver function, ceruloplasmin, copper studies may be appropriate. Neuroimaging is useful to exclude structural causes and where appropriate to study the anatomy for potential deep brain stimulation. Genetic screening for DYT and other mutations and genetic counselling are vital for patients with early onset primary dystonia or a relative affected with condition.

Assessment for dystonia is usually performed using one of several validates rating scales:

- BFM-DRS (Burke-Fahn-Marsden Dystonia Rating Scale) is a 120-point rating scale used to test the severity of dystonia in nine body regions. This scale takes into account the severity and frequency of the dystonic movements. A higher score means greater impairment.
- CDIP-58 (Cervical Dystonia Impact Profile) includes 58 evaluative items forming eight scales. High scores indicate worse health.
- TWSTRS (Toronto Western Spasmodic Torticollis Rating Scale) is another commonly used rating scale for cervical dystonia. This exam consists of three sections: severity (range 0–30), disability (range 0–30), and pain (range 0–40).

Medical therapy

Depending on the severity of symptoms, a multidisciplinary approach to the management of dystonia is required comprising a combination of medications, allied healthcare (physiotherapy, psychological therapy, speech, and occupational therapy) and where appropriate surgery.

The use of rehabilitative physiotherapy for focal dystonias can be very effective with an aim to restore and maintain as much independence as possible. Cognitive behavioural therapy, autogenic training and counselling have an important role in the management of depression and anxiety which are often associated with the condition. Muscle spasms and abnormal posturing can cause significant pain and may require referral to pain management programmes. Where speech difficulties are present, referral to a speech and language therapist should be offered.

Medications are commonly utilized to provide symptomatic relief, though there is no one drug that is the definitive medication of choice and often a combination of several drugs is required to enable effective management.

- Levodopa—in primary dystonia, a trial of levodopa is vital to rule out dopa-responsive dystonia which can be managed in the long term on levodopa.
- Trihexyphenidyl—is usually the first line of management, though anticholinergic side effects need to be monitored.
- Baclofen is useful but can cause drowsiness, drooling, and droopiness of the trunk.
- Benzodiazepines—limited by respiratory depression and addiction.
- Clonidine—can cause somnolence.
- Gabapentin—may have additional benefit in stabilizing mood and sleep quality.
- Botulinum toxin A injection—especially useful for focal dystonia (e.g. blepharospasm, writer's cramp). It can be injected EMG/ultrasound assisted. Used off-licence in children, it is often used to treat pain and spasm in specific muscle groups.
- Intrathecal baclofen—this can prove effective for regional and total body dystonia with less risks of somnolence associated with oral baclofen.

Other support that may be considered includes dietary support, occupational therapy input, podiatry (especially for gait), genetic counselling, and social support.

Surgical management

Surgical approaches to movement disorders are an important consideration in the management of medically refractory cases. Increasingly, given their potential to avoid long-term complications of the disorder (e.g. deformity and contractures in dystonia), surgery is being used at earlier stages in the disease process. Contemporary functional neurosurgical techniques trace their origins to Dr Irving Cooper when he inadvertently ligated the anterior choroidal artery in a patient with PD resulting in serendipitous improvement in tremor and rigidity (Cooper, 1953). This was largely superseded by specific lesioning techniques which conferred beneficial results. However, concerns about irreversibility and complications associated with ablation, especially when done bilaterally, has resulted in high-frequency DBS becoming the gold standard surgical procedure for movement disorders.

Lesioning

This procedure involves acquiring stereotactic images and then passing an insulated radiofrequency electrode to basal ganglia nuclei coagulating a small area within the target nucleus. The effects are usually immediate. These techniques have largely been superseded by DBS due to concerns over irreversibility. Its use has dwindled over the decades; however, this ablative procedure is still a useful procedure in the armamentarium of a functional neurosurgeon. It has the advantage of being cheap, having a low infection profile, is relatively safe, and avoids repeated visits for adjustment of stimulation parameters or battery changes.

The recent introduction of the high-intensity focused ultrasound (HIFU) technology, allowing incision-less lesioning of target nuclei under the guidance of real time MRI thermometry, is likely to further improve the safety profile of lesioning surgery.

Stimulation

DBS involves identification of basal ganglia target nuclei utilizing high-resolution imaging, especially MRI, and subsequent implantation of permanent electrode leads using stereotactic techniques. The procedure is usually performed under local anaesthetic to allow for neuro-physiological and clinical confirmation of optimal electrode placement. The leads are then connected subcutaneously via extension wires to an implantable pulse generator (IPG) which is implanted in the chest/abdominal wall. The IPG serves both as a battery and a programming device, amenable to adjustment externally to alter the electrical output from the leads.

Transplantation
